where $b$ = 153 (SI) or 375 (USCS) and the subscript $c$ refers to true liquid temperature, which under these conditions was about 0.56°C (1°F) above the vapor head temperature. This work was done with water.

No detailed tests have been reported for the performance of propeller calandrias. Not enough is known regarding the performance of the propellers themselves under the cavitating conditions usually encountered to permit prediction of circulation rates. In many cases, it appears that the propeller does no good in accelerating heat transfer over the transfer for natural circulation (Fig. 11-23).

**Miscellaneous Evaporator Types** *Horizontal-tube evaporators* operating with partially or fully submerged heating surfaces behave in much the same way as short-tube verticals, and heat-transfer coefficients are of the same order of magnitude. Some test results for water were published by Badger [*Trans. Am. Inst. Chem. Eng.* **13:** 139 (1921)]. When operating unsubmerged, their heat-transfer performance is roughly comparable to that of the falling-film vertical tube evaporator. Condensing coefficients inside the

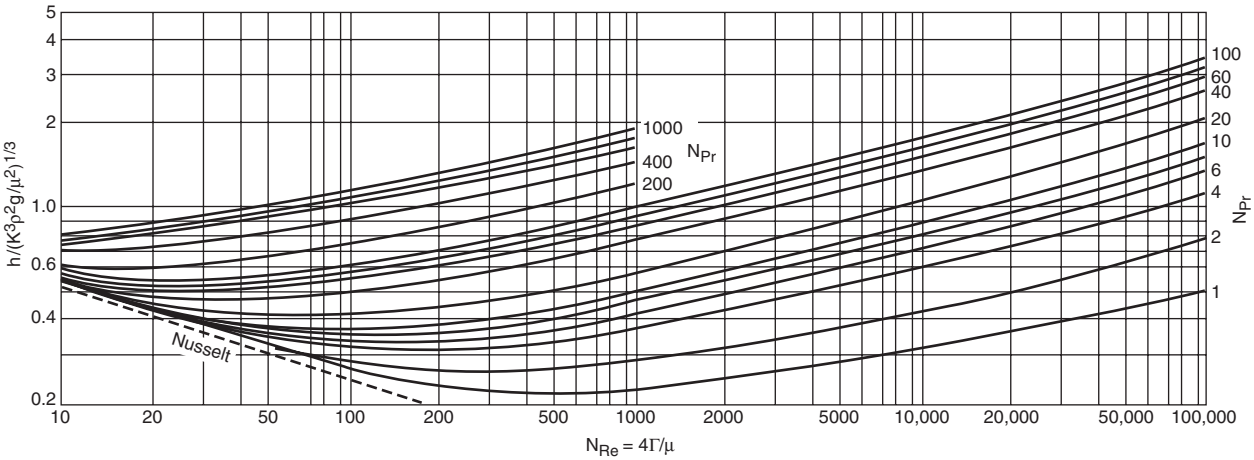

**FIG. 11-22** Kunz and Yerazunis correlation for falling-film heat transfer.

tubes can be derived from Nusselt's theory which, based on a constant-heat flux rather than a constant film $\Delta T$, gives

$$\frac{h}{(k^3\rho^2 g/\mu^2)^{1/3}} = 1.59(4\Gamma/\mu)^{-1/3} \qquad (11\text{-}33a)$$

For the boiling side, a correlation based on seawater tests gives

$$\frac{h}{(k^3\rho^2 g/\mu^2)^{1/3}} = 0.0147(4\Gamma/\mu)^{1/3}(D)^{-1/3} \qquad (11\text{-}33b)$$

where $\Gamma$ is based on feed rate per unit length of the top tube in each vertical row of tubes and $D$ is in meters.

Heat-transfer coefficients in clean coiled-tube evaporators for seawater are shown in Fig. 11-24 [Hillier, *Proc. Inst. Mech. Eng. (London)*, **1B**(7): 295 (1953)]. The tubes were of copper.

Heat-transfer coefficients in *agitated-film evaporators* depend primarily on liquid viscosity. This type is usually justifiable only for very viscous materials. Figure 11-25 shows general ranges of overall coefficients [Hauschild, *Chem. Ing. Tech.* **25:** 573 (1953); Lindsey, *Chem. Eng.* **60**(4): 227 (1953); and Leniger and Veldstra, *Chem. Ing. Tech.* **31:** 493 (1959)]. When used with nonviscous fluids, a wiped-film evaporator having fluted external surfaces can exhibit very high coefficients (Lustenader et al., *Trans. Am. Soc. Mech. Eng.* Paper 59-SA-30, 1959), although at a probably unwarranted first cost.

**Heat Transfer from Various Metal Surfaces** In an early work, Pridgeon and Badger [*Ind. Eng. Chem.* **16:** 474 (1924)] published test results on copper and iron tubes in a horizontal-tube evaporator that indicated an extreme *effect of surface cleanliness* on heat-transfer coefficients. However, the high degree of cleanliness needed for high coefficients was difficult to achieve, and the tube layout and liquid level were changed during the course of the tests so as to make direct comparison of results difficult. Other workers have found little or no effect of conditions of surface or tube material on boiling-film coefficients in the range of commercial operating conditions [Averin, *Izv. Akad. Nauk SSSR Otd. Tekh. Nauk*, no. 3, p. 116, 1954; and Coulson and McNelly, *Trans. Inst. Chem. Eng.* **34:** 247 (1956)].

Work in connection with desalination of seawater has shown that *specially modified surfaces* can have a profound effect on heat-transfer coefficients in evaporators. Figure 11-26 (Alexander and Hoffman, Oak Ridge National Laboratory TM-2203) compares overall coefficients for some of these surfaces when boiling freshwater in 0.051-m (2-in) tubes 2.44 m (8 ft) long at atmospheric pressure in both upflow and downflow. The area basis used was the nominal outside area. Tube 20 was a smooth 0.0016-m (0.062-in) wall aluminum brass tube that had accumulated about 6 years of fouling in seawater service and exhibited a fouling resistance of about $(2.6)(10^{-5})$ $(m^2 \cdot s \cdot K)/J$ [0.00015 $(ft^2 \cdot h \cdot °F)/Btu$]. Tube 23 was a clean aluminum tube with 20 spiral corrugations of 0.0032-m (⅛-in) radius on a 0.254-m (10-in) pitch indented into the tube. Tube 48 was a clean copper tube that had 50 longitudinal flutes pressed into the wall (General Electric double-flute profile, Diedrich, U.S. Patent 3,244,601, Apr. 5, 1966). Tubes 47 and 39 had a specially patterned porous sintered-metal deposit on the boiling side to promote nucleate boiling (Minton, U.S. Patent 3,384,154, May 21, 1968). Both of these tubes also had steam-side coatings to promote dropwise condensation—parylene for tube 47 and gold plating for tube 39.

Of these special surfaces, only the *double-fluted tube* has seen extended services. Most of the gain in heat-transfer coefficient is due to the condensing side; the flutes tend to collect the condensate and leave the lands bare [Carnavos, *Proc. First Int. Symp. Water Desalination* **2:** 205 (1965)].

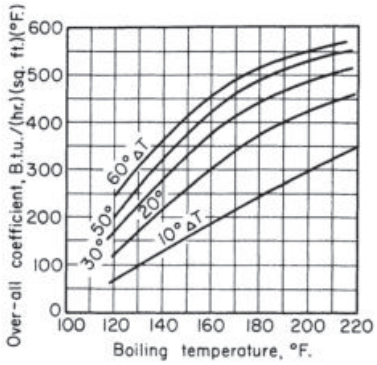

**FIG. 11-23** Heat-transfer coefficients for water in short-tube evaporators. °C = (°F − 32)/1.8; to convert British thermal units per hour per square foot per degree Fahrenheit to joules per square meter per second per kelvin, multiply by 5.6783.

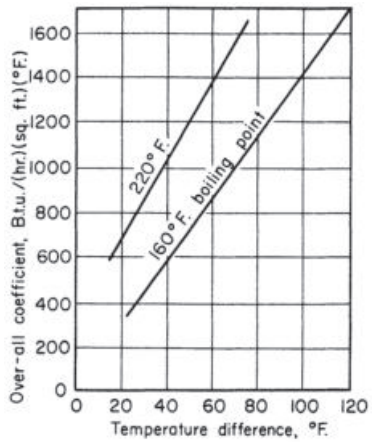

**FIG. 11-24** Heat-transfer coefficients for seawater in coil-tube evaporators. °C = (°F − 32)/1.8; to convert British thermal units per hour per square foot per degree Fahrenheit to joules per square meter per second per kelvin, multiply by 5.6783.

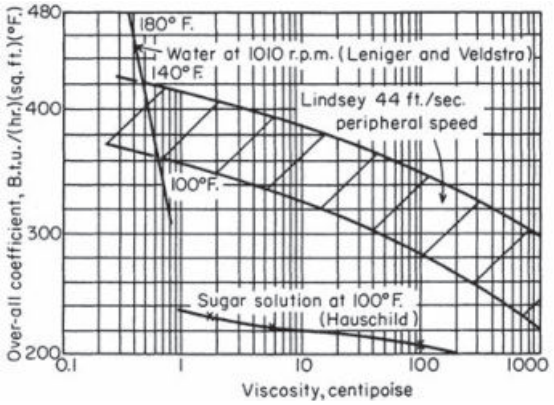

**FIG. 11-25** Overall heat-transfer coefficients in agitated-film evaporators. °C = (°F − 32)/1.8; to convert British thermal units per hour per square foot per degree Fahrenheit to joules per square meter per second per kelvin, multiply by 5.6783; to convert centipoises to pascal-seconds, multiply by $10^{-3}$.

The condensing-film coefficient (based on the actual outside area, which is 28 percent greater than the nominal area) may be approximated from the equation

$$h = b\left(\frac{k^3\rho^2 g}{\mu^2}\right)^{1/3}\left(\frac{\mu\lambda}{L}\right)^{1/3}\left(\frac{q}{A}\right)^{-0.833} \qquad (11\text{-}34a)$$

where $b = 2100$ (SI) or 1180 (USCS). The boiling-side coefficient (based on actual inside area) for salt water in downflow may be approximated from the equation

$$h = 0.035(k^3\rho^2 g/\mu^2)1/3(4\Gamma/\mu)^{1/6} \qquad (11\text{-}34b)$$

The boiling-film coefficient is about 30 percent lower for pure water than it is for salt water or seawater. There is as yet no accepted explanation for the superior performance in salt water. This phenomenon is also seen in evaporation from smooth tubes.

**Effect of Fluid Properties on Heat Transfer** Most of the heat-transfer data reported in the preceding paragraphs were obtained with water or with dilute solutions having properties close to those of water. Heat transfer with other materials will depend on the type of evaporator used. For forced-circulation evaporators, methods have been presented to calculate the effect

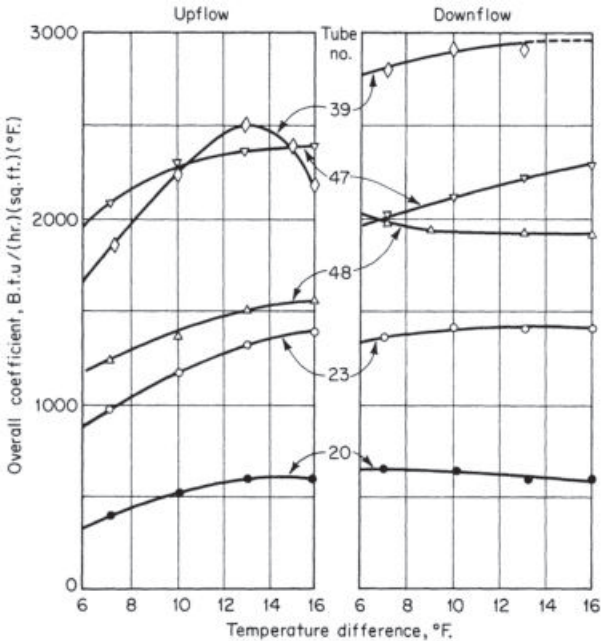

**FIG. 11-26** Heat-transfer coefficients for enhanced surfaces. °C = (°F − 32)/1.8; to convert British thermal units per hour per square foot per degree Fahrenheit to joules per square meter per second per kelvin, multiply by 5.6783. (*By permission from Oak Ridge National Laboratory TM-2203.*)

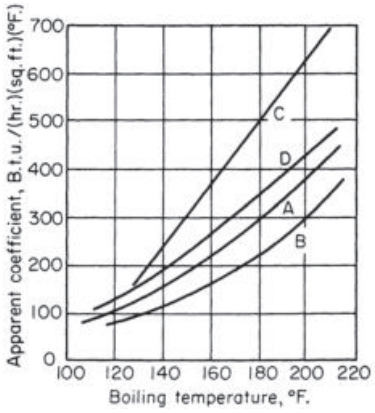

**FIG. 11-27** Kerr's tests with full-sized sugar evaporators. °C = (°F − 32)/1.8; to convert British thermal units per hour per square foot per degree Fahrenheit to joules per square meter per second per kelvin, multiply by 5.6783.

of changes in fluid properties. For natural-circulation evaporators, *viscosity* is the most important variable as far as aqueous solutions are concerned. Badger (*Heat Transfer and Evaporation*, Chemical Catalog, New York, 1926, pp. 133–134) found that, as a rough rule, overall heat-transfer coefficients varied in inverse proportion to viscosity if the boiling film was the main resistance to heat transfer. When handling molasses solutions in a forced-circulation evaporator in which boiling was allowed to occur in the tubes, Coates and Badger [*Trans. Am. Inst. Chem. Eng.* **32:** 49 (1936)] found that from 0.005 to 0.03 Pa·s (5 to 30 cP) the overall heat-transfer coefficient could be represented by $U = b/\mu_f^{1.24}$, where $b = 2.55$ (SI) or 7043 (USCS). Fragen and Badger [*Ind. Eng. Chem.* **28:** 534 (1936)] correlated overall coefficients on sugar and sulfite liquor in the same evaporator for viscosities to 0.242 Pa·s (242 cP) and found a relationship that included the viscosity raised only to the 0.25 power.

Little work has been published on the effect of viscosity on heat transfer in the long-tube vertical evaporator. Cessna, Leintz, and Badger [*Trans. Am. Inst. Chem. Eng.* **36:** 759 (1940)] found that the overall coefficient in the nonboiling zone varied inversely as the 0.7 power of viscosity (with sugar solutions). Coulson and Mehta [*Trans. Inst. Chem. Eng.* **31:** 208 (1953)] found the exponent to be –0.44, and Stroebe, Baker, and Badger arrived at an exponent of –0.3 for the effect of viscosity on the film coefficient in the boiling zone.

Kerr (Louisiana *Agr. Exp. Sta. Bull.* 149) obtained plant data shown in Fig. 11-27 on various types of full-sized evaporators for cane sugar. These are invariably forward-feed evaporators concentrating to about 50° Brix, corresponding to a viscosity on the order of 0.005 Pa·s (5 cP) in the last effect. In Fig. 11-27 curve *A* is for short-tube verticals with central downtake, *B* is for standard horizontal-tube evaporators, *C* is for Lillie evaporators (which were horizontal-tube machines with no liquor level but having recirculating liquor showered over the tubes), and *D* is for long-tube vertical evaporators. These curves show apparent coefficients, but sugar solutions have boiling-point rises low enough to not affect the results noticeably. Kerr also obtained the data shown in Fig. 11-28 on a laboratory short-tube vertical evaporator with 0.44- by 0.61-m (1¾- by 24-in) tubes. This work was done with sugar juices boiling at 57°C (135°F) and an 11°C (20°F) temperature difference.

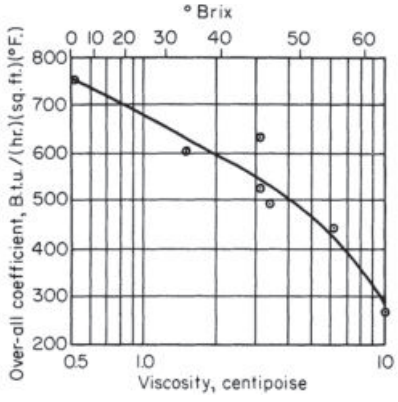

**FIG. 11-28** Effect of viscosity on heat transfer in short-tube vertical evaporator. To convert centipoises to pascal-seconds, multiply by $10^{-3}$; to convert British thermal units per hour per square foot per degree Fahrenheit to joules per square meter per second per kelvin, multiply by 5.6783.

**Effect of Noncondensibles on Heat Transfer** Most of the heat transfer in evaporators occurs not from pure steam but from vapor evolved in a preceding effect. This vapor usually contains inert gases—from air leakage if the preceding effect was under vacuum, from air entrained or dissolved in the feed, or from gases liberated by decomposition reactions. To prevent these inerts from seriously impeding heat transfer, the gases must be channeled past the heating surface and vented from the system while the gas concentration is still quite low. The influence of inert gases on heat transfer is due partially to the effect on $\Delta T$ of lowering the partial pressure and hence condensing temperature of the steam. The primary effect, however, results from the formation at the heating surface of an insulating blanket of gas through which the steam must diffuse before it can condense. The latter effect can be treated as an added resistance or fouling factor equal to $6.5 \times 10^{-5}$ times the local mole percent inert gas (in $J^{-1} \cdot s \cdot m^2 \cdot K$) [Standiford, *Chem. Eng. Prog.* **75**: 59–62 (July 1979)]. The effect on $\Delta T$ is readily calculated from Dalton's law. Inert-gas concentrations may vary by a factor of 100 or more between vapor inlet and vent outlet, so these relationships should be integrated through the tube bundle.

## CRYOGENIC HEAT EXCHANGERS

Most cryogenic fluids behave similar to room-temperature fluids as far as thermal/hydraulic design is concerned. For tubular exchangers, the Colburn equation and the ordinary Dittus-Boelter correlation, with slight modification, work well for single-phase cryogenic fluids as long as the critical point for the fluid is not closely approached. For critical-point calculations, a number of publications may be found in the literature to direct the designer along the best path forward for the fluid under consideration. For example, the use of an unmodified Dittus-Boelter correlation appears to give satisfactory results under swirl flow conditions for flows near the critical point.

Beyond the normal good design practice of the experienced thermal designer, a primary factor influencing the type of heat exchanger used in cryogenic applications is the ability of the exchanger geometry to handle large temperature changes and potential cyclic operation. Two popular geometries for these applications are coiled tube exchangers and bayonet exchangers.

The coiled tube heat exchanger is well suited for designs where heat transfer between more than two fluid streams is needed. It is also capable of handling high pressures while accommodating the thermal expansion/contraction issues of low-temperature operation.

The bayonet heat exchanger is also highly suited for extremes of high pressures and differential expansion. For large duties, it is simple to design a double tube sheet shell and tube heat exchanger with each tube consisting of the scabbard/bayonet tube combination of the bayonet exchanger. Segmental baffles or extended surface may be used on the outside of the scabbard tube bundle for the shell-side fluid. For cryogenic vaporization, a wire wrapped on the outside of each bayonet tube with the cold fluid entering in the bayonet tubes and exiting while vaporizing along the annulus between the bayonet tube and the scabbard pipe produces as efficient a vaporization performance as is possible in a tubular exchanger.

A third compact-type exchanger sometimes used for single-phase applications is the plate-fin heat exchanger. Again, however, the issue is to take care that the construction can handle the high differential expansion/contraction forces that the process may inflict upon the exchanger.

In most cryogenic processes, there is at least one service where heat is transferred between a cryogen and a fluid which can easily freeze on the tube wall. If cyclic operation is not desired (where the service is shut down at regular intervals or flow is transferred to a second exchanger while thawing occurs in the first), the best approach is to determine the thickness of frozen fluid needed to produce a skin temperature (at the solid-to-liquid interface) equal to the freezing point temperature of the fluid where further freezing will cease. The heat exchanger is then designed to accommodate this amount of solid buildup without flow blockage or unacceptable deterioration of heat transfer. For this reason, in these applications, the cryogenic fluid is almost always located inside the tubes while the heating stream with freezing potential is placed on the outside where a larger tube pitch can be used to create the space needed for the amount of solid buildup that will occur at thermodynamic equilibrium. When properly designed, these heat exchangers will operate free of problems at steady-state conditions for as long as necessary.

## BATCH OPERATIONS: HEATING AND COOLING OF VESSELS

**Nomenclature** (Use consistent units.) $A$ = heat-transfer surface; $C$, $c$ = specific heats of hot and cold fluids, respectively; $L_0$ = flow rate of liquid added to tank; $M$ = mass of fluid in tank; $T$, $t$ = temperature of hot and cold fluids, respectively; $T_1$, $t_1$ = temperatures at beginning of heating or cooling period or at inlet; $T_2$, $t_2$ = temperature at end of period or at outlet; $T_0$, $t_0$ = temperature of liquid added to tank; $U$ = coefficient of heat transfer; and $W$, $w$ = flow rate through external exchanger of hot and cold fluids, respectively.

**Applications** One typical application in heat transfer with batch operations is the heating of a reactor mix, maintaining temperature during a reaction period, and then cooling the products after the reaction is complete. This subsection is concerned with the heating and cooling of such systems in either unknown or specified periods.

The technique for deriving expressions relating time for heating or cooling agitated batches to coil or jacket area, heat-transfer coefficients, and the heat capacity of the vessel contents was developed by Bowman, Mueller, and Nagle [*Trans. Am. Soc. Mech. Eng.* **62:** 283–294 (1940)] and extended by Fisher [*Ind. Eng. Chem.* **36:** 939–942 (1944)] and Chaddock and Sanders [*Trans. Am. Inst. Chem. Eng.* **40:** 203–210 (1944)] to external heat exchangers. Kern (*Process Heat Transfer*, McGraw-Hill, New York, 1950, chap. 18) collected and published the results of these investigators.

The assumptions made were that (1) $U$ is constant for the process and over the entire surface, (2) liquid flow rates are constant, (3) specific heats are constant for the process, (4) the heating or cooling medium has a constant inlet temperature, (5) agitation produces a uniform batch fluid temperature, (6) no partial phase changes occur, and (7) heat losses are negligible. The developed equations are as follows. If any of the assumptions do not apply to a system being designed, new equations should be developed or appropriate corrections made. Heat exchangers are counterflow except for the 1-2 exchangers, which are one-shell-pass, two-tube-pass, parallel-flow counterflow.

*Coil-in-Tank or Jacketed Vessel: Isothermal Heating Medium*

$$\ln(T_1 - t_1)/(T_1 - t_2) = UA\theta/Mc \tag{11-35}$$

*Cooling-in-Tank or Jacketed Vessel: Isothermal Cooling Medium*

$$\ln (T_1 - t_1)/(T_2 - t_1) = UA\theta/MC \tag{11-35a}$$

*Coil-in-Tank or Jacketed Vessel: Nonisothermal Heating Medium*

$$\ln\frac{T_1 - t_1}{T_1 - t_2} = \frac{WC}{Mc}\left(\frac{K_1 - 1}{K_1}\right)\theta \tag{11-35b}$$

where $K_1 = e^{UA/WC}$.

*Coil-in-Tank: Nonisothermal Cooling Medium*

$$\ln\frac{T_1 - t_1}{T_2 - t_1} = \frac{wc}{MC}\left(\frac{K_2 - 1}{K_2}\right)\theta \tag{11-35c}$$

where $K_2 = e^{UA/wc}$.

*External Heat Exchanger: Isothermal Heating Medium*

$$\ln\frac{T_1 - t_1}{T_1 - t_2} = \frac{wc}{MC}\left(\frac{K_2 - 1}{K_2}\right)\theta \tag{11-35d}$$

*External Exchanger: Isothermal Cooling Medium*

$$\ln\frac{T_1 - t_1}{T_2 - t_1} = \frac{WC}{MC}\left(\frac{K_1 - 1}{K_1}\right)\theta \tag{11-35e}$$

*External Exchanger: Nonisothermal Heating Medium*

$$\ln\frac{T_1 - t_1}{T_2 - t_1} = \left(\frac{K_3 - 1}{M}\right)\left(\frac{wWC}{K_3 wc - WC}\right)\theta \tag{11-35f}$$

where $K_3 = e^{UA(1/WC - 1/wc)}$.

*External Exchanger: Nonisothermal Cooling Medium*

$$\ln\frac{T_1 - t_1}{T_2 - t_1} = \left(\frac{K_4 - 1}{M}\right)\left(\frac{Wwc}{K_4 wc - WC}\right)\theta \tag{11-35g}$$

where $K_4 = e^{UA(1/WC - 1/wc)}$.

*External Exchanger with Liquid Continuously Added to Tank: Isothermal Heating Medium*

$$\ln\left[\frac{t_1 - t_0 - \frac{w}{L_0}\left(\frac{K_2 - 1}{K_2}\right)(T_1 - t_1)}{t_2 - t_0 - \frac{w}{L_0}\left(\frac{K_2 - 1}{K_2}\right)(T_1 - t_2)}\right] = \left[\frac{w}{L_0}\left(\frac{K_2 - 1}{K_2}\right) + 1\right]\ln\frac{M + L_0\theta}{M} \tag{11-35h}$$

If the addition of liquid to the tank causes an average endothermic or exothermic heat of solution $\pm q_s$ J/kg (Btu/lb) of makeup, it may be included by adding $\pm q_s/c_0$ to both the numerator and the denominator of the left side. The subscript 0 refers to the makeup.

*External Exchanger with Liquid Continuously Added to Tank: Isothermal Cooling Medium*

$$\ln\left[\frac{T_0 - T_1 - \frac{W}{L_0}\left(\frac{K_1-1}{K_1}\right)(T_1 - t_1)}{T_0 - T_2 - \frac{W}{L_0}\left(\frac{K_1-1}{K_1}\right)(T_2 - t_1)}\right] = \left[1 - \frac{W}{L_0}\left(\frac{K_1-1}{K_1}\right)\right]\ln\frac{M + L_0\theta}{M} \qquad (11\text{-}35i)$$

The heat-of-solution effects can be included by adding $\pm q_s/C_0$ to both the numerator and the denominator of the left side.

*External Exchanger with Liquid Continuously Added to Tank: Nonisothermal Heating Medium*

$$\ln\left[\frac{t_0 - t_1 + \frac{wWC(K_5-1)(T_1 - t_1)}{L_0(K_5WC - wc)}}{t_0 - t_2 + \frac{wWC(K_5-1)(T_1 - t_2)}{L_0(K_5WC - wc)}}\right] = \left[\frac{wWC(K_5-1)}{L_0(K_5WC - wc)} + 1\right]\ln\frac{M + L_0\theta}{M} \qquad (11\text{-}35j)$$

where $K_5 = e^{(UA/wc)(1 - wc/WC)}$.

The heat-of-solution effects can be included by adding $\pm q_s/c_0$ to both the numerator and the denominator of the left side.

*External Exchanger with Liquid Continuously Added to Tank: Nonisothermal Cooling Medium*

$$\ln\left[\frac{T_0 - T_1 + \frac{Wwc(K_6-1)(T_1 - t_1)}{L_0(K_6wc - WC)}}{T_0 - T_2 + \frac{Wwc(K_6-1)(T_2 - t_1)}{L_0(K_6wc - WC)}}\right] = \left[\frac{Wwc(K_6-1)}{L_0(K_6wc - WC)} + 1\right]\ln\frac{M + L_0\theta}{M} \qquad (11\text{-}35k)$$

where $K_6 = e^{(UA/WC)(1 - WC/wc)}$.

The heat-of-solution effects can be included by adding $\pm q_s/C_0$ to both the numerator and the denominator of the left side.

*Heating and Cooling Agitated Batches: 1-2 Parallel Flow-Counterflow*

$$\frac{UA}{wc} = \frac{1}{\sqrt{R^2+1}}\left[\ln\frac{2 - S(R+1-\sqrt{R^2+1})}{2 - S(R+1-\sqrt{R^2+1})}\right] \qquad (11\text{-}35l)$$

$$R = \frac{T_1 - T_2}{t' - t} = \frac{wc}{WC} \quad \text{and} \quad S = \frac{t' - t}{T_1 - t}$$

$$\frac{2 - S(R+1-\sqrt{R^2+1})}{2 - S(R+1+\sqrt{R^2+1})} = e^{(UA/wc)\sqrt{R^2+1}} = K_7$$

$$S = \frac{2(K_7 - 1)}{K_7(R+1+R^2+1) - (R+1-R^2+1)} \qquad (11\text{-}35m)$$

*External 1-2 Exchanger: Heating*

$$\ln\left[(T_1 - t_1)/(T_1 - t_2)\right] = (Sw/M)\theta \qquad (11\text{-}35n)$$

*External 1-2 Exchanger: Cooling*

$$\ln\left[(T_1 - t_1)/(T_2 - t_1)\right] = S(wc/MC)\theta \qquad (11\text{-}35o)$$

The cases of multipass exchangers with liquid continuously added to the tank are covered by Kern, as cited earlier. An alternative method for all multipass-exchanger gases, including those presented as well as cases with two or more shells in series, is as follows:

1. Determine *UA* for using the applicable equations for counterflow heat exchangers.
2. Use the initial batch temperature $T_1$ or $t_1$.
3. Calculate the outlet temperature from the exchanger of each fluid. (This will require trial-and-error methods.)
4. Note the $F_T$ correction factor for the corrected mean temperature difference. (See Fig. 11-4.)
5. Repeat steps 2, 3, and 4 by using the final batch temperature $T_2$ and $t_2$.
6. Use the average of the two values for *F*, then increase the required multipass *UA* as follows:

$$UA(\text{multipass}) = UA(\text{counterflow})/F_T$$

In general, values of $F_T$ below 0.8 are uneconomical and should be avoided. The value of $F_T$ can be raised by increasing the flow rate of either or both of the flow streams. Increasing flow rates to give values well above 0.8 is a matter of economic justification.

If $F_T$ varies widely from one end of the range to the other, $F_T$ should be determined for one or more intermediate points. The average should then be determined for each step which has been established and the average of these taken for use in step 6.

**Effect of External Heat Loss or Gain** If heat loss or gain through the vessel walls cannot be neglected, equations that include this heat transfer can be developed by using energy balances similar to those used for the derivations of equations given previously. Basically, these equations must be modified by adding a heat-loss or heat-gain term.

A simpler procedure, which is probably acceptable for most practical cases, is to adjust the ratio of *UA* or θ either up or down in accordance with the required modification in total heat load over time θ.

Another procedure, which is more accurate for the external-heat exchanger cases, is to use an equivalent value for *MC* ( for a vessel being heated) derived from the following energy balance:

$$Q = (Mc)_e(t_2 - t_1) = Mc(t_2 - t_1) + U'A'(MTD')\theta \qquad (11\text{-}35p)$$

where *Q* is the total heat transferred over time θ, $U'A'$ is the heat-transfer coefficient for heat loss times the area for heat loss, and $MTD'$ is the mean temperature difference for the heat loss.

A similar energy balance would apply to a vessel being cooled.

**Internal Coil or Jacket Plus External Heat Exchanger** This case can be most simply handled by treating it as two separate problems: *M* is divided into two separate masses $M_1$ and $M - M_1$, and the appropriate equations given earlier are applied to each part of the system. Time θ, of course, must be the same for both parts.

**Equivalent-Area Concept** The preceding equations for batch operations, particularly Eq. (11-35), can be applied for the calculation of heat loss from tanks which are allowed to cool over an extended time. However, different surfaces of a tank, such as the top (which would not be in contact with the tank contents) and the bottom, may have coefficients of heat transfer different from those of the vertical-tank walls. The simplest way to resolve this difficulty is to use an equivalent area $A_e$ in the appropriate equations, where

$$A_e = A_bU_b/U_s + A_tU_t/U_s + A_s \qquad (11\text{-}35q)$$

and the subscripts *b*, *s*, and *t* refer to the bottom, sides, and top, respectively. Usually *U* is taken as $U_s$. Table 11-1 lists typical values for $U_s$ and expressions for $A_e$ for various tank configurations.

**Nonagitated Batches** Cases in which vessel contents are vertically stratified, rather than uniform in temperature, have been treated by Kern (*Process Heat Transfer*, McGraw-Hill, New York, 1950, chap. 18). These are of little practical importance except for tall, slender vessels heated or cooled with external exchangers. The result is that a smaller exchanger is required than for an equivalent agitated batch system that is uniform.

**Storage Tanks** The equations for batch operations with agitation may be applied to storage tanks even though the tanks are not agitated. This approach gives conservative results. The important cases (non-steady-state) are as follows:

1. *Tanks cool; contents remain liquid.* This case is relatively simple and can be easily handled by the equations given earlier.
2. *Tanks cool, contents partially freeze, and solids drop to bottom or rise to top.* This case requires a two-step calculation. The first step is handled as in case 1. The second step is calculated by assuming an isothermal system at the freezing point. It is possible, given time and a sufficiently low ambient temperature, for tank contents to freeze solid.
3. *Tanks cool and partially freeze; solids form a layer of self-insulation.* This complex case, which has been known to occur with heavy hydrocarbons and mixtures of hydrocarbons, has been discussed by Stuhlbarg [*Pet. Refiner* **38:** 143 (Apr. 1, 1959)]. The contents in the center of such tanks have been known to remain warm and liquid even after several years of cooling.

It is very important that a melt-out riser be installed whenever tank contents are expected to freeze on prolonged shutdown. The purpose is to provide a molten chimney through the crust for relief of thermal expansion or cavitation if fluids are to be pumped out or recirculated through an external exchanger. An external heat tracer, properly located, will serve the same purpose but may require greater remelt time before pumping can be started.

## THERMAL DESIGN OF TANK COILS

The thermal design of tank coils involves the determination of the area of heat-transfer surface required to maintain the contents of the tank at a constant temperature or to raise or lower the temperature of the contents by a specified magnitude over a fixed time.

**TABLE 11-1 Typical Values for Use with Eqs. (11-36) to (11-44)***

| Application | Fluid | $U_s$ | $A_s$ |
|---|---|---|---|
| Tanks on legs, outdoors, not insulated | Oil | 3.7 | $0.22\,A_t + A_b + A_s$ |
| | Water at 150°F | 5.1 | $0.16\,A_t + A_b + A_s$ |
| Tanks on legs, outdoors, insulated 1 in. | Oil | 0.45 | $0.7\,A_t + A_b + A_s$ |

*Based on typical coefficients.
†The ratio $(t - t_g)(t - t')$ assumed at 0.85 for outdoor tanks. °C = (°F − 32)/1.8; to convert British thermal units per hour-square foot-degrees Fahrenheit to joules per square meter-second-kelvins, multiply by 5.6783.

**Nomenclature** $A$ = area; $A_b$ = area of tank bottom; $A_c$ = area of coil; $A_e$ = equivalent area; $A_s$ = area of sides; $A_t$ = area of top; $A_1$ = equivalent area receiving heat from external coils; $A_2$ = equivalent area not covered with external coils; $c$ = heat capacity of liquid phase of tank contents; $D_t$ = diameter of tank; $F$ = design (safety) factor; $h$ = film coefficient; $h_a$ = coefficient of ambient air; $h_c$ = coefficient of coil; $h_h$ = coefficient of heating medium; $h_i$ = coefficient of liquid phase of tank contents or tube-side coefficient referred to outside of coil; $h_z$ = coefficient of insulation; $k$ = thermal conductivity; $k_g$ = thermal conductivity of ground below tank; $M$ = mass of tank contents when full; $t$ = temperature; $t_a$ = temperature of ambient air; $t_d$ = temperature of dead-air space; $t_f$ = temperature of contents at end of heating; $t_g$ = temperature of ground below tank; $t_h$ = temperature of heating medium; $t_0$ = temperature of contents at beginning of heating; $U$ = overall coefficient; $U_b$ = coefficient at tank bottom; $U_c$ = coefficient of coil; $U_d$ = coefficient of dead air to the tank contents; $U_i$ = coefficient through insulation; $U_s$ = coefficient at sides; $U_t$ = coefficient at top; and $U_2$ = coefficient at area $A_2$.

Typical coil coefficients are listed in Table 11-2. More exact values can be calculated by using the methods for natural convection or forced convection given elsewhere in this section.

**Maintenance of Temperature** Tanks are often maintained at temperature with internal coils if the following equations are assumed to be applicable:

$$q = U_s A_e (T - t') \tag{11-36}$$

and

$$A_c = q/U_c(\text{MTD}) \tag{11-36a}$$

These make no allowance for unexpected shutdowns. One method of allowing for shutdown is to add a safety factor to Eq. (11-36*a*).

In the case of a tank maintained at temperature with internal coils, the coils are usually designed to cover only a portion of the tank. The temperature $t_d$ of the dead-air space between the coils and the tank is obtained from

$$U_d A_1 (t_d - t) = U_2 A_2 (t - t') \tag{11-37}$$

The heat load is

$$q = U_d A_1 (t_d - t) + A_1 U_i (t_d - t') \tag{11-38}$$

The coil area is

$$A_c = \frac{qF}{U_c (t_h - t_d)_m} \tag{11-39}$$

where $F$ is a safety factor.

**Heating**

***Heating with Internal Coil from Initial Temperature for Specified Time***

$$Q = Mc(t_f - t_o) \tag{11-40}$$

$$A_c = \left[\frac{Q}{\theta_h} + U_s A_e \left(\frac{t_f + t_o}{2} - t'\right)\right]\left[\frac{1}{U_c[t_h - (t_f + t_o)/2]}\right](F) \tag{11-41}$$

NOTES: Chilton, Drew, and Jebens [*Ind. Eng. Chem.* **36:** 510 (1944)] give film coefficients for heating and cooling agitated fluids using a coil in a jacketed vessel.

Because of the many factors affecting heat transfer, such as viscosity, temperature difference, and coil size, the values in this table should be used primarily for preliminary design estimates and checking calculated coefficients.

°C = (°F − 32)/1.8; to convert British thermal units per hour-square foot-degrees Fahrenheit to joules per square meter-second-kelvins, multiply by 5.6783.

where $\theta_h$ is the length of heating period. This equation may also be used when the tank contents have cooled from $t_f$ to $t_o$ and must be reheated to $t_f$. If the contents cool during a time $\theta_c$, the temperature at the end of this cooling period is obtained from

$$\ln\left(\frac{t_f - t'}{t_o - t'}\right) = \frac{U_s A_e \theta_c}{Mc} \tag{11-42}$$

***Heating with External Coil from Initial Temperature Specified Time*** The temperature of the dead-air space is obtained from

$$U_d A_1[t_d - 0.5(t_f - t_o)] = U_2 A_2[0.5(t_f - t_o) - t'] + Q/\theta_h \tag{11-43}$$

The heat load is

$$q = U_i A_1(t_d - t') + U_2 A_2[0.5(t_f - t_o) - t'] + Q/\theta_h \tag{11-44}$$

The coil area is obtained from Eq. (11-39).

The safety factor used in the calculations is a matter of judgment based on confidence in the design. A value of 1.10 is normally not considered excessive. Typical design parameters are shown in Tables 11-1 and 11-2.

## HEATING AND COOLING OF TANKS

**Tank Coils** *Pipe tank coils* are made in a wide variety of configurations, depending upon the application and shape of the vessel. *Helical* and *spiral* coils are most commonly shop-fabricated, while the *hairpin* pattern is generally field-fabricated. The helical coils are used principally in process tanks and pressure vessels when large areas for rapid heating or cooling are required. In general, heating coils are placed low in the tank, and cooling coils are placed high or distributed uniformly throughout the vertical height.

Stocks that tend to solidify on cooling require uniform coverage of the bottom or agitation. A maximum spacing of 0.6 m (2 ft) between turns of 50.8-mm (2-in) and larger pipe and a close approach to the tank wall are recommended. For smaller pipe or for low-temperature heating media, closer spacing should be used. In the case of the common hairpin coils in vertical cylindrical tanks, this means adding an encircling ring within 152 mm (6 in) of the tank wall (see Fig. 11-29*a* for this and other typical coil layouts). The coils should be set directly on the bottom or raised not more than 50.8 to 152 mm (2 to 6 in), depending upon the difficulty of remelting the solids, in order to permit free movement of product within the vessel. The coil inlet should be above the liquid level (or an internal melt-out riser installed) to provide a molten path for liquid expansion or venting of vapors.

Coils may be sloped to facilitate drainage. When it is impossible to do so and remain close enough to the bottom to get proper remelting, the coils should be blown out after use in cold weather to avoid damage by freezing.

Most coils are firmly clamped (but not welded) to supports. *Supports* should allow expansion but be rigid enough to prevent uncontrolled motion (see Fig. 11-29*b*). Nuts and bolts should be securely fastened. Reinforcement of the inlet and outlet connections through the tank wall is recommended, since bending stresses due to thermal expansion are usually high at such points.

In general, 50.8- and 63.4-mm (2- and 2½-in) coils are the most economical for shop fabrication and 38.1- and 50.8-mm (1½- and 2-in) for field fabrication. The tube-side heat-transfer coefficient, high-pressure, or layout problems may lead to the use of smaller-size pipe.

The wall thickness selected varies with the service and material. Carbon-steel coils are often made from schedule 80 or heavier pipe to allow for corrosion. When stainless-steel or other high-alloy coils are not subject to corrosion or excessive pressure, they may be of schedule 5 or 10 pipe to keep costs at a minimum, although high-quality welding is required for these thin walls to ensure trouble-free service.

Methods for calculating heat loss from tanks and the sizing of tank coils have been published by Stuhlbarg [*Pet. Refiner* **38:** 143 (April 1959)].

*Fin-tube coils* are used for fluids that have poor heat-transfer characteristics to provide greater surface for the same configuration at reduced cost or when temperature-driven fouling is to be minimized. Fin tubing is not generally used when bottom coverage is important. *Fin-tube tank heaters* are compact, prefabricated bundles which can be brought into tanks through manholes. These are normally installed vertically with longitudinal fins to produce good convection currents. To keep the heaters low in the tank, they can be installed horizontally with helical fins or with perforated longitudinal fins to prevent entrapment. Fin tubing is often used for heat-sensitive material because of the lower surface temperature for the same heating medium, resulting in a lesser tendency to foul.

*Plate* or *panel* coils made from two metal sheets with one or both embossed to form passages for a heating or cooling medium can be used in lieu of pipe coils. Panel coils are relatively lightweight, easy to install, and easily removed for cleaning. They are available in a range of standard sizes and in both flat and curved patterns. Process tanks have been built by using panel coils for the sides or bottom. A serpentine construction is generally utilized when liquid flows through the unit. Header-type construction is used with steam or other condensing media.

Standard *glass coils* with 0.18 to 11.1 $m^2$ (2 to 120 $ft^2$) of heat-transfer surface are available. Also available are plate-type units made of *impervious graphite*.

**Teflon Immersion Coils** Immersion coils made of Teflon fluorocarbon resin are available with 2.5-mm- (0.10-in-) ID tubes to increase overall heat-transfer efficiency. The flexible bundles are available with 100, 160, 280, 500, and 650 tubes with standard lengths varying in 0.6-m (2-ft) increments between 1.2 and 4.8 m (4 and 16 ft). These coils are most commonly used in metal-finishing baths and are adaptable to service in reaction vessels, crystallizers, and tanks where corrosive fluids are used.

**Bayonet Heaters** A bayonet-tube element consists of an outer tube and an inner tube. These elements are inserted into tanks and process vessels for heating and cooling purposes. Often the outer tube is of expensive alloy or nonmetallic (e.g., glass, impervious graphite), while the inner tube is of carbon steel. In glass construction, elements with 50.8- or 76.2-mm (2- or 3-in) glass pipe [with lengths to 2.7 m (9 ft)] are in contact with the external fluid, with an inner tube of metal.

**External Coils and Tracers** Tanks, vessels, and pipelines can be equipped for heating or cooling purposes with external coils. These are generally 9.8 to 19 mm (⅜ to ¾ in) so as to provide good distribution over the surface and are often of soft copper or aluminum, which can be bent by hand to the contour of the tank or line. When it is necessary to avoid "hot spots," the tracer is so mounted that it does not touch the tank.

External coils spaced away from the tank wall exhibit a coefficient of around 5.7 $W/(m^2 \cdot °C)$ [1 $Btu/(h \cdot ft^2$ of coil surface $\cdot °F)$]. Direct contact with the tank wall produces higher coefficients, but these are difficult to predict since they are strongly dependent upon the degree of contact. The use of *heat-transfer cements* does improve performance. These puttylike materials of high thermal conductivity are troweled or caulked into the space between the coil and the tank or pipe surface.

Costs of the cements (in 1960) varied from 37 to 63 cents per pound, with requirements running from about 0.27 lb/ft of ⅜-in outside-diameter tubing to 1.48 lb/ft of 1-in pipe. Panel coils require ½ to 1 $lb/ft^2$. A rule of thumb for preliminary estimating is that the per-foot installed cost of tracer with cement is about double that of the tracer alone.

**Jacketed Vessels** Jacketing is often used for vessels needing frequent cleaning and for glass-lined vessels that are difficult to equip with internal coils. The jacket eliminates the need for the coil yet gives a better overall coefficient than external coils do. However, only a limited heat-transfer area is available. The conventional jacket is of simple construction and is frequently used. It is most effective with a condensing vapor. A liquid heat-transfer fluid does not maintain uniform flow characteristics in such a jacket. Nozzles, which set up a swirling motion in the jacket, are effective in improving

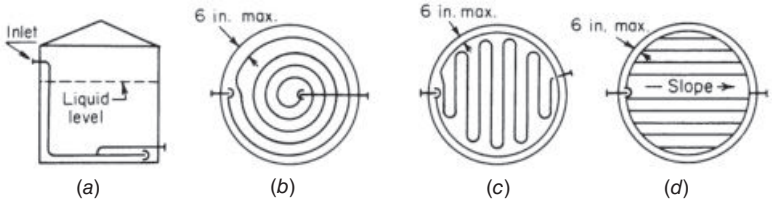

**FIG. 11-29*a*** Typical coil designs for good bottom coverage. (*a*) Elevated inlet on spiral coil. (*b*) Spiral with recircling ring. (*c*) Hairpin with encircling ring. (*d*) Ring header type.

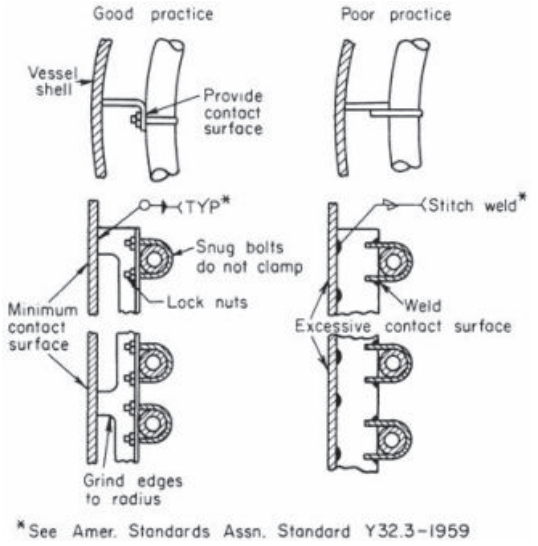

**FIG. 11-29*b*** Right and wrong ways to support coils. [*Chem. Eng.*, 172 (May 16, 1960).]

heat transfer. Wall thicknesses are often high unless reinforcement rings are installed.

*Spiral baffles*, which are sometimes installed for liquid services to improve heat transfer and prevent channeling, can be designed to serve as reinforcements. A spiral-wound channel welded to the vessel wall is an alternative to the spiral baffle which is more predictable in performance, since cross-baffle leakage is eliminated, and is reportedly lower in cost [Feichtinger, *Chem. Eng.* **67:** 197 (Sept. 5, 1960)].

The half-pipe jacket is used when high jacket pressures are required. The flow pattern of a liquid heat-transfer fluid can be controlled and designed for effective heat transfer. The dimple jacket offers structural advantages and is the most economical for high jacket pressures. The low volumetric capacity produces a fast response to temperature changes.

## EXTENDED OR FINNED SURFACES

**Finned-Surface Application** Extended or finned surfaces are often used when one film coefficient is substantially lower than the other, the goal being to make $h_o A_{oe} \approx h_i A_i$. A few typical fin configurations are shown in Fig. 11-30*a*. Longitudinal fins are used in double-pipe exchangers. Transverse fins are used in cross-flow and shell-and-tube configurations.

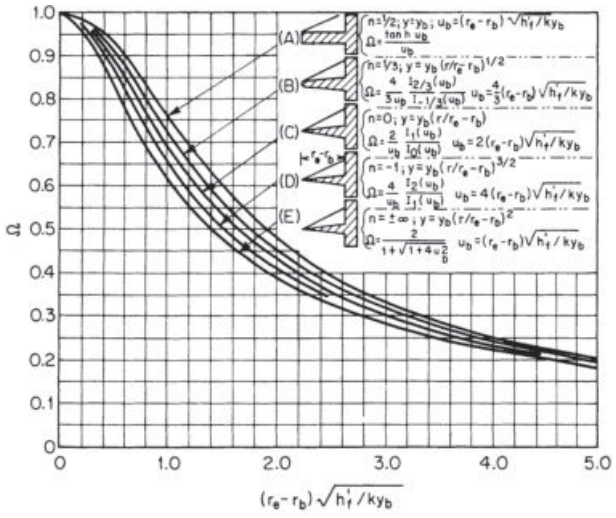

**FIG. 11-30*a*** Efficiencies for several longitudinal fin configurations.

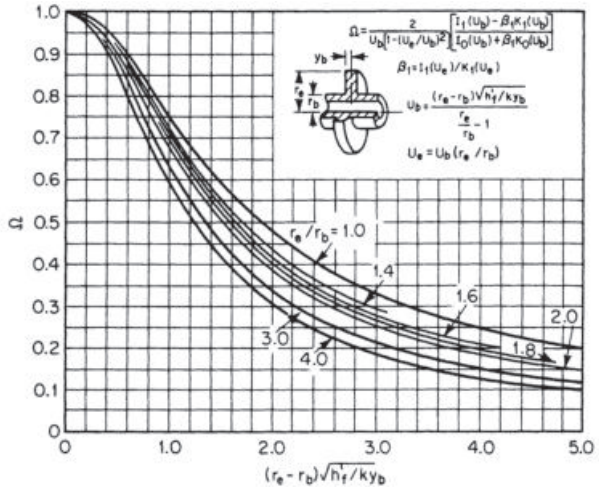

**FIG. 11-30*b*** Efficiencies for annular fins of constant thickness.

High transverse fins are used mainly with low-pressure gases; low fins are used for boiling and condensation of nonaqueous streams as well as for sensible-heat transfer. Finned surfaces have proved to be a successful means of controlling temperature-driven fouling such as coking and scaling. Fin spacing should be great enough to avoid entrapment of particulate matter in the fluid stream (5-mm minimum spacing).

The area added by the fin is not as efficient for heat transfer as bare tube surface owing to resistance to conduction through the fin. The effective heat-transfer area is

$$A_{oe} = A_{uf} + A_f \Omega \tag{11-45}$$

The fin efficiency is found from mathematically derived relations, in which the film heat-transfer coefficient is assumed to be constant over the entire fin and temperature gradients across the thickness of the fin have been neglected (see Kraus, *Extended Surfaces*, Spartan Books, Baltimore, Md., 1963). The efficiency curves for some common fin configurations are given in Fig. 11-30*a* and *b*.

**High Fins** To calculate heat-transfer coefficients for cross-flow to a transversely finned surface, it is best to use a correlation based on experimental data for that surface. Such data are not often available, and a more general correlation must be used, making allowance for the possible error. Probably the best general correlation for bundles of finned tubes is given by Schmidt [*Kaltetechnik* **15:** 98–102, 370–378 (1963)]:

$$hD_r/k = K(D_r \rho V'_{\max}/\mu)^{0.625} R_f^{-0.375} N_{\mathrm{Pr}}^{1/3} \tag{11-46}$$

where $K = 0.45$ for staggered tube arrays and 0.30 for in-line tube arrays; $D_r$ is the root or base diameter of the tube; $V'_{\max}$ is the maximum velocity through the tube bank, i.e., the velocity through the minimum flow area between adjacent tubes; and $R_f$ is the ratio of the total outside surface area of the tube (including fins) to the surface of a tube having the same root diameter but without fins.

*Pressure drop* is particularly sensitive to geometric parameters, and available correlations should be extrapolated to geometries different from those on which the correlation is based only with great caution and conservatism. The best correlation is that of Robinson and Briggs [*Chem. Eng. Prog.* **62:** Symp. Ser. 64, 177–184 (1966)].

**Low Fins** Low-finned tubing is generally used in shell-and-tube configurations. For sensible-heat transfer, only minor modifications are needed to permit the shell-side method given earlier to be used for both heat transfer and pressure [see Briggs, Katz, and Young, *Chem. Eng. Prog.* **59**(11): 49–59 (1963)]. For condensing on low-finned tubes in horizontal bundles, the Nusselt correlation is generally satisfactory for low-surface-tension [$\sigma < (3)(10^{-6})$ N/m (30 dyn/cm)] condensates; fins of finned surfaces should not be closely spaced for high-surface-tension condensates (notably water), which do not drain easily.

The modified Palen-Small method can be employed for reboiler design using finned tubes, but the maximum flux is calculated from $A_o$, the total outside heat-transfer area including fins. The resulting value of $q_{\max}$ refers to $A_o$.

## FOULING AND SCALING

*Fouling* refers to any change in the solid boundary separating two heat-transfer fluids, whether by dirt accumulation or other means, which results in a decrease in the rate of heat transfer occurring across that boundary. Fouling may be classified by mechanism into six basic categories:

1. *Corrosion fouling.* The heat-transfer surface reacts chemically with elements of the fluid stream, producing a less conductive corrosion layer on all or part of the surface.
2. *Biofouling.* Organisms present in the fluid stream are attracted to the warm heat-transfer surface where they attach, grow, and reproduce. The two subgroups are microbiofoulants such as slime and algae and macrobiofoulants such as snails and barnacles.
3. *Particulate fouling.* Particles held in suspension in the flow stream will deposit out on the heat-transfer surface in areas of sufficiently lower velocity.
4. *Chemical reaction fouling* (e.g., coking). Chemical reaction of the fluid takes place on the heat-transfer surface, producing an adhering solid product of reaction.
5. *Precipitation fouling* (e.g., scaling). A fluid containing some dissolved material becomes supersaturated with respect to this material at the temperatures seen at the heat-transfer surface. This results in a crystallization of the material which "plates out" on the warmer surface.
6. *Freezing fouling.* Overcooling of a fluid below the fluid's freezing point at the heat-transfer surface causes solidification and coating of the heat-transfer surface.

**Control of Fouling** Once the combination of mechanisms contributing to a particular fouling problem is recognized, methods to substantially reduce the fouling rate may be implemented. For the case of *corrosion fouling*, the common solution is to choose a less corrosive material of construction, balancing material cost with equipment life. In cases of *biofouling*, the use of copper alloys and/or chemical treatment of the fluid stream to control organism growth and reproduction is the most common solution.

In the case of *particulate fouling*, one of the more common types, ensuring a sufficient flow velocity and minimizing areas of lower velocities and stagnant flows to help keep particles in suspension are the most common means of dealing with the problem. For water, the recommended tube-side minimum velocity is about 0.9 to 1.0 m/s. This may not always be possible for moderate to high-viscosity fluids where the resulting pressure drop can be prohibitive.

Special care should be taken in the application of any velocity requirement to the shell side of segmental-baffled bundles due to the many different flow streams and velocities present during operation, the unavoidable existence of high-fouling areas of flow stagnation, and the danger of flow-induced tube vibration. In general, shell-side particulate fouling will be greatest for segmentally baffled bundles in the regions of low velocity, and the TEMA fouling factors (which are based upon the use of this bundle type) should be used. However, since the 1940s, there have been a host of successful, low-fouling exchangers developed, some tubular and others not, which have in common the elimination of the cross-flow plate baffle and provide practically no regions of flow stagnation at the heat-transfer surface. Some examples are the plate and frame exchanger, the spiral-plate exchanger, and the twisted tube exchanger, all of which have dispensed with baffles altogether and use the heat-transfer surface itself for bundle support. The general rule for these designs is to provide between 25 and 30 percent excess surface to compensate for potential fouling, although this can vary in special applications.

For the remaining classifications—*polymerization*, *precipitation*, and *freezing*—fouling is the direct result of temperature extremes at the heat-transfer surface and is reduced by reducing the temperature difference between the heat-transfer surface and the bulk-fluid stream. Conventional wisdom says to increase velocity, thus increasing the local heat-transfer coefficient to bring the heat-transfer surface temperature closer to the bulk-fluid temperature. However, due to a practical limit on the amount of heat-transfer coefficient increase available by increasing velocity, this approach, although better than nothing, is often not satisfactory by itself.

A more effective means of reducing the temperature difference is by using, in concert with adequate velocities, some form of extended surface. As discussed by Shilling (*Proceedings of the 10th International Heat Transfer Conference*, Brighton, U.K., **4:** 423, 1994), this will tend to reduce the temperature extremes between the fluid and heat-transfer surface and not only reduce the rate of fouling but also make the heat exchanger generally less sensitive to the effects of any fouling that does occur. In cases where unfinned tubing in a triangular tube layout would not be acceptable because fouling buildup and eventual mechanical cleaning are inevitable, an extended surface should be used only when the exchanger construction allows access for cleaning.

**Fouling Transients and Operating Periods** Three common behaviors are noted in the development of a fouling film over time. One is *asymptotic fouling* in which the speed of fouling resistance increase decreases over time as it approaches some asymptotic value beyond which no further fouling can occur. This is commonly found in temperature-driven fouling. A second behavior is *linear fouling* in which the increase in fouling resistance follows a straight line over the time of operation. This could be experienced in a case of severe particulate fouling where the accumulation of dirt during the time of operation did not appreciably increase velocities to mitigate the problem. The third behavior, *falling rate fouling*, is neither linear nor asymptotic but instead lies somewhere between these two extremes. The rate of fouling decreases with time but does not appear to approach an asymptotic maximum during the time of operation. This is the most common type of fouling in the process industry and is usually the result of a combination of different fouling mechanisms occurring together.

The optimum operating period between cleanings depends upon the rate and type of fouling, the heat exchanger used (i.e., baffle type, use of extended surface, and velocity and pressure drop design constraints), and the ease with which the heat exchanger may be removed from service for cleaning. As noted above, care must be taken in the use of fouling factors for exchanger design, especially if the exchanger configuration has been selected specifically to minimize fouling accumulation. An oversurfaced heat exchanger which will not foul enough to operate properly can be almost as much of a problem as an undersized exchanger. This is especially true in steam-heated exchangers where the ratio of design MTD to minimum achievable MTD is less than $U_{clean}$ divided by $U_{fouled}$.

**Removal of Fouling Deposits** Chemical removal of fouling can be achieved in some cases by weak acid, special solvents, and so on. Other deposits adhere weakly and can be washed off by periodic operation at very high velocities or by flushing with a high-velocity steam or water jet or using a sand-water slurry. These methods may be applied to both the shell side and tube side without pulling the bundle. Many fouling deposits, however, must be removed by positive mechanical action such as rodding, turbining, or scraping the surface. These techniques may be applied inside of tubes without pulling the bundle but can be applied on the shell side only after bundle removal. Even then there is limited access because of the tube pitch, and rotated square or large triangular layouts are recommended. In many cases, it has been found that designs developed to minimize fouling often develop a fouling layer which is more easily removed.

**Fouling Resistances** There are no published methods for predicting fouling resistances a priori. The accumulated experience of exchanger designers and users was assembled more than 40 years ago based primarily upon segmental-baffled exchanger bundles and may be found in the *Standards of Tubular Exchanger Manufacturers Association* (TEMA). In the absence of other information, the fouling resistances contained therein may be used.

## TYPICAL HEAT-TRANSFER COEFFICIENTS

Typical overall heat-transfer coefficients are given in Tables 11-3 through 11-8. Values from these tables may be used for preliminary estimating purposes. They should not be used in place of the design methods described elsewhere in this section, although they may serve as a useful check on the results obtained by those design methods.

## THERMAL DESIGN FOR SOLIDS PROCESSING

Solids in divided form, such as powders, pellets, and lumps, are heated and/or cooled in chemical processing for a variety of objectives such as solidification or fusing (Sec. 11), drying and water removal (Sec. 20), solvent recovery (Secs. 13 and 20), sublimation (Sec. 17), chemical reactions (Sec. 20), and oxidation. For process and mechanical-design considerations, see the referenced sections.

*Thermal design* concerns itself with sizing the equipment to effect the heat transfer necessary to carry on the process. The design equation is the familiar one basic to all modes of heat transfer, namely,

$$A = Q/U\,\Delta t \tag{11-47}$$

where $A$ = effective heat-transfer surface, $Q$ = quantity of heat required to be transferred, $\Delta t$ = temperature difference of the process, and $U$ = overall heat-transfer coefficient. It is helpful to define the modes of heat transfer and the corresponding overall coefficient, $U_{co}$, as $U_{co}$ = overall heat-transfer coefficient for (indirect through-a-wall) *conduction*, $U_{cv}$ = overall heat-transfer coefficient for the little-used *convection* mechanism, $U_{ct}$ = heat-transfer coefficient for the *contactive* mechanism in which the gaseous-phase heat carrier passes directly through the solids bed, and $U_{ra}$ = heat-transfer coefficient for *radiation.*

There are two general methods for determining numerical values for $U_{co}$, $U_{cv}$, $U_{ct}$, and $U_{ra}$. One is by analysis of actual operating data. Values so obtained are used on geometrically similar systems of a size not too different from the equipment from which the data were obtained. The second

| J Reduced crude | 17 | .005 | | | 55 | 45 | 40 | | | | | | | |
| K Heavy fuel oil (tar) | 10 | .005 | | | 50 | 40 | 35 | | | | | | | |

Fouling factor, water side 0.0002; heating or cooling streams are shown at top of columns as C, D, F, G, etc.; to convert British thermal units per hour-square foot-degrees Fahrenheit to joules per square meter-second-kelvins, multiply by 5.6783; to convert hours per square foot-degree Fahrenheit-British thermal units to square meters per second-kelvin-joules, multiply by 0.1761.
*Cooler, water-cooled, rates are about 5 percent lower.
†With heavy gas oil (H) as heating medium, rates are about 5 percent lower.

**TABLE 11-5 Overall Coefficients for Air-Cooled Exchangers on Bare-Tube Basis**

Btu/(°F · ft² · h)

| Condensing | Coefficient | Liquid cooling | Coefficient |
|---|---|---|---|
| Ammonia | 110 | Engine-jacket water | 125 |
| Freon-12 | 70 | Fuel oil | 25 |
| Gasoline | 80 | Light gas oil | 65 |
| Light hydrocarbons | 90 | Light hydrocarbons | 85 |
| Light naphtha | 75 | Light naphtha | 70 |
| Heavy naphtha | 65 | Reformer liquid streams | 70 |
| Reformer reactor effluent | 70 | Residuum | 15 |
| Low-pressure steam | 135 | Tar | 7 |
| Overhead vapors | 65 | | |

| Gas cooling | Operating pressure, lb./sq. in. gage | Pressure drop, lb./sq. in. | Coefficient |
|---|---|---|---|
| Air or flue gas | 50 | 0.1 to 0.5 | 10 |
| | 100 | 2 | 20 |
| | 100 | 5 | 30 |
| Hydrocarbon gas | 35 | 1 | 35 |
| | 125 | 3 | 55 |
| | 1000 | 5 | 80 |
| Ammonia reactor stream | | | 85 |

Bare-tube external surface is 0.262 ft²/ft.

Fin-tube surface/bare-tube surface ratio is 16.9.

To convert British thermal units per hour-square foot-degrees Fahrenheit to joules per square meter-second-kelvins, multiply by 5.6783; to convert pounds-force per square inch to kilopascals, multiply by 6.895.

method is predictive and is based on the material properties and certain operating parameters. Relative values of the coefficients for the various modes of heat transfer at temperatures up to 980°C (1800°F) are as follows (Holt, Paper 11, Fourth National Heat Transfer Conference, Buffalo, 1960):

| | |
|---|---|
| Convective | 1 |
| Radiant | 2 |
| Conductive | 20 |
| Contactive | 200 |

Because heat-transfer equipment for solids is generally an adaptation of a primarily material-handling device, the area of heat transfer is often small in relation to the overall size of the equipment. Also peculiar to solids heat transfer is that the $\Delta t$ varies for the different heat-transfer mechanisms. With a knowledge of these mechanisms, the $\Delta t$ term generally is readily estimated from temperature limitations imposed by the burden characteristics and/or the construction.

**Conductive Heat Transfer** Heat-transfer equipment in which heat is transferred by conduction is constructed so that the solids load (burden) is separated from the heating medium by a wall.

For a high proportion of applications, $\Delta t$ is the log-mean temperature difference. Values of $U_{co}$ are reported in Secs. 11, 15, 17, and 19.

A *predictive* equation for $U_{co}$ is

$$U_{co} = \left(\frac{h}{h - 2c\alpha/d_m}\right)\left(\frac{2c\alpha}{d_m}\right) \tag{11-48}$$

where $h$ = wall film coefficient, $c$ = volumetric heat capacity, $d_m$ = depth of the burden, and $\alpha$ = thermal diffusivity. Relevant thermal properties of various materials are given in Table 11-9. For details of terminology, equation development, numerical values of terms in typical equipment and use, see Holt [*Chem. Eng.* **69:** 107 (Jan. 8, 1962)].

Equation (11-48) is applicable to burdens in the solid, liquid, or gaseous phase, either static or in laminar motion; it is applicable to solidification equipment and to divided-solids equipment such as metal belts, moving trays, stationary vertical tubes, and stationary-shell fluidizers.

*Fixed- (or packed-) bed operation* occurs when the fluid velocity is low or the particle size is large so that fluidization does not occur. For such operation, Jakob (*Heat Transfer*, vol. 2, Wiley, New York, 1957) gives

$$hD_t/k = b_1 bD_t^{0.17}(D_pG/\mu)^{0.83}(c\mu/k) \tag{11-49a}$$

where $b_1 = 1.22$ (SI) or 1.0 (USCS), $h = U_{co}$ = overall coefficient between the inner container surface and the fluid stream,

$$b = 0.2366 + 0.0092\left(\frac{D_p}{D_t}\right) - 4.0672\left(\frac{D_p}{D_t}\right)^2 + 18.229\left(\frac{D_p}{D_t}\right)^3 - 11.837\left(\frac{D_p}{D_t}\right)^4 \tag{11-49b}$$

where $D_p$ = particle diameter, $D_t$ = vessel diameter (note that $D_p/D_t$ has units of feet per foot in the equation), $G$ = superficial mass velocity, $k$ = fluid

**TABLE 11-6 Panel Coils Immersed in Liquid: Overall Average Heat-Transfer Coefficients***

$U$ expressed in Btu/(h · ft² · °F)

*Values listed are for moderate nonproximity agitation. CS = carbon steel.

thermal conductivity, $\mu$ = fluid viscosity, and $c$ = fluid specific heat. Other correlations are those of Leva [*Ind. Eng. Chem.* **42:** 2498 (1950)]:

$$h = 0.813\frac{k}{D_t}e^{-6D_p/D_t}\left(\frac{D_pG}{\mu}\right)^{0.90} \quad \text{for} \quad \frac{D_p}{D_t} < 0.35 \qquad (11\text{-}50a)$$

$$h = 0.125\frac{k}{D_t}\left(\frac{D_pG}{\mu}\right)^{0.75} \quad \text{for} \quad 0.35 < \frac{D_p}{D_t} < 0.60 \qquad (11\text{-}50b)$$

and Calderbank and Pogerski [*Trans. Inst. Chem. Eng.* (London), **35:** 195 (1957)]:

$$hD_p/k = 3.6(D_pG/\mu\epsilon_v)^{0.365} \qquad (11\text{-}51)$$

where $\epsilon_v$ = fraction voids in the bed.

A technique for calculating radial temperature gradients in a packed bed is given by Smith (*Chemical Engineering Kinetics*, McGraw-Hill, New York, 1956).

*Fluidization* occurs when the fluid flow rate is great enough that the pressure drop across the bed equals the weight of the bed. As stated previously, the solids film thickness adjacent to the wall $d_m$ is difficult to measure and/or predict. Wen and Fau [*Chem. Eng.* **64**(7): 254 (1957)] give for *external walls*

$$h = bk(c_s\rho_s)^{0.4}(G\eta/\mu N_f)^{0.36} \qquad (11\text{-}51a)$$

where $b$ = 0.29 (SI) or 11.6 (USCS), $c_s$ = heat capacity of solid, $\rho_s$ = particle density, $\eta$ = fluidization efficiency (Fig. 11-31) and $N_f$ = bed expansion ratio (Fig. 11-32). *For internal walls*, Wen and Fau give

$$h_i = bhG^{-0.37} \qquad (11\text{-}51b)$$

**TABLE 11-8 External Coils; Typical Overall Coefficients***

$U$ expressed in Btu/(h · ft² · °F)

| Type of coil | Coil spacing, in* | Fluid in coil | Fluid in vessel | Temp. range, °F | U† without cement | U with heat-transfer cement |

To convert British thermal units per hour-square foot-degrees Fahrenheit to joules per meter-second-kelvins, multiply by 1.7307; to convert British thermal units per cubic foot-degrees Fahrenheit to joules per cubic meter-kelvins, multiply by $(6.707)(10^4)$; and to convert square feet per hour to square meters per second, multiply by $(2.581)(10^{-5})$.

where $b = 0.78$ (SI) or 9 (USCS), $h_i$ is the coefficient for internal walls, and $h$ is calculated from Eq. (11-51*a*). The minimum fluidizing velocity $G_{mf}$ is defined by

$$G_{mf} = \frac{b\rho_g^{1.1}(\rho_s - \rho_g)^{0.9} D_p^2}{\mu} \tag{11-51c}$$

where $b = (1.23)(10^{-2})$ (SI) or $(5.23)(10^5)$ (USCS).

Wender and Cooper [*Am. Inst. Chem. Eng. J.* **4:** 15 (1958)] developed an empirical correlation for *internal walls:*

$$\frac{hD_p/k}{1-\epsilon_v}\left(\frac{k}{c\rho}\right)^{0.43} = bC_R\left(\frac{D_pG}{\mu}\right)^{0.23}\left(\frac{c_s}{c_g}\right)^{0.80}\left(\frac{\rho_s}{\rho_g}\right)^{0.66} \tag{11-52a}$$

where $b = (3.51)(10^{-4})$ (SI) or 0.033 (USCS) and $C_R$ = correction for displacement of the immersed tube from the axis of the vessel (see the reference). For external walls:

$$\frac{hD_p}{k_g(1-\epsilon_v)(c_s\rho_s/c_g\rho_g)} = f(1+7.5e^{-x}) \tag{11-52b}$$

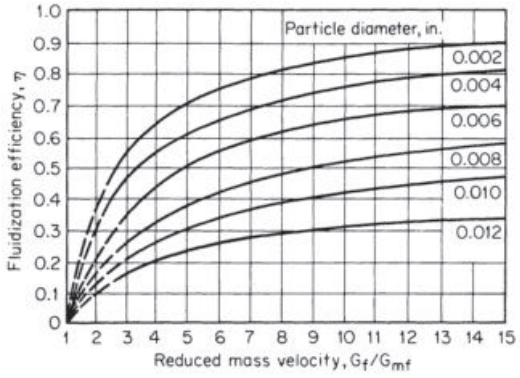

**FIG. 11-31** Fluidization efficiency.

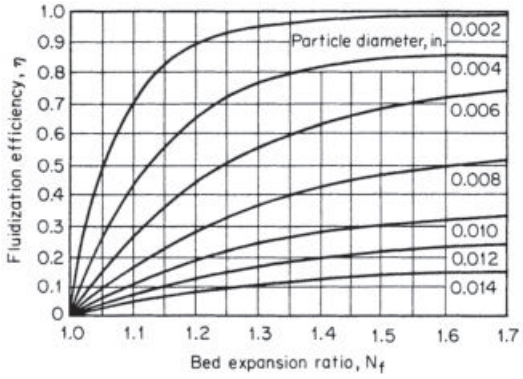

**FIG. 11-32** Bed expansion ratio.

where $x = 0.44L_Hc_s/D_tc_g$ and $f$ is given by Fig. 11-33. An important feature of this equation is the inclusion of the ratio of bed depth to vessel diameter $L_H/D_t$.

For *dilute fluidized beds* on the shell side of an unbaffled tubular bundle, Genetti and Knudsen [*Inst. Chem. Eng. (London)* Symp. Ser. 3:172 (1968)] obtained the relation:

$$\frac{hD_p}{k} = \frac{5\phi(1-\epsilon_v)}{\left[1+\frac{580}{N_{Re}}\left(\frac{k_s}{D_p^{1.5}C_s\rho_s g^{0.5}}\right)\left(\frac{\rho_s}{\rho_g}\right)^{1.1}\left(\frac{G_{mf}}{G}\right)^{7/3}\right]^2} \tag{11-53a}$$

where $\phi$ = particle surface area per area of sphere of same diameter. When particle transport occurred through the bundle, the heat-transfer coefficients could be predicted by

$$j_H = 0.14(N_{Re}/\phi)^{-0.68} \tag{11-53b}$$

In Eqs. (11-53*a*) and (11-53*b*), $N_{Re}$ is based on particle diameter and superficial fluid velocity.

Zenz and Othmer (*Fluidization and Fluid Particle Systems*, Reinhold, original from University of Michigan, 1960) give an excellent summary of fluidized bed-to-wall heat-transfer investigations.

*Solidification* involves heavy heat loads transferred essentially at a steady temperature difference. It also involves the varying values of liquid- and solid-phase thickness and thermal diffusivity. When these are substantial and/or in the case of a liquid flowing over a changing solid layer interface, Siegel and Savino (ASME Paper 67-WA/Ht-34, November 1967) offer equations and charts for prediction of the layer-growth time. For solidification (or melting) of a slab or a semi-infinite bar, initially at its transition temperature, the position of the interface is given by the one-dimensional Newmann's method given in Carslaw and Jaeger (*Conduction of Heat in Solids*, Clarendon Press, Oxford, 1959).

Later work by Hashem and Sliepcevich [*Chem. Eng. Prog.* **63:** 79, 35, 42 (1967)] offers more accurate second-order finite-difference equations.

The heat-transfer rate is found to be substantially higher under conditions of *agitation.* The heat transfer is usually said to occur by combined conductive and convective modes. A discussion and an explanation are given by Holt [*Chem. Eng.* **69**(1): 110 (1962)]. Prediction of $U_{co}$ by Eq. (11-48) can be accomplished by replacing $\alpha$ by $\alpha_e$, the effective thermal diffusivity of the bed. To date so little work has been performed in evaluating the effect of mixing parameters that few predictions can be made. However, for agitated liquid-phase devices, Eq. (18-19) is applicable. Holt [*Chem. Eng.* **69**(1): 110 (1962)] shows that this equation can be converted for solids heat transfer to yield

$$U_{co} = a'c_sD_t^{-0.3}N^{0.7}(\cos\omega)^{0.2} \tag{11-54}$$

where $D_t$ = agitator or vessel diameter; $N$ = turning speed, r/min; $\omega$ = effective angle of repose of the burden; and $a'$ = proportionality constant. This is applicable for such devices as agitated pans, agitated kettles, spiral conveyors, and rotating shells.

The solids passage time through *rotary devices* is given by Saemann [*Chem. Eng. Prog.* **47:** 508, (1951)]:

$$\theta = 0.318L\sin\omega/S_rND_t \tag{11-55a}$$

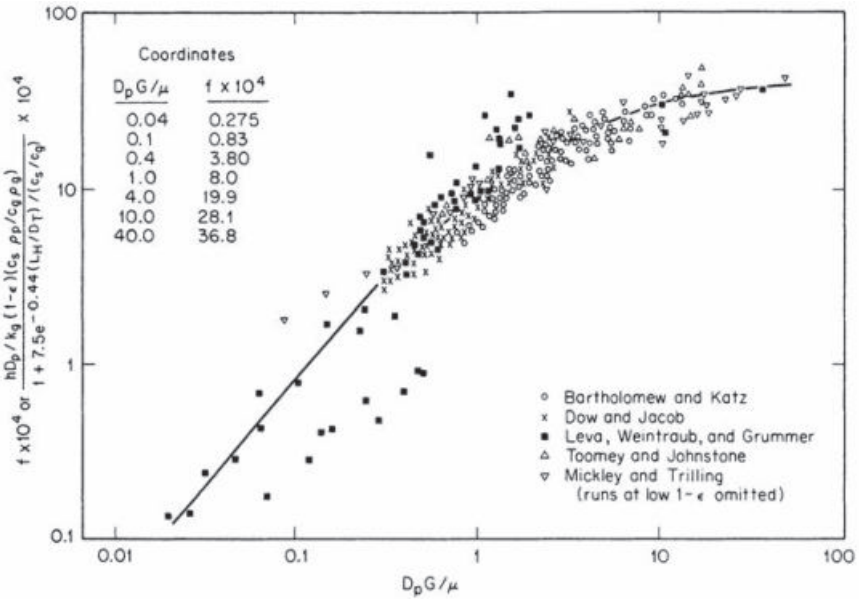

**FIG. 11-33** The $f$ factor for Eq. (11-52*b*).

and by Marshall and Friedman [*Chem. Eng. Prog.* **45**: 482–493, 573–588 (1949)]:

$$\theta = (0.23L/S_r N^{0.9} D_t) \pm (0.6BLG/F_a) \tag{11-55b}$$

where the second term of Eq. (11-55*b*) is positive for counterflow of air, negative for concurrent flow, and zero for indirect rotary shells. From these equations a predictive equation is developed for rotary-shell devices, which is analogous to Eq. (11-54):

$$U_{co} = \frac{b' c_s D_t N^{0.9} Y}{(\Delta t) L \sin \omega} \tag{11-56}$$

where $\theta$ = solids-bed passage time through the shell, min; $S_r$ = shell slope; $L$ = shell length; $Y$ = percent fill; and $b'$ = proportionality constant.

*Vibratory devices* which constantly agitate the solids bed maintain a relatively constant value for $U_{co}$ such that

$$U_{co} = a' c_s \alpha_e \tag{11-57}$$

with $U_{co}$ having a nominal value of 114 J/(m$^2 \cdot$ s $\cdot$ K) [20 Btu/(h $\cdot$ ft$^2 \cdot$ °F)].

**Contactive (Direct) Heat Transfer** Contactive heat-transfer equipment is so constructed that the particulate burden in solid phase is directly exposed to and permeated by the heating or cooling medium (Sec. 20). The carrier may either heat or cool the solids. A large amount of the industrial heat processing of solids is effected by this mechanism. Physically, these can be classified into packed beds and various degrees of agitated beds from dilute to dense fluidized beds.

The temperature difference for heat transfer is the log-mean temperature difference when the particles are large and/or the beds packed, or the difference between the inlet fluid temperature $t_3$ and average exhausting fluid temperature $t_4$, expressed as $\Delta_3 t_4$, for small particles. The use of the log mean for packed beds has been confirmed by Thodos and Wilkins (Second American Institute of Chemical Engineers-IIQPR Meeting, Paper 30D, Tampa, Fla., May 1968). When fluid and solid flow directions are axially concurrent and particle size is small, as in a vertical-shell fluid bed, the temperature of the exiting solids $t_2$ (which is also that of exiting gas $t_4$) is used as $\Delta_3 t_2$, as shown by Levenspiel, Olson, and Walton [*Ind. Eng. Chem.* **44:** 1478 (1952)], Marshall [*Chem. Eng. Prog.* **50:** Monogr. Ser. 2, 77 (1954)], Leva (*Fluidization*, McGraw-Hill, New York, 1959), and Holt (Fourth Int. Heat Transfer Conf. Paper 11, American Institute of Chemical Engineers-American Society of Mechanical Engineers, Buffalo, N.Y., 1960). This temperature difference is also applicable for well-fluidized beds of small particles in cross-flow as in various vibratory carriers.

The *packed-bed* to *fluid heat-transfer coefficient* has been investigated by Baumeister and Bennett [*Am. Inst. Chem. Eng. J.* **4:** 69 (1958)], who proposed the equation

$$j_H = (h/cG)(c\mu/k)^{2/3} = aN_{\mathrm{Re}}^m \tag{11-58}$$

where $N_{\mathrm{Re}}$ is based on particle diameter and superficial fluid velocity. Values of $a$ and $m$ are as follows:

| $D_t/D_p$ (dimensionless) | $a$ | $m$ |
|---|---|---|
| 10.7 | 1.58 | −0.40 |
| 16.0 | 0.95 | −0.30 |
| 25.7 | 0.92 | −0.28 |
| >30 | 0.90 | −0.28 |

Glaser and Thodos [*Am. Inst. Chem. Eng. J.* **4:** 63 (1958)] give a correlation involving individual particle shape and bed porosity. Kunii and Suzuki [*Int. J. Heat Mass Transfer* **10:** 845 (1967)] discuss heat and mass transfer in packed beds of fine particles.

*Particle-to-fluid* heat-transfer coefficients in gas *fluidized beds* are predicted by the relation (F. A. Zenz and D. F. Othmer, *Fluidization and Fluid Particle Systems*, Reinhold, original from University of Michigan, 1960)

$$\frac{hD_p}{k} = 0.017(D_p G_{mf}/\mu)^{1.21} \tag{11-59a}$$

where $G_{mf}$ is the superficial mass velocity at incipient fluidization.

A more general equation is given by Frantz [*Chem. Eng.* **69**(20): 89 (1962)]:

$$\frac{hD_p}{k} = 0.015(D_p G/\mu)^{1.6}(c\mu/k)^{0.67} \tag{11-59b}$$

where $h$ is based on true gas temperature.

*Bed-to-wall coefficients in dilute-phase transport* generally can be predicted by an equation of the form of Eq. (5-50). For example, Bonilla et al. (American Institute of Chemical Engineers Heat Transfer Symp., Atlantic City, N.J., December 1951) found for 1- to 2-μm chalk particles in water up to 8 percent by volume that the coefficient on Eq. (5-50) is 0.029 where $k$, ρ, and $c$ were arithmetic weighted averages and the viscosity was taken equal to the coefficient of rigidity. Farber and Morley [*Ind. Eng. Chem.* **49:** 1143 (1957)] found the coefficient on Eq. (5-50) to be 0.025 for the upward flow of air transporting silica-alumina catalyst particles at rates less than 2 kg solids/kg air (2 lb solids/lb air). Physical properties used were those of the transporting gas. See Zenz and Othmer (*Fluidization and Fluid Particle Systems*, Reinhold, original from University of Michigan, 1960) for additional details covering wider porosity ranges.

The thermal performance of *cylindrical rotating shell* units is based upon a volumetric heat-transfer coefficient

$$U_{ct} = \frac{Q}{V_r(\Delta t)} \tag{11-60a}$$

where $V_r$ = volume. This term indirectly includes an area factor so that thermal performance is governed by a cross-sectional area rather than by a heated area. Use of the heated area is possible, however:

$$U_{ct} = \frac{Q}{(\Delta_3 t_2)A} \quad \text{or} \quad U_{ct} = \frac{Q}{(\Delta_3 t_4)A} \tag{11-60b}$$

For *heat transfer directly to solids*, predictive equations give directly the volume $V$ or the heat-transfer area $A$, as determined by heat balance and air flow rate. For devices with gas flow normal to a fluidized-solids bed,

$$A = \frac{Q}{\Delta t_p (c\rho_g)(F_g)} \tag{11-61}$$

where $\Delta t_p = \Delta_3 t_4$ as explained above, $c\rho$ = volumetric specific heat, and $F_g$ = gas flow rate. For air, $c\rho$ at normal temperature and pressure is about 1100 J/(m$^3$·K) [0.0167 Btu/(ft$^3$·°F)]; so

$$A = \frac{bQ}{(\Delta_3 t_4)F_g} \tag{11-62}$$

where $b$ = 0.0009 (SI) or 60 (USCS). Another such equation—for stationary vertical-shell and some horizontal rotary-shell and pneumatic-transport devices in which the gas flow is parallel with and directionally concurrent with the fluidized bed—is the same as Eq. (11-62) with $\Delta_3 t_4$ replaced by $\Delta_3 t_2$. If the operation involves drying or chemical reaction, the heat load $Q$ is much greater than for sensible-heat transfer only. Also the gas flow rate to provide moisture carry-off and stoichiometric requirements must be considered and simultaneously provided. A good treatise on the latter is given by Pinkey and Plint (*Miner. Process.* June 1968, p. 17).

*Evaporative cooling* is a special patented technique that often can be advantageously employed in cooling solids by contactive heat transfer. The drying operation is terminated *before* the desired final moisture content is reached, and the solids temperature is at a moderate value. The cooling operation involves contacting the burden (preferably fluidized) with air at normal temperature and pressure. The air adiabatically absorbs and carries off a large part of the moisture and, in doing so, picks up heat from the warm (or hot) solids particles to supply the latent heat demand of evaporation. For entering solids at temperatures of 180°C (350°F) and less with normal heat capacity values of 0.85 to 1.0 kJ/(kg·K) [0.2 to 0.25 Btu/(lb·°F)], the effect can be calculated by the following procedure:

1. Use 285 m$^3$ (1000 ft$^3$) of air flow at normal temperature and pressure at 40 percent relative humidity to carry off 0.45 kg (1 lb) of water [latent heat 2326 kJ/kg (1000 Btu/lb)] and to lower temperature by 22°C to 28°C (40°F to 50°F).
2. Use the lowered solids temperature as $t_3$ and calculate the remainder of the heat to be removed in the regular manner by Eq. (11-62). The required air quantity for (2) must be equal to or greater than that for (1).

When the solids heat capacity is higher (as is the case for most organic materials), the temperature reduction is inversely proportional to the heat capacity.

A nominal result of this technique is that the required air flow rate and equipment size are about two-thirds of that when evaporative cooling is not used. See Sec. 20 for equipment available.

**Convective Heat Transfer** Equipment using the true convective mechanism when the heated particles are mixed with (and remain with) the cold particles is used so infrequently that performance and sizing equations are not available. Such a device is the pebble heater as described by Norton (*Chem. Metall. Eng.* July 1946). For operation data, see Sec. 9.

Convective heat transfer is often used as an adjunct to other modes, particularly to the conductive mode. It is often more convenient to consider the agitative effect a performance improvement influence on the thermal diffusivity factor $\alpha$, modifying it to $\alpha_e$, the effective value.

*A pseudo-convective heat-transfer* operation is one in which the heating gas (generally air) is passed over a bed of solids. Its use is almost exclusively limited to drying operations (see Sec. 12, tray and shelf dryers). The operation, sometimes termed *direct*, is more akin to the conductive mechanism. For this operation, Tsao and Wheelock [*Chem. Eng.* **74**(13): 201 (1967)] predict the heat-transfer coefficient when radiative and conductive effects are absent by

$$h = bG^{0.8} \tag{11-63}$$

where $b$ = 14.31 (SI) or 0.0128 (USCS), $h$ = convective heat transfer, and $G$ = gas flow rate.

The *drying rate* is given by

$$K_{cv} = \frac{h(T_d - T_w)}{\lambda} \tag{11-64}$$

where $K_{cv}$ = drying rate, for constant-rate period, kg/(m$^2$·s) [lb/(h·ft$^2$)]; $T_d$ and $T_w$ = respective dry-bulb and wet-bulb temperatures of the air; and $\lambda$ = latent heat of evaporation at temperature $T_w$. Note here that the temperature-difference determination of the operation is a simple linear one and of a steady-state nature. Also note that the operation is a function of the air flow rate. Further, the solids are granular with a fairly uniform size, have reasonable capillary voids, are of a firm texture, and have the particle surface wetted.

The coefficient $h$ is also used to predict (in the constant-rate period) the total overall air-to-solids heat-transfer coefficient $U_{cv}$ by

$$1/U_{cv} = 1/h + x/k \tag{11-65}$$

where $k$ = solids thermal conductivity and $x$ is evaluated from

$$x = \frac{z(X_c - X_o)}{X_c - X_e} \tag{11-65a}$$

where $z$ = bed (or slab) thickness and is the total thickness when drying and/or heat transfer is from one side only but is one-half of the thickness when drying and/or heat transfer is simultaneously from both sides; $X_o$, $X_c$, and $X_e$ are, respectively, the initial (or feed-stock), critical, and equilibrium (with the drying air) moisture contents of the solids, all in kg $H_2O$/kg dry solids (lb $H_2O$/lb dry solids). This coefficient is used to predict the *instantaneous* drying rate

$$-\frac{W}{A}\frac{dX}{d\theta} = \frac{U_{cv}(T_d - T_w)}{\lambda} \tag{11-66}$$

By rearrangement, this can be made into a design equation as follows:

$$A = -\frac{W\lambda(dX/d\theta)}{U_{cv}(T_d - T_w)} \tag{11-67}$$

where $W$ = weight of dry solids in the equipment, $\lambda$ = latent heat of evaporation, and $\theta$ = drying time. The reader should refer to the full reference article by Tsao and Wheelock for other solids conditions qualifying the use of these equations.

**Radiative Heat Transfer** Heat-transfer equipment using the radiative mechanism for divided solids is constructed as a "table" which is stationary, as with trays, or moving, as with a belt, and/or agitated, as with a vibrated pan, to distribute and expose the burden in a plane parallel to (but not in contact with) the plane of the radiant-heat sources. Presence of air is not necessary (see Sec. 12 for vacuum-shelf dryers and Sec. 22 for resublimation). In fact, if air in the intervening space has a high humidity or $CO_2$ content, it acts as an energy absorber, thereby depressing the performance.

For the radiative mechanism, the temperature difference is evaluated as

$$D_t = T_e^4 - T_r^4 \tag{11-68}$$

where $T_e$ = absolute temperature of the radiant-heat source, K (°R), and $T_r$ = absolute temperature of the bed of divided solids, K (°R).

Numerical values for $U_{ra}$ for use in the general design equation may be calculated from experimental data by

$$U_{ra} = \frac{Q}{A(T_e^4 - T_r^4)} \tag{11-69}$$

The literature to date offers practically no such values. However, enough proprietary work has been performed to present a reliable evaluation for the comparison of mechanisms (see Introduction: Modes of Heat Transfer).

For the radiative mechanism of heat transfer to solids, the rate equation for parallel-surface operations is

$$q_{ra} = b(T_e^4 - T_r^4)i_f \tag{11-70}$$

where $b$ = (5.67)(10$^{-8}$) (SI) or (0.172)(10$^{-8}$) (USCS), $q_{ra}$ = radiative heat flux, and $i_f$ = an interchange factor which is evaluated from

$$1/i_f = 1/e_s + 1/e_r - 1 \tag{11-70a}$$

where $e_s$ = coefficient of emissivity of the source and $e_r$ = "emissivity" (or "absorptivity") of the receiver, which is the divided-solids bed. For the emissivity values, particularly of the heat source $e_s$, an important consideration is the wavelength at which the radiant source emits as well as the flux density of the emission. Data for these values are available from Polentz [*Chem. Eng.* **65**(7): 137; (8): 151 (1958)] and Adlam (*Radiant Heating*, Industrial Press, New York, p. 40). Both give radiated flux density versus wavelength at varying temperatures. Often the seemingly cooler but longer wavelength source is the better selection.

Emitting sources are (1) pipes, tubes, and platters carrying steam, 2100 kPa (300 lbf/in$^2$); (2) electric conducting glass plates, 150°C to 315°C (300°F to 600°F) range; (3) lightbulb type (tungsten-filament resistance

heater); (4) modules of refractory brick for gas burning at high temperatures and high fluxes; and (5) modules of quartz tubes, also operable at high temperatures and fluxes. For some emissivity values see Table 11-10.

For *predictive work*, where $U_{ra}$ is desired for sizing, this can be obtained by dividing the flux rate $q_{ra}$ by $\Delta t$:

$$U_{ra} = q_{ra}/(T_e^4 - T_r^4) = i_f b \tag{11-71}$$

where $b = (5.67)(10^{-8})$ (SI) or $(0.172)(10^{-8})$ (USCS). Hence

$$A = \frac{Q}{U_{ra}(T_e^4 - T_r^4)} \tag{11-72}$$

where $A$ = bed area of solids in the equipment.

**TABLE 11-10 Normal Total Emissivity of Various Surfaces**

A. Metals and Their Oxides

| Surface | $t$, °F.* | Emissivity* | Surface | $t$, °F.* | Emissivity* |

*When two temperatures and two emissivities are given, they correspond, first to first and second to second, and linear interpolation is permissible. °C = (°F − 32)/1.8.
†Although this value is probably high, it is given for comparison with the data by the same investigator to show the effect of oil layers. See Aluminum, Part A of this table.

These are important considerations in the application of the foregoing equations:

1. Since the temperature of the emitter is generally known (preselected or readily determined in an actual operation), the absorptivity value $e_r$ is the unknown. This absorptivity is partly a measure of the ability of radiant heat to penetrate the body of a solid particle (or a moisture film) instantly, as compared with diffusional heat transfer by conduction. Such instant penetration greatly reduces processing time and case-hardening effects. Moisture release and other mass transfer, however, still progress by diffusional means.

2. In one of the major applications of radiative devices (drying), the surface-held moisture is a good heat absorber in the 2- to 7-μm wavelength range. Therefore, the absorptivity, color, and nature of the solids are of little importance.

3. For drying, it is important to provide a small amount of venting air to carry away the water vapor. This is needed for two reasons. First, water vapor is a good absorber of 2- to 7-μm energy. Second, water vapor accumulation depresses further vapor release by the solids. If the air over the solids is kept fairly dry by venting, very little heat is carried off, because dry air does not absorb radiant heat.

4. For some of the devices, when the overall conversion efficiency has been determined, the application is primarily a matter of computing the required heat load. It should be kept in mind, however, that there are two conversion efficiencies that must be differentiated. One measure of efficiency is that with which the source converts input energy to output radiated energy. The other is the overall efficiency that measures the proportion of input energy that is actually absorbed by the solids. This latter is, of course, the one that really matters.

Other applications of radiant-heat processing of solids are the toasting, puffing, and baking of foods and the low-temperature roasting and preheating of plastic powder or pellets. Since the determination of heat loads for these operations is not well established, bench and pilot tests are generally necessary. Such processes require a fast input of heat and higher heat fluxes than can generally be provided by indirect equipment. Because of this, infrared-equipment size and space requirements are often much lower.

Although direct contactive heat transfer can provide high temperatures and heat concentrations and at the same time be small in size, its use may not always be preferable because of undesired side effects such as drying, contamination, case hardening, shrinkage, off color, and dusting.

When radiating and receiving surfaces are not in parallel, as in rotary-kiln devices, and the solids burden bed may be only intermittently exposed and/or agitated, the calculation and procedures become very complex, with photometric methods of optics requiring consideration. The following equation for heat transfer, which allows for convective effects, is commonly used by designers of *high-temperature furnaces:*

$$q_{ra} = Q/A = b\sigma\,[(T_g/100)^4 - (T_s/100)^4] \qquad (11\text{-}73)$$

where $b = 5.67$ (SI) or 0.172 (USCS); $Q$ = total furnace heat transfer; $\sigma$ = an emissivity factor with recommended values of 0.74 for gas, 0.75 for oil, and 0.81 for coal; $A$ = effective area for absorbing heat (here the solids burden exposed area); $T_g$ = exiting combustion gas absolute temperature; and $T_s$ = absorbing surface temperature.

In rotary devices, reradiation from the exposed shell surface to the solids bed is a major design consideration. A treatise on furnaces, including radiative heat-transfer effects, is given by Ellwood and Danatos [*Chem. Eng.* **73**(8): 174 (1966)]. For discussion of radiation heat-transfer computational methods, heat fluxes obtainable, and emissivity values, see Schornshort and Viskanta (ASME Paper 68-H 7-32), Sherman (ASME Paper 56-A-111), and the following subsection.

## SCRAPED-SURFACE EXCHANGERS

Scraped-surface exchangers have a rotating element with spring-loaded scraper blades to scrape the inside surface (Fig. 11-34). Generally a double-pipe construction is used; the scraping mechanism is in the inner pipe,

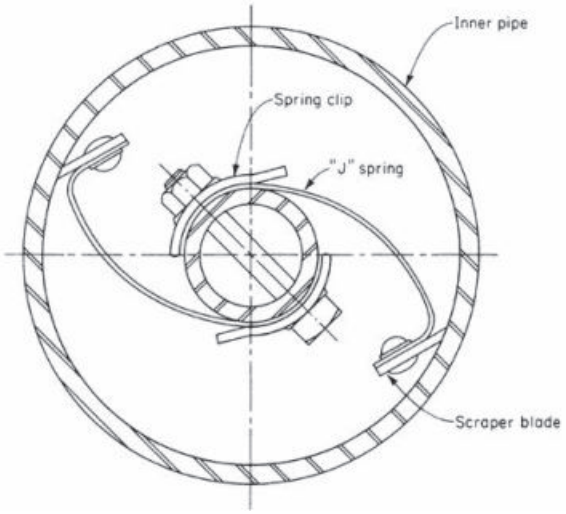

**FIG. 11-34** Scraper blade of scraped-surface exchanger. (*Henry Vogt Machine Co., Inc.*)

where the process fluid flows; and the cooling or heating medium is in the outer pipe. The most common size has 6-in inside and 8-in outside pipes. Also available are 3- by 4-in, 8- by 10-in, and 12- by 14-in sizes (in × 25.4 = mm). These double-pipe units are commonly connected in series and arranged in double stands.

For *chilling* and *crystallizing* with an evaporating refrigerant, a 27-in shell with seven 6-in pipes is available (Henry Vogt Machine Co.). In direct contact with the scraped surface is the process fluid which may deposit crystals upon chilling or be extremely fouling or of very high viscosity. Motors, chain drives, appropriate guards, and so on are required for the rotating element. For chilling service with a refrigerant in the outer shell, an accumulator drum is mounted on top of the unit.

Scraped-surface exchangers are particularly suitable for heat transfer with crystallization, heat transfer with severe fouling of surfaces, heat transfer with solvent extraction, and heat transfer of high-viscosity fluids. They are extensively used in paraffin-wax plants and in petrochemical plants for crystallization.

# TEMA-STYLE SHELL-AND-TUBE HEAT EXCHANGERS

## TYPES AND DEFINITIONS

TEMA-style shell-and-tube-type exchangers constitute the bulk of the unfired heat-transfer equipment in chemical-process plants, although increasing emphasis has been developing in other designs. These exchangers are illustrated in Fig. 11-35, and their features are summarized in Table 11-11.

**TEMA Numbering and Type Designation** Recommended practice for the designation of TEMA-style shell-and-tube heat exchangers by numbers and letters has been established by the Tubular Exchanger Manufacturers Association. This information from the sixth edition of the TEMA Standards is reproduced in the following paragraphs.

It is recommended that heat exchanger size and type be designated by numbers and letters.

1. *Size.* Sizes of shells (and tube bundles) shall be designated by numbers describing shell (and tube-bundle) diameters and tube lengths as follows:

2. *Diameter.* The nominal diameter shall be the inside diameter of the shell in inches, rounded off to the nearest integer. For kettle reboilers the nominal diameter shall be the port diameter followed by the shell diameter, each rounded off to the nearest integer.

3. *Length.* The nominal length shall be the tube length in inches. Tube length for straight tubes shall be taken as the actual overall length. For U tubes the length shall be taken as the straight length from end of tube to bend tangent.

4. *Type.* Type designation shall be by letters describing stationary head, shell (omitted for bundles only), and rear head, in that order, as indicated in Fig. 11-1.

**Typical Examples**

1. Split-ring floating heat exchanger with removable channel and cover, single-pass shell, 591-mm (23¼-in) inside diameter with tubes 4.9 m (16 ft) long. SIZE 23–192 TYPE AES.

2. U-tube exchanger with bonnet-type stationary head, split-flow shell, 483-mm (19-in) inside diameter with tubes 21-m (7-ft) straight length. SIZE 19–84 TYPE GBU.

3. Pull-through floating-heat-kettle type of reboiler having stationary head integral with tube sheet, 584-mm (23-in) port diameter and 940-mm (37-in) inside shell diameter with tubes 4.9-m (16-ft) long. SIZE 23/37–192 TYPE CKT.

4. Fixed-tube sheet exchanger with removable channel and cover, bonnet-type rear head, two-pass shell, 841-mm (33⅛-in) diameter with tubes 2.4 m (8 ft) long. SIZE 33–96 TYPE AFM.

5. Fixed-tube sheet exchanger having stationary and rear heads integral with tube sheets, single-pass shell, 432-mm (17-in) inside diameter with tubes 4.9 m (16 ft) long. SIZE 17–192 TYPE CEN.

**Functional Definitions** Heat-transfer equipment can be designated by type (e.g., fixed tube sheet, outside packed head, etc.) or by function (chiller, condenser, cooler, etc.). Almost any type of unit can be used to perform any of or all the listed functions. Many of these terms have been defined by Donahue [*Pet. Process.* 103 (March 1956)].

| Equipment | Function |
|---|---|
| Chiller | Cools a fluid to a temperature below that obtainable if only water were used as a coolant. It uses a refrigerant such as ammonia or Freon. |
| Condenser | Condenses a vapor or mixture of vapors, either alone or in the presence of a noncondensible gas. |
| Partial condenser | Condenses vapors at a point high enough to provide a temperature difference sufficient to preheat a cold stream of process fluid. This saves heat and eliminates the need for providing a separate preheater (using flame or steam). |
| Final condenser | Condenses the vapors to a final storage temperature of approximately 37.8°C (100°F). It uses water cooling, which means that the transferred heat is lost to the process. |
| Cooler | Cools liquids or gases by means of water. |
| Exchanger | Performs a double function: (1) heats a cold fluid by (2) using a hot fluid which it cools. None of the transferred heat is lost. |
| Heater | Imparts sensible heat to a liquid or a gas by means of condensing steam or Dowtherm. |
| Reboiler | Connected to the bottom of a fractionating tower, it provides the reboil heat necessary for distillation. The heating medium may be either steam or a hot-process fluid. |
| Thermosiphon reboiler | Natural circulation of the boiling medium is obtained by maintaining sufficient liquid head to provide for circulation. |
| Forced-circulation reboiler | A pump is used to force liquid through the reboiler. |
| Steam generator | Generates steam for use elsewhere in the plant by using the available high-level heat in tar or a heavy oil. |
| Superheater | Heats a vapor above the saturation temperature. |
| Vaporizer | A heater that vaporizes part of the liquid. |
| Waste-heat boiler | Produces steam; similar to steam generator, except that the heating medium is a hot gas or liquid produced in a chemical reaction. |

## GENERAL DESIGN CONSIDERATIONS

**Selection of Flow Path** In selecting the flow path for two fluids through an exchanger, several general approaches are used. The tube-side fluid is more corrosive or dirtier or at a higher pressure. The shell-side fluid is a liquid of high viscosity or a gas.

When alloy construction for one of the two fluids is required, a carbon-steel shell combined with alloy tube-side parts is less expensive than alloy in contact with the shell-side fluid combined with carbon-steel headers.

Cleaning of the inside of tubes is more readily done than cleaning of exterior surfaces.

For gauge pressures in excess of 2068 kPa (300 lbf/in$^2$) for one of the fluids, the less expensive construction has the high-pressure fluid in the tubes.

For a given pressure drop, higher heat-transfer coefficients are obtained on the shell side than on the tube side.

Heat exchanger shutdowns are most often caused by fouling, corrosion, and erosion.

**Construction Codes** "Rules for Construction of Pressure Vessels, Division 1," which is part of Section VIII of the ASME Boiler and Pressure Vessel Code (American Society of Mechanical Engineers), serves as a construction code by providing minimum standards. New editions of the code are usually issued every 3 years. Interim revisions are made semiannually in the form of addenda. Compliance with ASME Code requirements is mandatory in much of the United States and Canada. Originally these rules were not prepared for heat exchangers. However, the welded joint between tube sheet and shell of the fixed-tube-sheet heat exchanger is now included. A nonmandatory appendix on from the tube to tube-sheet joints is also included. Additional rules for heat exchangers are being developed.

*Standards of Tubular Exchanger Manufacturers Association*, 6th ed., 1978 (commonly referred to as the TEMA Standards), serve to supplement and define the ASME Code for all shell-and-tube type of heat exchanger applications (other than double-pipe construction). TEMA Class R design is "for the generally severe requirements of petroleum and related processing applications. Equipment fabricated in accordance with these standards is designed for safety and durability under the rigorous service and maintenance conditions in such applications." TEMA Class C design is "for the generally moderate requirements of commercial and general process applications," while TEMA Class B is "for chemical process service."

The mechanical design requirements are identical for all three classes of construction. The differences between the TEMA classes are minor and were listed by Rubin [*Hydrocarbon Process* **59:** 92 (June 1980)].

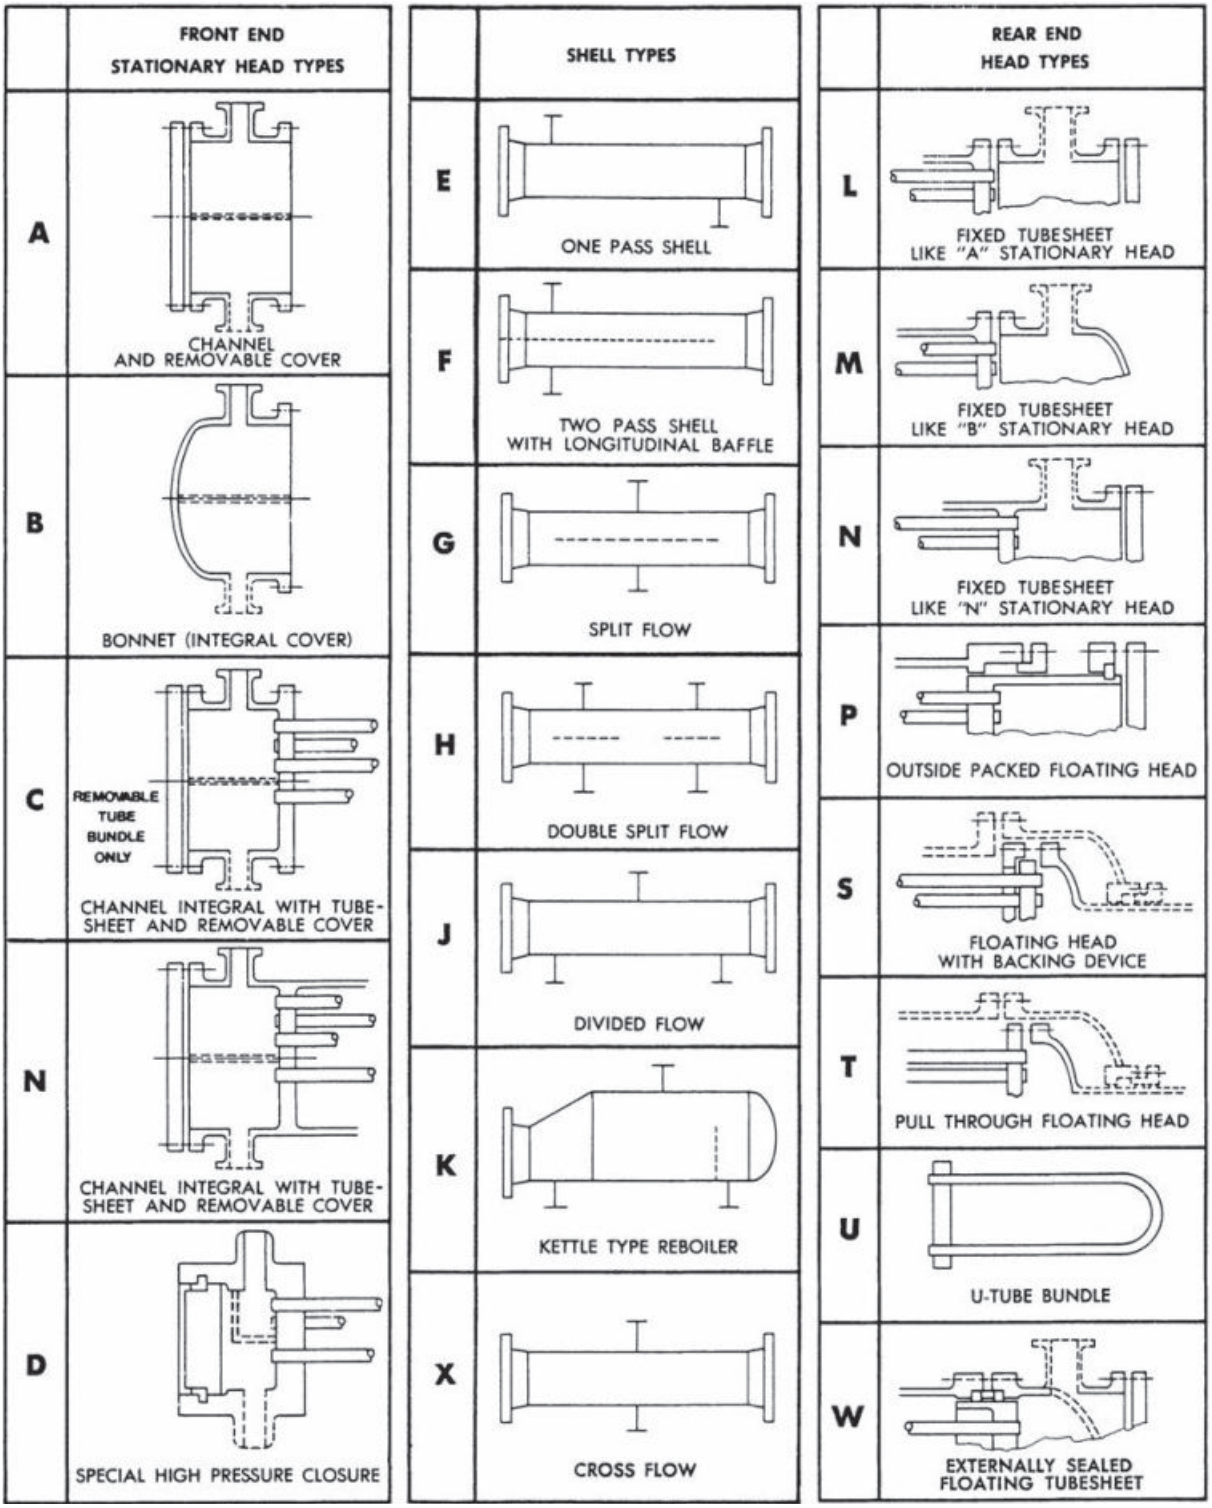

**FIG. 11-35** TEMA-type designations for shell-and-tube heat exchangers. (*Standards of Tubular Exchanger Manufacturers Association, 6th ed., 1978.)*

**TABLE 11-11 Features of TEMA Shell-and-Tube-Type Exchangers***

| Type of design | Fixed tube sheet | U-tube | Packed lantern-ring floating head | Internal floating head (split backing ring) | Outside-packed floating head | Pull-through floating head |
|---|---|---|---|---|---|---|
| T.E.M.A. rear-head type | L or M or N | U | W | S | P | T |
| Relative cost increases from A (least expensive) through E (most expensive) | B | A | C | E | D | E |
| Provision for differential expansion | Expansion joint in shell | Individual tubes free to expand | Floating head | Floating head | Floating head | Floating head |
| Removable bundle | No | Yes | Yes | Yes | Yes | Yes |
| Replacement bundle possible | No | Yes | Yes | Yes | Yes | Yes |
| Individual tubes replaceable | Yes | Only those in outside row† | Yes | Yes | Yes | Yes |
| Tube cleaning by chemicals inside and outside | Yes | Yes | Yes | Yes | Yes | Yes |
| Interior tube cleaning mechanically | Yes | Special tools required | Yes | Yes | Yes | Yes |
| Exterior tube cleaning mechanically: | | | | | | |
| Triangular pitch | No | No‡ | No‡ | No‡ | No‡ | No‡ |
| Square pitch | No | Yes | Yes | Yes | Yes | Yes |
| Hydraulic-jet cleaning: | | | | | | |
| Tube interior | Yes | Special tools required | Yes | Yes | Yes | Yes |
| Tube exterior | No | Yes | Yes | Yes | Yes | Yes |
| Double tube sheet feasible | Yes | Yes | No | No | Yes | No |
| Number of tube passes | No practical limitations | Any even number possible | Limited to one or two passes | No practical limitations§ | No practical limitations | No practical limitations§ |
| Internal gaskets eliminated | Yes | Yes | Yes | No | Yes | No |

NOTE: Relative costs A and B are not significantly different and interchange for long lengths of tubing.

*Modified from page a-8 of the Patterson-Kelley Co. Manual No. 700A, Heat Exchangers.

†U-tube bundles have been built with tube supports which permit the U-bends to be spread apart and tubes inside of the bundle replaced.

‡Normal triangular pitch does not permit mechanical cleaning. With a wide triangular pitch, which is equal to 2 (tube diameter plus cleaning lane)/$\sqrt{3}$, mechanical cleaning is possible on removable bundles. This wide spacing is infrequently used.

§For odd number of tube side passes, floating head requires packed joint or expansion joint.

Among the topics of the TEMA Standards are nomenclature, fabrication tolerances, inspection, guarantees, tubes, shells, baffles and support plates, floating heads, gaskets, tube sheets, channels, nozzles, end flanges and bolting, material specifications, and fouling resistances.

*Shell and Tube Heat Exchangers for General Refinery Services*, API Standard 660, 4th ed., 1982, is published by the American Petroleum Institute to supplement both the TEMA Standards and the ASME Code. Many companies in the chemical and petroleum processing fields have their own standards to supplement these various requirements. *The Interrelationships between Codes, Standards, and Customer Specifications for Process Heat Transfer Equipment* is a symposium volume which was edited by F. L. Rubin and published by ASME in December 1979. (See discussion of pressure vessel codes in Sec. 6.)

Design pressures and temperatures for exchangers usually are specified with a margin of safety beyond the conditions expected in service. Design pressure is generally about 172 kPa (25 lbf/in$^2$) greater than the maximum expected during operation or at pump shutoff. Design temperature is commonly 14°C (25°F) greater than the maximum temperature in service.

**Tube Bundle Vibration** Damage from tube vibration has become an increasing problem as plate baffled heat exchangers are designed for higher flow rates and pressure drops. The most effective method of dealing with this problem is the avoidance of cross-flow by use of tube support baffles which promote only longitudinal flow. However, even then, strict attention must be paid to the bundle area under the shell inlet nozzle where flow is introduced through the side of the shell. TEMA has devoted an entire section in its standards to this topic. In general, the mechanisms of tube vibration are as follows:

***Vortex Shedding*** The vortex-shedding frequency of the fluid in cross-flow over the tubes may coincide with a natural frequency of the tubes and excite large resonant vibration amplitudes.

***Fluid-Elastic Coupling*** Fluid flowing over tubes causes them to vibrate with a whirling motion. The mechanism of fluid-elastic coupling occurs when a "critical" velocity is exceeded and the vibration then becomes self-excited and grows in amplitude. This mechanism frequently occurs in process heat exchangers which suffer vibration damage.

***Pressure Fluctuation*** Turbulent pressure fluctuations which develop in the wake of a cylinder or are carried to the cylinder from upstream may provide a potential mechanism for tube vibration. The tubes respond to the portion of the energy spectrum that is close to their natural frequency.

***Acoustic Coupling*** When the shell-side fluid is a low-density gas, acoustic resonance or coupling develops when the standing waves in the shell are in phase with vortex shedding from the tubes. The standing waves are perpendicular to the axis of the tubes and to the direction of cross-flow. Damage to the tubes is rare. However, the noise can be extremely painful.

**Testing** Upon completion of shop fabrication and also during maintenance operations, it is desirable hydrostatically to test the shell side of tubular exchangers so that visual examination of tube ends can be made. Leaking tubes can be readily located and serviced. When leaks are determined without access to the tube ends, it is necessary to reroll or reweld all the tube–tube-sheet joints with possible damage to the satisfactory joints.

Testing for leaks in heat exchangers was discussed by Rubin [*Chem. Eng.* **68:** 160–166 (July 24, 1961)].

*Performance* testing of heat exchangers is described in the American Institute of Chemical Engineers' *Standard Testing Procedure for Heat Exchangers*, Sec. 1, "Sensible Heat Transfer in Shell-and-Tube-Type Equipment."

## PRINCIPAL TYPES OF CONSTRUCTION

Figure 11-36 shows details of the construction of the TEMA types of shell-and-tube heat exchangers. These and other types are discussed in the following paragraphs.

**Fixed-Tube-Sheet Heat Exchangers** Fixed-tube-sheet exchangers (Fig. 11-36*b*) are used more often than any other type, and the frequency of use has been increasing in recent years. The tubesheets are welded to the shell. Usually these extend beyond the shell and serve as flanges to which the tube-side headers are bolted. This construction requires that the shell-and-tube-sheet materials be weldable to each other.

When such welding is not possible, a "blind"-gasket type of construction is utilized. The blind gasket is not accessible for maintenance or replacement once the unit has been constructed. This construction is used for steam surface condensers, which operate under vacuum.

The tube-side header (or channel) may be welded to the tubesheet, as shown in Fig. 11-35 for type C and N heads. This type of construction is less costly than types B and M or A and L and still offers the advantage that tubes may be examined and replaced without disturbing the tube-side piping connections.

There is no limitation on the number of tube-side passes. Shell-side passes can number one or more, although shells with more than two shell-side passes are rarely used.

Tubes can completely fill the heat exchanger shell. Clearance between the outermost tubes and the shell is only the minimum necessary for fabrication. Between the inside of the shell and the baffles some clearance must be provided so that baffles can slide into the shell. Fabrication tolerances then require some additional clearance between the outside of the baffles and the outermost tubes. The edge distance between the *outer tube limit* (OTL) and the baffle diameter must be sufficient to prevent vibration of the tubes from breaking through the baffle holes. The outermost tube must be contained within the OTL. Clearances between the inside shell

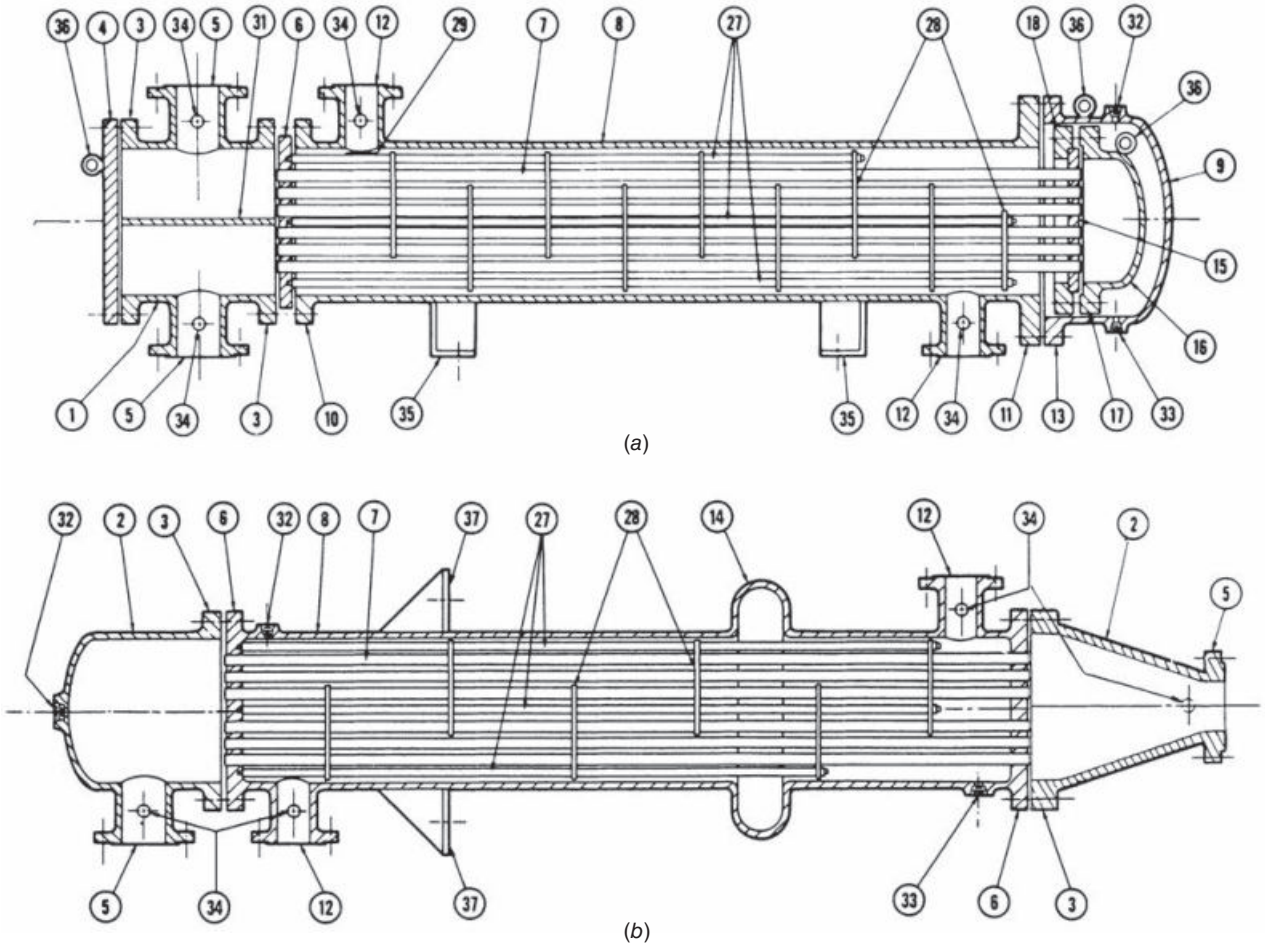

**FIG. 11-36** Heat exchanger component nomenclature. (*a*) Internal-floating-head exchanger (with floating-head backing device). Type AES. (*b*) Fixed-tube-sheet exchanger. Type BEM. (*Standards of the Tubular Exchanger Manufacturers Association, 6th ed., 1978.*)

diameter and OTL are 13 mm (½ in) for 635 mm (25 in) inside-diameter (ID) shells and up, 11 mm (7/16 in) for 254 through 610 mm (10 through 24 in) pipe shells, and slightly less for smaller-diameter pipe shells.

Tubes can be replaced. Tube-side headers, channel covers, gaskets, etc., are accessible for maintenance and replacement. Neither the shell-side baffle structure nor the blind gasket is accessible. During tube removal, a tube may break within the shell. When this occurs, it is most difficult to remove or to replace the tube. The usual procedure is to plug the appropriate holes in the tubesheets.

Differential expansion between the shell and the tubes can develop because of differences in length caused by thermal expansion. Various types of expansion joints are used to eliminate excessive stresses caused by expansion. The need for an expansion joint is a function of both the amount of differential expansion and the cycling conditions to be expected during operation. A number of types of expansion joints are available (Fig. 11-37).

1. *Flat plates.* Two concentric flat plates with a bar at the outer edges. The flat plates can flex to make some allowance for differential expansion. This design is generally used for vacuum service and gauge pressures below 103 kPa (15 lbf/in$^2$). All are subject to severe stress during differential expansion.

2. *Flanged-only heads.* The flat plates are flanged (or curved). The diameter of these heads is generally 203 mm (8 in) or greater than the shell diameter. The welded joint at the shell is subject to the stress referred to before, but the joint connecting the heads is subjected to less stress during expansion because of the curved shape.

3. *Flared shell or pipe segments.* The shell may be flared to connect with a pipe section, or a pipe may be halved and quartered to produce a ring.

4. *Formed heads.* A pair of dished-only or elliptical or flanged and dished heads can be used. These are welded together or connected by a ring. This type of joint is similar to the flanged-only-head type but apparently is subject to less stress.

5. *Flanged and flued heads.* A pair of flanged-only heads is provided with concentric reverse flue holes. These heads are relatively expensive because of the cost of the flue operation. The curved shape of the heads reduces the amount of stress at the welds to the shell and also connecting the heads.

6. *Toroidal.* The toroidal joint has a mathematically predictable smooth stress pattern of low magnitude, with maximum stresses at sidewalls of the corrugation and minimum stresses at top and bottom.

The foregoing designs were discussed as ring expansion joints by Kopp and Sayre, "Expansion Joints for Heat Exchangers" (ASME Misc. Pap., **6:** 211). All are statically indeterminate but are subjected to analysis by introducing various simplifying assumptions. Some joints in current industrial use are of lighter wall construction than is indicated by the method of this paper.

7. *Bellows.* Thin-wall bellows joints are produced by various manufacturers. These are designed for differential expansion and are tested for axial and transverse movement as well as for cyclical life. Bellows may be of stainless steel, nickel alloys, or copper. (Aluminum, Monel, phosphor bronze, and titanium bellows have been manufactured.) Welding nipples of the same composition as the heat exchanger shell are generally furnished. The bellows may be hydraulically formed from a single piece of metal or may consist of welded pieces. External insulation covers of carbon steel are often provided to protect the light-gauge bellows from damage. The cover also prevents insulation from interfering with movement of the bellows (see item 8).

8. *Toroidal bellows.* For high-pressure service, the bellows type of joint has been modified so that movement is taken up by thin-wall small-diameter bellows of a toroidal shape. The thickness of parts under high pressure is reduced considerably (see item 6).

Improper handling during manufacture, transit, installation, or maintenance of the heat exchanger equipped with the thin-wall-bellows type or toroidal type of expansion joint can damage the joint. In larger units these light-wall joints are particularly susceptible to damage, and some designers prefer the use of the heavier walls of formed heads.

**FIG. 11-36** (*Continued*) Heat exchanger component nomenclature. (*f*) Exchanger with packed floating tube sheet and lantern ring. Type AJW. (*Standards of the Tubular Exchanger Manufacturers Association, 6th ed., 1978.*)

Chemical-plant exchangers requiring expansion joints most commonly have used the flanged-and flued-head type. There is a trend toward more common use of the light-wall bellows type.

**U-Tube Heat Exchanger (Fig. 11-36*d*)** The tube bundle consists of a stationary tubesheet, U tubes (or hairpin tubes), baffles or support plates, and appropriate tie rods and spacers. The tube bundle can be removed from the heat exchanger shell. A tube-side header (stationary head) and a shell with integral shell cover, which is welded to the shell, are provided. Each tube is free to expand or contract without any limitation being placed upon it by the other tubes.

The U-tube bundle has the advantage of providing minimum clearance between the outer tube limit and the inside of the shell for any of the removable tube bundle constructions. Clearances are of the same magnitude as for fixed-tube-sheet heat exchangers.

The number of tube holes in a given shell is less than that for a fixed-tube-sheet exchanger because of limitations on bending tubes of a very short radius.

The U-tube design offers the advantage of reducing the number of joints. In high-pressure construction this feature becomes of considerable importance in reducing both initial and maintenance costs. The use of U-tube construction has increased significantly with the development of hydraulic tube cleaners, which can remove fouling residues from both the straight and the U-bend portions of the tubes.

Mechanical cleaning of the inside of the tubes was described by John [*Chem. Eng.* **66:** 187–192 (Dec. 14, 1959)]. Rods and conventional mechanical tube cleaners cannot pass from one end of the U tube to the other. Power-driven tube cleaners, which can clean both the straight legs of the tubes and the bends, are available.

Hydraulic jetting with water forced through spray nozzles at high pressure for cleaning tube interiors and exteriors of removal bundles is reported by Canaday ("Hydraulic Jetting Tools for Cleaning Heat Exchangers," ASME Pap. 58-A-217, unpublished).

The tank suction heater, as illustrated in Fig. 11-38, contains a U-tube bundle. This design is often used with outdoor storage tanks for heavy fuel oils, tar, molasses, and similar fluids whose viscosity must be lowered to permit easy pumping. Usually the tube-side heating medium is steam. One end of the heater shell is open, and the liquid being heated passes across the outside of the tubes. Pumping costs can be reduced without heating the entire contents of the tank. Bare-tube and integral low-fin tubes are provided with baffles. Longitudinal fin-tube heaters are not baffled. Fins are most often used to minimize the fouling potential in these fluids.

Kettle-type reboilers, evaporators, etc., are often U-tube exchangers with enlarged shell sections for vapor-liquid separation. The U-tube bundle replaces the floating-heat bundle of Fig. 11-36*e*.

The U-tube exchanger with copper tubes, cast-iron header, and other parts of carbon steel is used for water and steam services in office buildings, schools, hospitals, hotels, etc. Nonferrous tubesheets and admiralty or 90-10 copper-nickel tubes are the most frequently used substitute materials. These standard exchangers are available from a number of manufacturers at costs far below those of custom-built process industry equipment.

**Packed Lantern-Ring Exchanger (Fig. 11-36*f*)** This construction is the least costly of the straight-tube removable bundle types. The shell- and tube-side fluids are each contained by separate rings of packing separated by a lantern ring and are installed at the floating tubesheet. The lantern ring is provided with weep holes. Any leakage passing the packing goes through

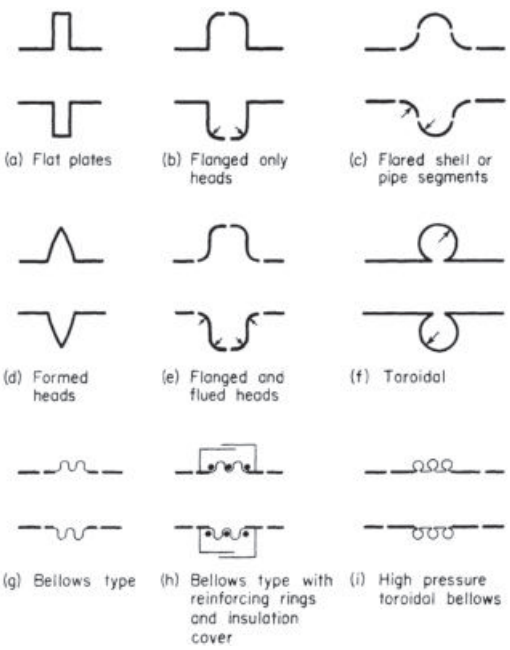

**FIG. 11-37** Expansion joints.

the weep holes and then drops to the ground. Leakage at the packing will not result in mixing within the exchanger of the two fluids.

The width of the floating tubesheet must be great enough to allow for the packings, the lantern ring, and differential expansion. Sometimes a small skirt is attached to a thin tubesheet to provide the required bearing surface for packings and the lantern ring.

The clearance between the outer tube limit and the inside of the shell is slightly larger than that for fixed-tube-sheet and U-tube exchangers. The use of a floating-tube-sheet skirt increases this clearance. Without the skirt the clearance must make allowance for tube-hole distortion during tube rolling near the outside edge of the tubesheet or for tube-end welding at the floating tubesheet.

The packed lantern ring construction is generally limited to design temperatures below 191°C (375°F) and to the mild services of water, steam, air, lubricating oil, etc. Design gauge pressure does not exceed 2068 kPa (300 lbf/in$^2$) for pipe shell exchangers and is limited to 1034 kPa (150 lbf/in$^2$) for 610- to 1067-mm- (24- to 42-in-) diameter shells.

**Outside Packed Floating-Head Exchanger (Fig. 11-36*c*)** The shell-side fluid is contained by rings of packing, which are compressed within a stuffing box by a packing follower ring. This construction was frequently used in the chemical industry, but in recent years usage has decreased. The removable-bundle construction accommodates differential expansion between shell and tubes and is used for shell-side service up to 4137 kPa gauge pressure (600 lbf/in$^2$) at 316°C (600°F). There are no limitations upon the number of tube-side passes or upon the tube-side design pressure and temperature. The outside packed floating-head exchanger was the most commonly used type of removable-bundle construction in chemical-plant service.

The floating-tube-sheet skirt, where in contact with the rings of packing, has a fine machine finish. A split shear ring is inserted into a groove in the floating-tube-sheet skirt. A slip-on backing flange, which in service is held in place by the shear ring, bolts to the external floating-head cover.

The floating-head cover is usually a circular disk. With an odd number of tube-side passes, an axial nozzle can be installed in such a floating-head cover. If a side nozzle is required, the circular disk is replaced by either a dished head or a channel barrel (similar to Fig. 11-36*f*) bolted between floating-head cover and floating-tube-sheet skirt.

The outer tube limit approaches the inside of the skirt but is farther removed from the inside of the shell than for any of the previously discussed constructions. Clearances between shell diameter and bundle OTL are 22 mm (⅞ in) for small-diameter pipe shells, 44 mm (1¾ in) for large-diameter pipe shells, and 58 mm (2$^1$⁄$_{16}$ in) for moderate-diameter plate shells.

**Internal Floating-Head Exchanger (Fig. 11-36*a*)** The internal floating-head design is used extensively in petroleum refinery service, but in recent years there has been a decline in usage.

The tube bundle is removable, and the floating tubesheet moves (or floats) to accommodate differential expansion between shell and tubes. The outer tube limit approaches the inside diameter of the gasket at the floating tubesheet. Clearances (between shell and OTL) are 29 mm (1⅛ in) for pipe shells and 37 mm (1$^7$⁄$_{16}$ in) for moderate-diameter plate shells.

A split backing ring and bolting usually hold the floating-head cover at the floating tubesheet. These are located beyond the end of the shell and within the larger-diameter shell cover. The shell cover, split backing ring, and floating-head cover must be removed before the tube bundle can pass through the exchanger shell.

With an even number of tube-side passes, the floating-head cover serves as return cover for the tube-side fluid. With an odd number of passes, a nozzle pipe must extend from the floating-head cover through the shell cover. Provision for both differential expansion and tube bundle removal must be made.

**Pull-Through Floating-Head Exchanger (Fig. 11-36*e*)** Construction is similar to that of the internal floating-head split-backing-ring exchanger except that the floating-head cover bolts directly to the floating tubesheet. The tube bundle can be withdrawn from the shell without removing either shell cover or floating-head cover. This feature reduces maintenance time during inspection and repair.

The large clearance between the tubes and the shell must provide for both the gasket and the bolting at the floating-head cover. This clearance is about 2 to 2½ times that required by the split-ring design. Sealing strips or dummy tubes are often installed to reduce bypassing of the tube bundle.

**Falling-Film Exchangers** Falling-film shell-and-tube heat exchangers have been developed for a wide variety of services and are described by Sack [*Chem. Eng. Prog.* **63:** 55 (July 1967)]. The fluid enters at the top of the vertical tubes. Distributors or slotted tubes put the liquid in film flow in the inside surface of the tubes, and the film adheres to the tube surface while falling to the bottom of the tubes. The film can be cooled, heated, evaporated, or frozen by means of the proper heat-transfer medium outside the tubes. Tube distributors have been developed for a wide range of applications. Fixed tubesheets, with or without expansion joints, and outside packed head designs are used.

Principal advantages are the high rate of heat transfer, no internal pressure drop, short time of contact (very important for heat-sensitive materials), easy accessibility to tubes for cleaning, and, in some cases, prevention of leakage from one side to another.

These falling-film exchangers are used in various services as described in the following paragraphs.

***Liquid Coolers and Condensers*** Dirty water can be used as the cooling medium. The top of the cooler is open to the atmosphere for access to tubes. These can be cleaned without shutting down the cooler by removing the distributors one at a time and scrubbing the tubes.

***Evaporators*** These are used extensively for the concentration of ammonium nitrate, urea, and other chemicals sensitive to heat when minimum contact time is desirable. Air is sometimes introduced in the tubes to lower the partial pressure of liquids whose boiling points are high. These evaporators are built for pressure or vacuum and with top or bottom vapor removal.

***Absorbers*** These have a two-phase flow system. The absorbing medium is put in film flow during its fall downward on the tubes as it is cooled by a cooling medium outside the tubes. The film absorbs the gas that is introduced into the tubes. This operation can be cocurrent or countercurrent.

***Freezers*** By cooling the falling film to its freezing point, these exchangers convert a variety of chemicals to the solid phase. The most common application is the production of sized ice and paradichlorobenzene. Selective freezing is used for isolating isomers. By melting the solid material and refreezing in several stages, a higher degree of purity of product can be obtained.

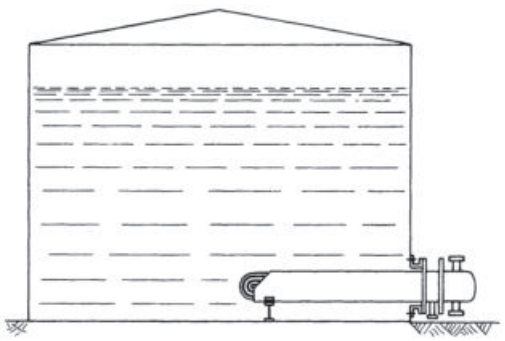

**FIG. 11-38** Tank suction heater.

## TUBE-SIDE CONSTRUCTION

**Tube-Side Header** The tube-side header (or stationary head) contains one or more flow nozzles.

The *bonnet* (Fig. 11-35B) bolts to the shell. It is necessary to remove the bonnet to examine the tube ends. The fixed-tube-sheet exchanger of Fig. 11-36*b* has bonnets at both ends of the shell.

The *channel* (Fig. 11-35A) has a removable channel cover. The tube ends can be examined by removing this cover without disturbing the piping connections to the channel nozzles. The channel can bolt to the shell as shown in Fig. 11-36*a* and *c.* Type C and type N channels of Fig. 11-35 are welded to the tubesheet. This design is comparable in cost with the bonnet but has the advantages of permitting access to the tubes without disturbing the piping connections and of eliminating a gasketed joint.

**Special High-Pressure Closures (Fig. 11-35D)** The channel barrel and the tubesheet are generally forged. The removable channel cover is seated in place by hydrostatic pressure, while a shear ring subjected to shearing stress absorbs the end force. For pressures above 6205 kPa (900 lbf/in$^2$) these designs are generally more economical than bolted constructions, which require larger flanges and bolting as pressure increases in order to contain the end force with bolts in tension. Relatively light-gauge internal pass partitions are provided to direct the flow of tube-side fluids but are designed only for the differential pressure across the tube bundle.

**Tube-Side Passes** Most exchangers have an even number of tube-side passes. The fixed-tube-sheet exchanger (which has no shell cover) usually has a return cover without any flow nozzles, as shown in Fig. 11-35M; types L and N are also used. All removable-bundle designs (except for the U tube) have a floating-head cover directing the flow of tube-side fluid at the floating tubesheet.

**Tubes** Standard heat exchanger tubing has ¼-, ⅜-, ½-, ⅝-, ¾-, 1-, 1¼-, and 1½-in outside diameter (in × 25.4 = mm). Wall thickness is measured in *Birmingham wire gauge* (BWG) units. A comprehensive list of tubing characteristics and sizes is given in Table 11-12. The most commonly used tubes in chemical plants and petroleum refineries are 19- and 25-mm (¾- and 1-in) outside diameter (OD). Standard tube lengths are 8, 10, 12, 16, and 20 ft, with 20 ft now the most common ( ft × 0.3048 = m).

Manufacturing tolerances for steel, stainless-steel, and nickel-alloy tubes are such that the tubing is produced to either average or minimum wall thickness. Seamless carbon-steel tube of minimum wall thickness may vary from 0 to 20 percent above the nominal wall thickness. Average-wall seamless tubing has an allowable variation of ±10 percent. Welded carbon-steel tube is produced to closer tolerances (0 to +18 percent on minimum wall; ±9 percent on average wall). Tubing of aluminum, copper, and their alloys can be drawn easily and usually is made to minimum wall specifications.

Common practice is to specify the *exchanger surface* in terms of total external square feet of tubing. The effective outside heat-transfer surface is based on the length of tubes measured between the inner faces of tubesheets. In most heat exchangers, there is little difference between the total and the effective surface. Significant differences are usually found in high-pressure and double-tube-sheet designs.

*Integrally finned tube,* which is available in a variety of alloys and sizes, is being used in shell-and-tube heat exchangers. The fins are radially extruded from thick-walled tube to a height of 1.6 mm (1/16 in) spaced at 1.33 mm (19 fins per inch) or to a height of 3.2 mm (⅛ in) spaced at 2.3 mm (11 fins per inch). The external surface is approximately 2½ times the outside surface of a bare tube with the same outside diameter. Also available are 0.93-mm-high (0.037-in-high) fins spaced 0.91 mm (28 fins per inch) with an external surface about 3.5 times the surface of the bare tube. Bare ends of nominal tube diameter are provided, while the fin height is slightly less than this diameter. The tube can be inserted into a conventional tube bundle and rolled or welded to the tubesheet by the same means used for bare tubes. An integrally finned tube rolled into a tubesheet with double serrations and flared at the inlet is shown in Fig. 11-39. Internally finned tubes have been manufactured but have limited application.

*Longitudinal fins* are commonly used in double-pipe exchangers upon the outside of the inner tube. U-tube and conventional removable tube bundles are also made from such tubing. The ratio of external to internal surface generally is about 10:1 or 15:1.

*Transverse fins* upon tubes are used in low-pressure gas services. The primary application is in air-cooled heat exchangers (as discussed under that heading), but shell-and-tube exchangers with these tubes are in service.

**Rolled Tube Joints** Expanded tube—tube-sheet joints are standard. Properly rolled joints have uniform tightness to minimize tube fractures, stress corrosion, tube-sheet ligament pushover and enlargement, and dishing of the tubesheet. Tubes are expanded into the tubesheet for a length of two tube diameters, or 50 mm (2 in), or tube-sheet thickness minus 3 mm (⅛ in). Generally tubes are rolled for the last of these alternatives. The expanded portion should never extend beyond the shell-side face of the tubesheet, since removing such a tube is extremely difficult. Methods and tools for tube removal and tube rolling were discussed by John [*Chem. Eng.* **66:** 77–80 (Dec. 28, 1959)], and rolling techniques by Bach [*Pet. Refiner* **39:** 8, 104 (1960)].

Tube ends may be projecting, flush, flared, or beaded (listed in order of usage). The flare or bell-mouth tube end is usually restricted to water service in condensers and serves to reduce erosion near the tube inlet.

For moderate general process requirements at gauge pressures less than 2058 kPa (300 lbf/in$^2$) and less than 177°C (350°F), tube-sheet holes without grooves are standard. For all other services with expanded tubes, at least two grooves in each tube hole are common. The number of grooves is sometimes changed to one or three in proportion to tube-sheet thickness.

Expanding the tube into the *grooved tube holes* provides a stronger joint but results in greater difficulties during tube removal.

**Welded Tube Joints** When suitable materials of construction are used, the tube ends may be welded to the tubesheets. Welded joints may be seal-welded "for additional tightness beyond that of tube rolling" or may be strength-welded. Strength-welded joints have been found satisfactory in very severe services. Welded joints may or may not be rolled before or after welding.

The variables in tube-end welding were discussed in two unpublished papers (Emhardt, "Heat Exchanger Tube-to-Tubesheet Joints," ASME Pap. 69-WA/HT-47; and Reynolds, "Tube Welding for Conventional and Nuclear Power Plant Heat Exchangers," ASME Pap. 69-WA/HT-24), which were presented at the November 1969 meeting of the American Society of Mechanical Engineers.

Tube-end rolling before welding may leave lubricant from the tube expander in the tube hole. Fouling during normal operation followed by maintenance operations will leave various impurities in and near the tube ends. Satisfactory welds are rarely possible under such conditions, since tube-end welding requires extreme cleanliness in the area to be welded.

Tube *expansion after welding* has been found useful for low and moderate pressures. In high-pressure service tube rolling has not been able to prevent leakage after weld failure.

**Double-Tube-Sheet Joints** This design prevents the passage of either fluid into the other because of leakage at the tube–tube-sheet joints, which are generally the weakest points in heat exchangers. Any leakage at these joints admits the fluid to the gap between the tubesheets. Mechanical design, fabrication, and maintenance of double-tube-sheet designs require special consideration.

## SHELL-SIDE CONSTRUCTION

**Shell Sizes** Heat exchanger shells are generally made from standard-wall steel pipe in sizes up to 305-mm (12-in) diameter; from 9.5-mm (⅜-in) wall pipe in sizes from 356 to 610 mm (14 to 24 in); and from steel plate rolled at discrete intervals in larger sizes. Clearances between the outer tube limit and the shell are discussed elsewhere in connection with the different types of construction.

The following formulas may be used to estimate tube counts for various bundle sizes and tube passes. The estimated values include the removal of tubes to provide an entrance area for shell nozzle sizes of one-fifth the shell diameter. Due to the large effect from other parameters such as design pressure/corrosion allowance, baffle cuts, seal strips, and so on, these are to be used as estimates only. Exact tube counts are part of the design package of most reputable exchanger design software and are normally used for the final design.

*Triangular* tube layouts with pitch equal to 1.25 times the tube outside diameter:

$C = 0.75(D/d) - 36$, where $D$ = bundle OD and $d$ = tube OD.

Range of accuracy: $-24 \le C \le 24$.

$$1\ \textit{Tube Pass:}\ N_t = 1298. + 74.86C + 1.283C^2 - 0.0078C^3 - 0.0006C^4 \quad (11\text{-}74a)$$

$$2\ \textit{Tube Pass:}\ N_t = 1266. + 73.58C + 1.234C^2 - 0.0071C^3 - 0.0005C^4 \quad (11\text{-}74b)$$

$$4\ \textit{Tube Pass:}\ N_t = 1196. + 70.79C + 1.180C^2 - 0.0059C^3 - 0.0004C^4 \quad (11\text{-}74c)$$

$$6\ \textit{Tube Pass:}\ N_t = 1166. + 70.72C + 1.269C^2 - 0.0074C^3 - 0.0006C^4 \quad (11\text{-}74d)$$

*Square* tube layouts with pitch equal to 1.25 times the tube outside diameter:

$C = (D/d) - 36$, where $D$ = bundle OD and $d$ = tube OD.

Range of accuracy: $-24 \le C \le 24$.

$$1\ \textit{Tube Pass:}\ N_t = 593.6 + 33.52C + 0.3782C^2 - 0.0012C^3 + 0.0001C^4 \quad (11\text{-}75a)$$

$$2\ \textit{Tube Pass:}\ N_t = 578.8 + 33.36C + 0.3847C^2 - 0.0013C^3 + 0.0001C^4 \quad (11\text{-}75b)$$

$$4\ \textit{Tube Pass:}\ N_t = 562.0 + 33.04C + 0.3661C^2 - 0.0016C^3 + 0.0002C^4 \quad (11\text{-}75c)$$

$$6\ \textit{Tube Pass:}\ N_t = 550.4 + 32.49C + 0.3873C^2 - 0.0013C^3 + 0.0001C^4 \quad (11\text{-}75d)$$

$^\dagger$Liquid velocity $= \dfrac{\text{lb per tube hour}}{C \times \text{sp gr of liquid}}$ ft/s (sp gr of water at 60°F = 1.0)

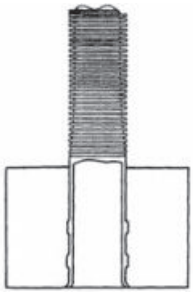

**FIG. 11-39** Integrally finned tube rolled into tube sheet with double serrations and flared inlet. (*Woverine Division, UOP, Inc.*)

**Shell-Side Arrangements** The *one-pass shell* (Fig. 11-35E) is the most commonly used arrangement. Condensers from single-component vapors often have the nozzles moved to the center of the shell for vacuum and steam services.

A solid longitudinal baffle is provided to form a two-pass shell (Fig. 11-35F). It may be insulated to improve thermal efficiency. (See further discussion on baffles.) A two-pass shell can improve thermal effectiveness at a cost lower than for two shells in series.

For *split flow* (Fig. 11-35G), the longitudinal baffle may be solid or perforated. The latter feature is used with condensing vapors.

A *double-split-flow* design is shown in Fig. 11-35H. The longitudinal baffles may be solid or perforated.

The divided flow design (Fig. 11-35J) mechanically is like the one-pass shell except for the addition of a nozzle. Divided flow is used to meet low-pressure-drop requirements.

The *kettle reboiler* is shown in Fig. 11-35K. When nucleate boiling is to be done on the shell side, this common design provides adequate dome space for separation of vapor and liquid above the tube bundle and surge capacity beyond the weir near the shell cover.

## BAFFLES AND TUBE BUNDLES

The *tube bundle* is the most important part of a tubular heat exchanger. The tubes generally constitute the most expensive component of the exchanger and are the one most likely to corrode. Tubesheets, baffles, or support plates, tie rods, and usually spacers complete the bundle.

Minimum *baffle spacing* is generally one-fifth of the shell diameter and not less than 50.8 mm (2 in). Maximum baffle spacing is limited by the requirement to provide adequate support for the tubes. The maximum unsupported tube span in inches equals $74d^{0.75}$ (where $d$ is the tube OD in inches). The unsupported tube span is reduced by about 12 percent for aluminum, copper, and their alloys.

Baffles are provided for heat-transfer purposes. When shell-side baffles are not required for heat-transfer purposes, as may be the case in condensers or reboilers, tube supports are installed.

**Segmental Baffles** Segmental or cross-flow baffles are standard. Single, double, and triple segmental baffles are used. Baffle cuts are illustrated in Fig. 11-40. The double segmental baffle reduces cross-flow velocity

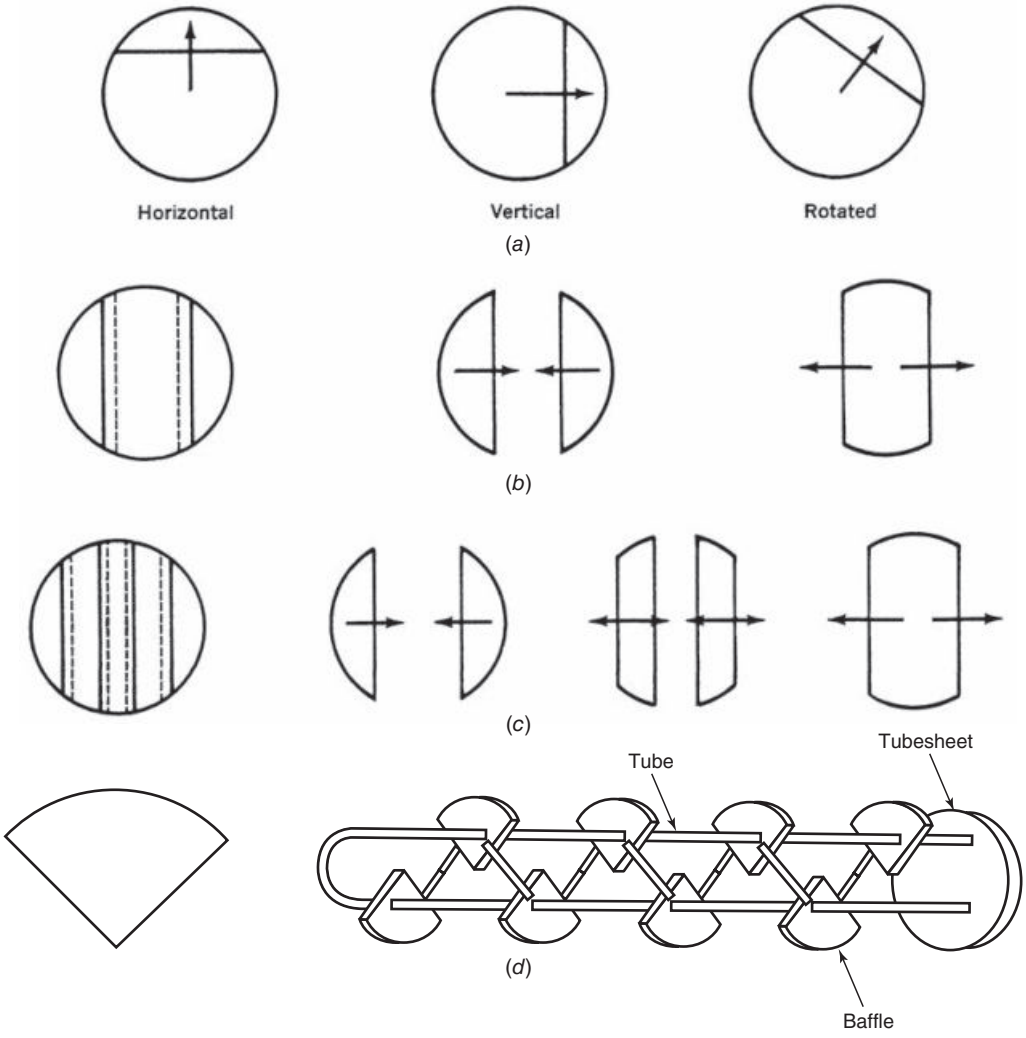

**FIG. 11-40** Plate baffles. (*a*) Baffle cuts for single segmental baffles. (*b*) Baffle cuts for double segmental baffles. (*c*) Baffle cuts for triple segmental baffles. (*d*) Helical baffle construction.

for a given baffle spacing. The triple segmental baffle reduces both cross-flow and long-flow velocities and has been identified as the "window-cut" baffle.

Baffle cuts are expressed as the ratio of segment opening height to shell inside diameter. Cross-flow baffles with horizontal cut are shown in Fig. 11-36*a, c,* and *f.* This arrangement is not satisfactory for horizontal condensers, since the condensate can be trapped between baffles, or for dirty fluids in which the dirt might settle out. Vertical-cut baffles are used for side-to-side flow in horizontal exchangers with condensing fluids or dirty fluids. Baffles are notched to ensure complete drainage when the units are taken out of service. (These notches permit some bypassing of the tube bundle during normal operation.)

Tubes are most commonly arranged on an equilateral triangular pitch. Tubes are arranged on a square pitch primarily for mechanical cleaning purposes in removable-bundle exchangers.

*Maximum baffle cut* is limited to about 45 percent for single segmental baffles so that every pair of baffles will support each tube. Tube bundles are generally provided with baffles cut so that at least one row of tubes passes through all the baffles or support plates. These tubes hold the entire bundle together. In pipe-shell exchangers with a horizontal baffle cut and a horizontal pass rib for directing tube-side flow in the channel, the maximum baffle cut, which permits a minimum of one row of tubes to pass through all baffles, is approximately 33 percent in small shells and 40 percent in larger pipe shells.

Maximum shell-side heat-transfer rates in forced convection are apparently obtained by cross-flow of the fluid at right angles to the tubes. To maximize this type of flow, some heat exchangers are built with segmental-cut baffles and with "no tubes in the window" (or the baffle cutout). Maximum baffle spacing may thus equal maximum unsupported-tube span, while conventional baffle spacing is limited to one-half of this span.

The maximum baffle spacing for no tubes in the window of single segmental baffles is unlimited when intermediate supports are provided. These are cut on both sides of the baffle and therefore do not affect the flow of the shell-side fluid. Each support engages all the tubes; the supports are spaced to provide adequate support for the tubes.

**Rod Baffles** Rod or bar baffles have either rods or bars extending through the lanes between rows of tubes. A baffle set can consist of a baffle with rods in all the vertical lanes and another baffle with rods in all the horizontal lanes between the tubes. The shell-side flow is uniform and parallel to the tubes. Stagnant areas do not exist.

One device uses four baffles in a baffle set. Only half of either the vertical or the horizontal tube lanes in a baffle have rods. The new design apparently provides a maximum shell-side heat-transfer coefficient for a given pressure drop.

**Tie Rods and Spacers** Tie rods are used to hold the baffles in place with spacers, which are pieces of tubing or pipe placed on the rods to locate the baffles. Occasionally baffles are welded to the tie rods, and spacers are eliminated. Properly located tie rods and spacers serve both to hold the bundle together and to reduce bypassing of the tubes.

In very large fixed-tube-sheet units, in which concentricity of shells decreases, baffles are occasionally welded to the shell to eliminate bypassing between the baffle and the shell.

Metal baffles are standard. Occasionally plastic baffles are used either to reduce corrosion or in vibratory service, in which metal baffles may cut the tubes.

**Impingement Baffle** The tube bundle is customarily protected against impingement by the incoming fluid at the shell inlet nozzle when the shell-side fluid is at a high velocity, is condensing, or is a two-phase fluid. Minimum entrance area about the nozzle is generally equal to the inlet nozzle area. Exit nozzles also require adequate area between the tubes and the nozzles. A full bundle without any provision for shell inlet nozzle area can increase the velocity of the inlet fluid by as much as 300 percent with a consequent loss in pressure.

Impingement baffles are generally made of rectangular plate, although circular plates are more desirable. Rods and other devices are sometimes used to protect the tubes from impingement. To maintain a maximum tube count, the impingement plate is often placed in a conical nozzle opening or in a dome cap above the shell.

Impingement baffles or flow distribution devices are recommended for axial tube-side nozzles when entrance velocity is high.

**Vapor Distribution** Relatively large shell inlet nozzles, which may be used in condensers under low pressure or vacuum, require provision for uniform vapor distribution.

**Tube-Bundle Bypassing** Shell-side heat-transfer rates are maximized when bypassing of the tube bundle is at a minimum. The most significant bypass stream is generally between the outer tube limit and the inside of the shell. The clearance between tubes and shell is at a minimum for fixed-tube-sheet construction and is greatest for straight-tube removable bundles.

Arrangements to reduce tube-bundle bypassing include these:

*Dummy tubes.* These tubes do not pass through the tubesheets and can be located close to the inside of the shell.

*Tie rods with spacers.* These hold the baffles in place but can be located to prevent bypassing.

*Sealing strips.* These longitudinal strips either extend from baffle to baffle or may be inserted in slots cut into the baffles.

Dummy tubes or tie rods with spacers may be located within the pass partition lanes (and between the baffle cuts) to ensure maximum bundle penetration by the shell-side fluid.

When tubes are omitted from the tube layout to provide the entrance area about an impingement plate, the need for sealing strips or other devices to cause proper bundle penetration by the shell-side fluid is increased.

**Helical Baffles** An increasingly popular variant to the segmental baffle is the helical baffle. These are quadrant-shaped plate baffles installed at an angle to the axial bundle centerline to produce a pseudo-spiraling flow down the length of the tube bundle (Fig. 11-40*d*). This baffle has the advantage of producing shell-side heat-transfer coefficients similar to those of the segmental baffle with much less shell-side pressure loss for the same size of shell. In the case of equal pressure drops, the helical baffle exchanger will be smaller than the segmental baffle exchanger; or, for identical shell sizes, the helical baffle exchanger will permit a much higher throughput of flow for the same process inlet/outlet temperatures.

A great amount of proprietary research has been conducted by a few companies into the workings of helical baffled heat exchangers. The only known open literature method for estimating helical baffle performance has been "Comparison of Correction Factors for Shell-and-Tube Heat Exchangers with Segmental or Helical Baffles" by Stehlik, Nemcansky, Kral, and Swanson [*Heat Transfer Engineering* **15**(1): 55–65 (1994)].

Unique design variables for helical baffles include the baffle angle, adjacent baffle contact diameter (which sets the baffle spacing and is usually about one-half of the shell ID), and the number of baffle starts (i.e., number of intermediate baffle starts). Of course, consideration is also given to the tube layout, tube pitch, use of seal strips, and all the other configuration characteristics common to any plate baffled bundle.

A helical baffle bundle built in this way produces two distinct flow regions. The area outside of the adjacent baffle contact diameter tends to produce a stable helical cross-flow. However, inside the diameter where adjacent baffles touch is a second region where vortical flow is induced but in which the intensity of the rotational component tends to decrease as one approaches the center of the bundle. For a fixed flow rate and helix angle, this tendency may be minimized by proper selection of the baffle contact diameter. With the correct selection, stream temperatures may be made to be close to uniform across the bundle cross section through the shell. However, below a critical velocity ( for the baffle configuration and fluid state), the tendency for nonuniformity of temperatures increases as velocity decreases until ever-increasing portions of the central core surface area pinch out with respect to temperature and become ineffective for further heat transfer.

The design approach involves varying the baffle spacing for the primary purpose of balancing the flows in the two regions and maximizing the effectiveness of the total surface area. In many cases, a shallower helix angle is chosen in conjunction with the baffle spacing in order to minimize the central core component while still achieving a reduced overall bundle pressure drop.

**Longitudinal Flow Baffles** In fixed-tube-sheet construction with multipass shells, the baffle is usually welded to the shell as positive assurance against bypassing results. Removable tube bundles have a sealing device between the shell and the longitudinal baffle. Flexible light-gauge sealing strips and various packing devices have been used. Removable U-tube bundles with four tube-side passes and two shell-side passes can be installed in shells with the longitudinal baffle welded in place.

In split-flow shells, the longitudinal baffle may be installed without a positive seal at the edges if design conditions are not seriously affected by a limited amount of bypassing.

Fouling in petroleum refinery service has necessitated rough treatment of tube bundles during cleaning operations. Many refineries avoid the use of longitudinal baffles, since the sealing devices are subject to damage during cleaning and maintenance operations.

## CORROSION IN HEAT EXCHANGERS

Some of the special considerations in regard to heat exchanger corrosion are discussed in this subsection. An extended presentation in Sec. 23 covers corrosion and its various forms as well as materials of construction.

**Materials of Construction** The most common material of construction for heat exchangers is carbon steel. Stainless-steel construction throughout is sometimes used in chemical-plant service and on rare occasions in petroleum refining. Many exchangers are constructed from dissimilar metals. Such combinations are functioning satisfactorily in certain

**TABLE 11-13 Dissimilar Materials in Heat-Exchanger Construction**

Relative cost: from A (least expensive) to E (most expensive).

services. Extreme care in their selection is required since electrolytic attack can develop.

Carbon-steel and alloy combinations appear in Table 11-13. "Alloys" in chemical- and petrochemical-plant service in approximate order of use are stainless-steel series 300, nickel, Monel, copper alloy, aluminum, Inconel, stainless-steel series 400, and other alloys. In petroleum refinery service, the frequency order shifts, with copper alloy ( for water-cooled units) in first place and low-alloy steel in second place. In some segments of the petroleum industry, copper alloy, stainless series 400, low-alloy steel, and aluminum are becoming the most commonly used alloys.

Copper-alloy tubing, particularly inhibited admiralty, is generally used with cooling water. Copper-alloy tubesheets and baffles are generally of naval brass.

Aluminum alloy (and in particular alclad aluminum) tubing is sometimes used in water service. The alclad alloy has a sacrificial aluminum-alloy layer metallurgically bonded to a core alloy.

Tube-side headers for water service are made in a wide variety of materials: carbon steel, copper alloy, cast iron, and lead-lined or plastic-lined or specially painted carbon steel.

**Bimetallic Tubes** When corrosive requirements or temperature conditions do not permit the use of a single alloy for the tubes, bimetallic (or duplex) tubes may be used. These can be made from almost any possible combination of metals. Tube sizes and gauges can be varied. For thin gauges the wall thickness is generally divided equally between the two components. In heavier gauges the more expensive component may comprise from one-fifth to one-third of the total thickness.

The component materials comply with applicable ASTM specifications, but after manufacture the outer component may increase in hardness beyond specification limits, and special care is required during the tube-rolling operation. When the harder material is on the outside, precautions must be taken to expand the tube properly. When the inner material is considerably softer, rolling may not be practical unless ferrules of the soft material are used.

To eliminate galvanic action, the outer tube material may be stripped from the tube ends and replaced with ferrules of the inner tube material. When the end of a tube with a ferrule is expanded or welded to a tubesheet, the tube-side fluid can contact only the inner tube material, while the outer material is exposed to the shell-side fluid.

Bimetallic tubes are available from a small number of tube mills and are manufactured only on special order and in large quantities.

**Clad Tubesheets** Usually tubesheets and other exchanger parts are made of a solid metal. Clad or bimetallic tubesheets are used to reduce costs or because no single metal is satisfactory for the corrosive conditions. The alloy material (e.g., stainless steel, Monel) is generally bonded or clad to a carbon-steel backing material. In fixed-tube-sheet construction, a copper alloy–clad tubesheet can be welded to a steel shell, while most copper-alloy tubesheets cannot be welded to steel in a manner acceptable to ASME Code authorities.

Clad tubesheets in service with carbon-steel backer material include stainless-steel types 304, 304L, 316, 316L, and 317, Monel, Inconel, nickel, naval rolled brass, copper, admiralty, silicon bronze, and titanium. Naval rolled brass and Monel clad on stainless steel are also in service.

Ferrous-alloy-clad tubesheets are generally prepared by a weld overlay process in which the alloy material is deposited by welding upon the face of the tubesheet. Precautions are required to produce a weld deposit free of defects, since these may permit the process fluid to attack the base metal below the alloy. Copper-alloy-clad tubesheets are prepared by brazing the alloy to the carbon-steel backing material.

Clad materials can be prepared by bonding techniques, which involve rolling, heat treatment, explosive bonding, etc. When properly manufactured, the two metals do not separate because of thermal expansion differences encountered in service. Applied tube-sheet facings prepared by tack welding at the outer edges of alloy and base metal or by bolting together the two metals are in limited use.

**Nonmetallic Construction** Shell-and-tube exchangers are available with glass tubes 14 mm (0.551 in) in diameter and 1 mm (0.039 in) thick with tube lengths from 2.015 m (79.3 in) to 4.015 m (158 in). Steel shell exchangers have a maximum design pressure of 517 kPa (75 lbf/in$^2$). Glass shell exchangers have a maximum design gauge pressure of 103 kPa (15 lbf/in$^2$). Shell diameters are 229 mm (9 in), 305 mm (12 in), and 457 mm (18 in). Heat-transfer surface ranges from 3.16 to 51 m$^2$ (34 to 550 ft$^2$). Each tube is free to expand, since a Teflon sealer sheet is used at the tube–tube sheet joint.

*Impervious graphite* heat exchanger equipment is made in a variety of forms, including outside packed-head shell-and-tube exchangers. They are fabricated with impervious graphite tubes and tube-side headers and metallic shells. Single units containing up to 1300 m$^2$ (14,000 ft$^2$) of heat-transfer surface are available.

Teflon heat exchangers of special construction are described later in this section.

**Fabrication** Expanding the tube into the tubesheet reduces the tube wall thickness and work-hardens the metal. The induced stresses can lead to *stress corrosion.* Differential expansion between tubes and shell in fixed-tube-sheet exchangers can develop stresses, which lead to stress corrosion.

When austenitic stainless-steel tubes are used for corrosion resistance, a close fit between the tube and the tube hole is recommended to minimize work hardening and the resulting loss of corrosion resistance.

To facilitate removal and replacement of tubes, it is customary to roller-expand the tubes to within 3 mm (⅛ in) of the shell-side face of the tubesheet. A 3-mm- (⅛-in-) long gap is thus created between the tube and the tube hole at this tube-sheet face. In some services this gap has been found to be a focal point for corrosion.

It is standard practice to provide a chamfer at the inside edges of tube holes in tubesheets to prevent cutting of the tubes and to remove burrs produced by drilling or reaming the tubesheet. In the lower tubesheet of vertical units, this chamfer serves as a pocket to collect material, dirt, etc., and acts as a corrosion center.

Adequate venting of exchangers is required both for proper operation and to reduce corrosion. Improper venting of the water side of exchangers can cause alternate wetting and drying and accompanying chloride concentration, which is particularly destructive to the series 300 stainless steels.

Certain corrosive conditions require that special consideration be given to complete drainage when the unit is taken out of service. Particular consideration is required for the upper surfaces of tubesheets in vertical heat exchangers, for sagging tubes, and for shell-side baffles in horizontal units.

## SHELL-AND-TUBE EXCHANGER COSTS

Basic costs of shell-and-tube heat exchangers made in the United States of carbon-steel construction in 1958 are shown in Fig. 11-41.

Cost data for shell-and-tube exchangers from 15 sources were correlated and found to be consistent when scaled by the Marshall and Swift index [Woods et al., *Can. J. Chem. Eng.* **54:** 469–489 (December 1976)].

Costs of shell-and-tube heat exchangers can be estimated from Fig. 11-41 and Tables 11-14 and 11-15. These 1960 costs should be updated by use of the Marshall and Swift Index, which appears in each issue of *Chemical Engineering.* Note that during periods of high and low demand for heat exchangers the prices in the marketplace may vary significantly from those determined by this method.

Small heat exchangers and exchangers bought in small quantities are likely to be more costly than indicated.

Standard heat exchangers (which are sometimes off-the-shelf items) are available in sizes ranging from 1.9 to 37 m$^2$ (20 to 400 ft$^2$) at costs lower than for custom-built units. Steel costs are approximately one-half, admiralty tube-side costs are two-thirds, and stainless costs are three-fourths of those for equivalent custom-built exchangers.

*Kettle-type reboiler* costs are 15 to 25 percent greater than for equivalent internal floating-head or U-tube exchangers. The higher extra cost is applicable with relatively large kettle-to-port-diameter ratios and with increased internals (e.g., vapor-liquid separators, foam breakers, sight glasses).

To estimate exchanger costs for varying construction details and alloys, first determine the base cost of a similar heat exchanger of basic construction (carbon steel, Class R, 150 lbf/in$^2$) from Fig. 11-41. From Table 11-14, select appropriate extras for higher pressure rating and for alloy construction of tubesheets and baffles, shell and shell cover, and channel and floating-head cover. Compute these extras in accordance with the notes at the bottom of the table. For tubes other than welded carbon steel, compute the extra cost by multiplying the exchanger surface by the appropriate cost per square foot from Table 11-15.

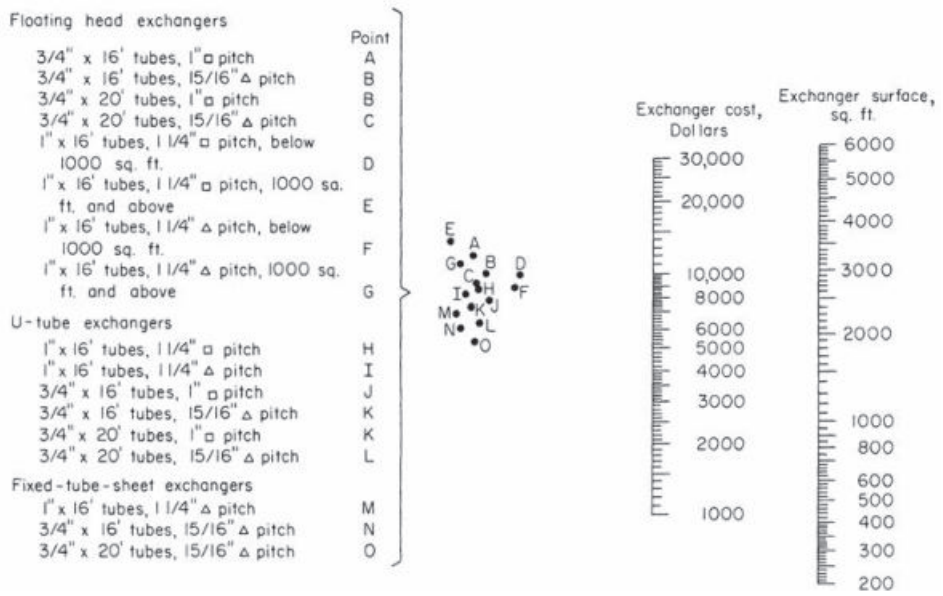

**FIG. 11-41** Costs of basic exchangers—all steel, TEMA Class R, 150 lbf/in$^2$, 1958. To convert pounds-force per square inch to kilopascals, multiply by 6.895; to convert square feet to square meters, multiply by 0.0929; to convert inches to millimeters, multiply by 25.4; and to convert feet to meters, multiply by 0.3048.

*Modified from E. N. Sieder and G. H. Elliot, *Pet. Refiner* **39**(5): 223 (1960).

†Total extra is 0.7 × pressure extra on shell side plus 0.3 × pressure extra on tube side.

‡Fixed-tube-sheet construction with ¾-in OD tube on 15/16-in triangular pitch provides 36 percent more surface.

§Fixed-tube-sheet construction with 1-in OD tube on 1¼-in triangular pitch provides 18 percent more surface.

For an all-steel heat exchanger with mixed design pressures the total extra for pressure is 0.7 × pressure extra on shell side plus 0.3 × pressure extra tube side.

For an exchanger with alloy parts and a design pressure of 150 lbf/in$^2$, the alloy extras are added. For shell and shell cover the combined alloy-pressure extra is the alloy extra times the shell-side pressure extra/100. For channel and floating-head cover the combined alloy-pressure extra is the alloy extra times the tube-side pressure extra/100. For tube sheets and baffles the combined alloy-pressure extra is the alloy extra times the higher-pressure extra times 0.9/100. (The 0.9 factor is included since baffle thickness does not increase because of pressure.)

NOTE: To convert pounds-force per square inch to kilopascals, multiply by 6.895; to convert square feet to square meters, multiply by 0.0929; and to convert inches to millimeters, multiply by 25.4.

| Monel | 4.25 | 5.22 | 6.68 | 4.01 | 4.97 | 6.47 |
| Low fin | | | | | | |
| Carbon steel | 0.22 | 0.23 | | 0.18 | 0.19 | |
| Admiralty | 0.58 | 0.75 | | 0.70 | 0.87 | |
| 90-10 cupronickel | 0.72 | 0.96 | | 0.86 | 1.06 | |

NOTE: To convert inches to millimeters, multiply by 25.4.

When points for 20-ft-long tubes do not appear in Fig. 11-41, use 0.95 times the cost of the equivalent 16-ft-long exchanger. Length variation of steel heat exchangers affects costs by approximately $1 per square foot. Shell diameters for a given surface are approximately equal for U-tube and floating-head construction.

Low-fin tubes (1/16-in-high fins) provide 2.5 times the surface per lineal foot. The surface required should be divided by 2.5; then use Fig. 11-41 to determine the basic cost of the heat exchanger. Actual surface times extra costs (from Table 11-15) should then be added to determine cost of the fin-tube exchanger.

## HAIRPIN/DOUBLE-PIPE HEAT EXCHANGERS

### PRINCIPLES OF CONSTRUCTION

Hairpin heat exchangers (often also referred to as "double pipes") are characterized by a construction form that imparts a U-shaped appearance to the heat exchanger. In its classical sense, the term *double pipe* refers to a heat exchanger consisting of a pipe within a pipe, usually of a straight-leg construction with no bends. However, due to the need for removable bundle construction and the ability to handle differential thermal expansion while avoiding the use of expansion joints (often the weak point of the exchanger), the current U-shaped configuration has become the standard in the industry (Fig. 11-42). A further departure from the classical definition comes when more than one pipe or tube is used to make a tube bundle, complete with tubesheets and tube supports similar to the TEMA-style exchanger.

Hairpin heat exchangers consist of two shell assemblies housing a common set of tubes and interconnected by a return-bend cover referred to as the *bonnet*. The shell is supported by means of bracket assemblies designed to cradle both shells simultaneously. These brackets are configured to permit the modular assembly of many hairpin sections into an exchanger bank for inexpensive future expansion capability and for providing the very long thermal lengths demanded by special process applications.

The bracket construction permits support of the exchanger without fixing the supports to the shell. This provides for thermal movement of the shells within the brackets and prevents the transfer of thermal stresses into the process piping. In special cases the brackets may be welded to the shell. However, this is usually avoided due to the resulting loss of flexibility in field installation and equipment reuse at other sites and an increase in piping stresses.

The hairpin heat exchanger, unlike the removable-bundle TEMA styles, is designed for bundle insertion and removal from the return end rather than from the tubesheet end. This is accomplished by means of removable split rings which slide into grooves machined around the outside of each tubesheet and lock the tubesheets to the external closure flanges. This provides a distinct advantage in maintenance since bundle removal takes place at the exchanger end farthest from the plant process piping without disturbing any gasketed joints of this piping.

**FIG. 11-42** Double-pipe exchanger section with longitudinal fins. (*Brown Fin-tube Co.*)

### FINNED DOUBLE PIPES

The design of the classical single-tube double-pipe heat exchanger is an exercise in pure longitudinal flow with the shell-side and tube-side coefficients differing primarily due to variations in flow areas. Adding longitudinal fins gives the more common double-pipe configuration (Table 11-16). Increasing the number of tubes yields the *multitube* hairpin.

### MULTITUBE HAIRPINS

For years, the slightly higher mechanical design complexity of the hairpin heat exchanger relegated it to only the smallest process requirements with shell sizes not exceeding 100 mm. In the early 1970s the maximum available sizes were increased to between 300 and 400 mm depending upon the manufacturer. At present, due to recent advances in design technology, hairpin exchangers are routinely produced in shell sizes between 51 mm (2 in) and 762 mm (30 in) for a wide range of pressures and temperatures and have been made in larger sizes as well. Table 11-17 gives common hairpin tube counts and areas for 19-mm- (¾-in-) OD tubes arranged on a 24-mm (15/16-in) triangular tube layout.

The hairpin width and the centerline distance of the two legs (shells) of the hairpin heat exchanger are limited by the outside diameter of the closure flanges at the tubesheets. This diameter, in turn, is a function of the design pressures. As a general rule, for low to moderate design pressures (less than 15 bar), the center-to-center distance is approximately 1.5 to

**TABLE 11-16 Double-Pipe Hairpin Section Data**

1.8 times the shell outside diameter, with this ratio decreasing slightly for the larger sizes.

One interesting consequence of this fact is the inability to construct a hairpin tube bundle having the smallest radius bends common to a conventional U-tube, TEMA shell, and tube bundle. In fact, in the larger hairpin sizes the tubes might be better described as curved rather than bent. The smallest U-bend diameters are greater than the outside diameter of shells less than 300 mm in size. The U-bend diameters are greater than 300 mm in larger shells. As a general rule, mechanical tube cleaning around the radius of a U-bend may be accomplished with a flexible shaft-cleaning tool for bend diameters greater than 10 times the tube's inside diameter. This permits the tool to pass around the curve of the tube bend without binding.

In all these configurations, maintaining longitudinal flow on both the shell side and the tube side allows the decision for placement of a fluid stream on either one side or the other to be based upon design efficiency (mass flow rates, fluid properties, pressure drops, and velocities), and not because there is any greater tendency to foul on one side than the other. Experience has shown that, in cases where fouling is influenced by flow velocity, overall fouling in tube bundles is less in properly designed longitudinal flow bundles where areas of low velocity can be avoided without flow-induced tube vibration.

This same freedom of stream choice is not as readily applied when a segmental baffle is used. In those designs, the baffle's creation of low velocities and stagnant flow areas on the outside of the bundle can result in increased shell-side fouling at various locations of the bundle. The basis for choosing the stream side in those cases will be similar to the common shell-and-tube heat exchanger. At times a specific selection of stream side must be made regardless of the tube support mechanism in expectation of an unresolvable fouling problem. However, this is often the exception rather than the rule.

### DESIGN APPLICATIONS

One benefit of the hairpin exchanger is its ability to handle high tube-side pressures at a lower cost than other removable-bundle exchangers. This is due in part to the lack of pass partitions at the tubesheets which complicate the gasketing design process. Present mechanical design technology has allowed the building of dependable, removable-bundle, hairpin multitubes at tube-side pressures of 825 bar (12,000 psi).

The best-known use of the hairpin exchanger is its operation in true countercurrent flow, which yields the most efficient design for processes that have a close temperature approach or temperature cross. However, maintaining countercurrent flow in a tubular heat exchanger usually implies one tube pass for each shell pass. As recently as 30 years ago, the lack of inexpensive, multiple-tube pass capability often diluted the advantages gained from countercurrent flow.

The early attempts to solve this problem led to investigations into the area of heat-transfer augmentation. This familiarity with augmentation techniques inevitably led to improvements in the efficiency and capacity of the small heat exchangers. The result has been the application of the hairpin heat exchanger to the solution of unique process problems, such as dependable, once-through, convective boilers offering high-exit qualities, especially in cases of process temperature crosses.

## AIR-COOLED HEAT EXCHANGERS

### INTRODUCTION TO AIR-COOLED HEAT EXCHANGERS

Atmospheric air has been used for many years to cool and condense fluids in areas of water scarcity. During the 1960s the use of air-cooled heat exchangers grew rapidly in the United States and elsewhere. In Europe, where seasonal variations in ambient temperatures are relatively small, air-cooled exchangers are used for the greater part of process cooling. In some new plants all cooling is done with air. Increased use of air-cooled heat exchangers has resulted from lack of available water, significant increases in water costs, and concern for water pollution.

Air-cooled heat exchangers include a tube bundle, which generally has spiral-wound fins upon the tubes, and a fan, which moves air across the tubes and is provided with a driver. Electric motors are the most commonly used drivers; typical drive arrangements require a V belt or a direct right-angle gear. A plenum and structural supports are basic components. Louvers are often used.

A bay generally has two tube bundles installed in parallel. These may be in the same or different services. Each bay is usually served by two (or more) fans and is furnished with a structure, a plenum, and other attendant equipment.

The location of air-cooled heat exchangers must take into consideration the large space requirements and the possible recirculation of heated air because of the effect of prevailing winds upon buildings, fired heaters, towers, various items of equipment, and other air-cooled exchangers. Inlet air temperature at the exchanger can be significantly higher than the ambient air temperature at a nearby weather station. See *Air-Cooled Heat Exchangers for General Refinery Services,* API Standard 661, 2d ed., January 1978, for information on refinery process air-cooled heat exchangers.

**Forced and Induced Draft** The forced-draft unit, illustrated in Fig. 11-43, pushes air across the finned-tube surface. The fans are located below the tube bundles. The induced-draft design has the fan above the bundle, and the air is pulled across the finned-tube surface. In theory, a primary advantage of the forced-draft unit is that less power is required. This is true when the air temperature rise exceeds 30°C (54°F).

Air-cooled heat exchangers are generally arranged in banks with several exchangers installed side by side. The height of the bundle aboveground

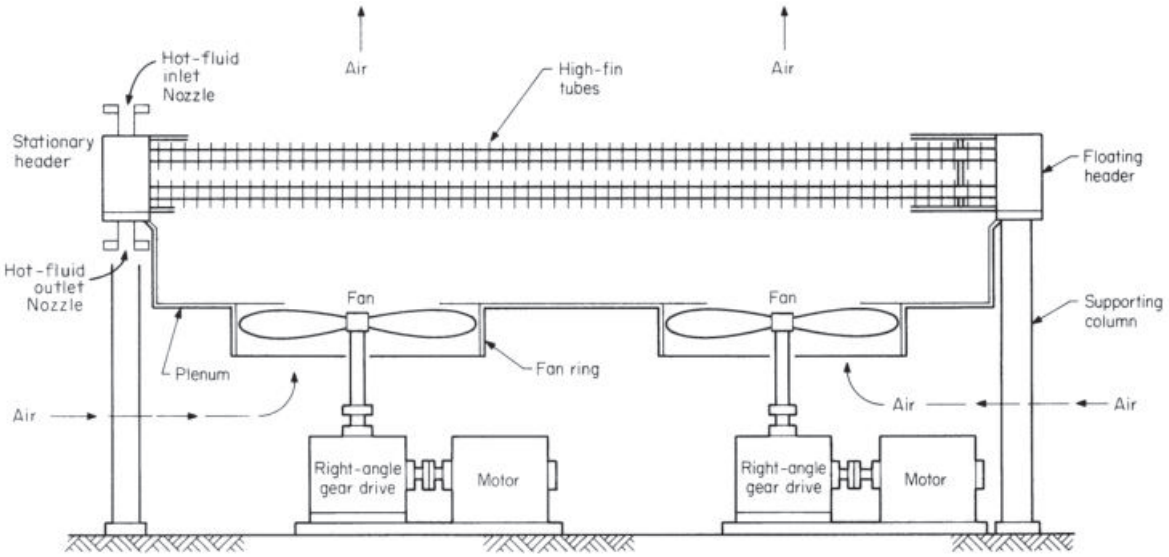

**FIG. 11-43** Forced-draft air-cooled heat exchanger. [*Chem. Eng.* 114 (Mar. 27, 1978).]

must be one-half of the tube length to produce an inlet velocity equal to the face velocity. This requirement applies both to ground-mounted exchangers and to those pipe-rack-installed exchangers which have a fire deck above the pipe rack.

The forced-draft design offers better accessibility to the fan for on-stream maintenance and fan blade adjustment. The design also provides a fan and V-belt assembly, which are not exposed to the hot-air stream that exits from the unit. Structural costs are lower, and mechanical life is longer.

Induced-draft design provides more even distribution of air across the bundle, since air velocity approaching the bundle is relatively low. This design is better suited for exchangers designed for a close approach of product outlet temperature to ambient-air temperature.

Induced-draft units are less likely to recirculate the hot exhaust air, since the exit air velocity is several times that of the forced-draft unit. Induced-draft design more readily permits the installation of the air-cooled equipment above other mechanical equipment such as pipe racks or shell-and-tube exchangers.

In a service in which sudden temperature change would cause upset and loss of product, the induced-draft unit gives greater protection in that only a fraction of the surface (as compared with the forced-draft unit) is exposed to rainfall, sleet, or snow.

**Tube Bundle** The principal parts of the tube bundle are the finned tubes and the header. Most commonly used is the plug header, which is a welded box illustrated in Fig. 11-44. The finned tubes are described in a subsequent paragraph. The components of a tube bundle are identified in the figure.

The second most commonly used header is a cover-plate header. The cover plate is bolted to the top, bottom, and end plates of the header. Removing the cover plate provides direct access to the tubes without the necessity of removing individual threaded plugs.

Other types of headers include the bonnet-type header, which is constructed similarly to the bonnet of shell-and-tube heat exchangers; manifold-type headers, which are made from pipe and have tubes welded into the manifold; and billet-type headers, made from a solid piece of material with machined channels for distributing the fluid. Serpentine-type tube bundles are sometimes used for very viscous fluids. A single continuous flow path through pipe is provided.

Tube bundles are designed to be rigid and self-contained and are mounted so that they expand independently of the supporting structure.

The face area of the tube bundle is its length times width. The net free area for air flow through the bundle is about 50 percent of the face area of the bundle.

The standard air *face velocity* (FV) is the velocity of standard air passing through the tube bundle and generally ranges from 1.5 to 3.6 m/s (300 to 700 ft/min).

**Tubing** The 25.4-mm (1-in) OD tube is most commonly used. Fin heights vary from 12.7 to 15.9 mm (0.5 to 0.625 in), fin spacing from 3.6 to 2.3 mm (7 to 11 per linear inch), and tube triangular pitch from 50.8 to

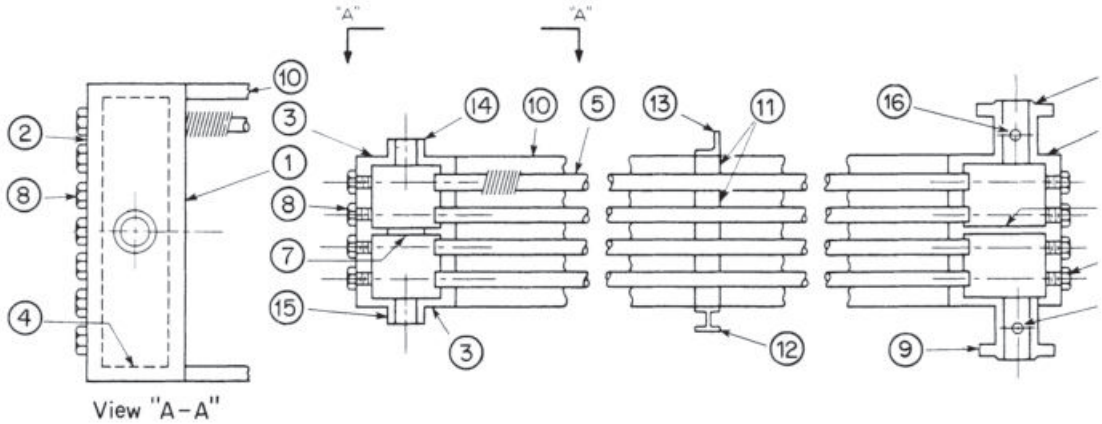

**FIG. 11-44** Typical construction of a tube bundle with plug headers: (1) tube sheet; (2) plug sheet; (3) top and bottom plates; (4) end plate; (5) tube; (6) pass partition; (7) stiffener; (8) plug; (9) nozzle; (10) side frame; (11) tube spacer; (12) tube-support cross member; (13) tube keeper; (14) vent; (15) drain; (16) instrument connection. (*API Standard 661.*)

63.5 mm (2.0 to 2.5 in). The ratio of extended surface to bare-tube outside surface varies from about 7 to 20. The 38-mm (1½-in) tube has been used for flue gas and viscous oil service. Tube size, fin heights, and fin spacing can be further varied.

Tube lengths vary and may be as great as 18.3 m (60 ft). When tube length exceeds 12.2 m (40 ft), three fans are generally installed in each bay. Frequently used tube lengths vary from 6.1 to 12.2 m (20 to 40 ft).

**Finned-Tube Construction** The following are descriptions of commonly used finned-tube constructions (Fig. 11-45).

1. *Embedded.* The rectangular-cross-section aluminum fin is wrapped under tension and mechanically embedded in a groove 0.25 ± 0.05 mm (0.010 ± 0.002 in) deep, spirally cut into the outside surface of a tube.
2. *Integral (or extruded).* An aluminum outer tube from which fins have been formed by extrusion is mechanically bonded to an inner tube or liner.
3. *Overlapped footed.* L-shaped aluminum fin is wrapped under tension over the outside surface of a tube, with the tube fully covered by the overlapped feet under and between the fins.
4. *Footed.* L-shaped aluminum fin is wrapped under tension over the outside surface of a tube with the tube fully covered by the feet between the fins.
5. *Bonded.* Tube fins are bonded to the outside surface by hot-dip galvanizing, brazing, or welding.

Typical metal design temperatures for these finned-tube constructions are 399°C (750°F) embedded, 288°C (550°F) integral, 232°C (450°F) overlapped footed, and 177°C (350°F) footed.

Tube ends are left bare to permit insertion of the tubes into appropriate holes in the headers or tubesheets. Tube ends are usually roller-expanded into these tube holes.

**Fans** Axial-flow fans are large-volume, low-pressure devices. Fan diameters are selected to give velocity pressures of approximately 2.5 mm (0.1 in) of water. Total fan efficiency ( fan, driver, and transmission device) is about 75 percent, and fan drives usually have a minimum of 95 percent mechanical efficiency.

Usually fans are provided with four or six blades. Larger fans may have more blades. Fan diameter is generally slightly less than the width of the bay.

At the fan-tip speeds required for economic performance, a large amount of noise is produced. The predominant source of noise is vortex shedding at the trailing edge of the fan blade. Noise control of air-cooled exchangers is required by the Occupational Safety and Health Act (OSHA). API Standard 661 (*Air-Cooled Heat Exchangers for General Refinery Services,* 2d ed., January 1978) has the purchaser specifying sound-pressure-level (SPL) values per fan at a location designated by the purchaser and also specifying sound-power-level (PWL) values per fan. These are designated at the following octave-band-center frequencies: 63, 125, 250, 1000, 2000, 4000, 8000, and also the dBa value (the dBa is a weighted single-value sound pressure level).

Reducing the fan-tip speed results in a straight-line reduction in air flow while the noise level decreases. The API Standard limits fan-tip speed to 61 m/s (12,000 ft/min) for typical constructions. Fan design changes that reduce noise include increasing the number of fan blades, increasing the width of the fan blades, and reducing the clearance between fan tip and fan ring.

Both the quantity of air and the developed static pressure of fans in air-cooled heat exchangers are lower than indicated by fan manufacturers' test data, which are applicable to testing-facility tolerances and not to heat exchanger constructions.

The axial-flow fan is inherently a device for moving a consistent volume of air when blade setting and speed of rotation are constant. Variation in the amount of air flow can be obtained by adjusting the blade angle of the fan and the speed of rotation. The blade angle can be (1) permanently fixed, (2) hand-adjustable, or (3) automatically adjusted. Air delivery and power are a direct function of blade pitch angle.

Fan mounting should provide a minimum of one-half to three-fourths diameter between fan and ground on a forced-draft heat exchanger and one-half diameter between tubes and fan on an induced-draft cooler.

Fan blades can be made of aluminum, molded plastic, laminated plastic, carbon steel, stainless steel, and Monel.

**Fan Drivers** Electric motors or steam turbines are most commonly used. These connect with gears or V belts. (Gas engines connected through gears and hydraulic motors either direct-connected or connected through gears are in use.) Fans may be driven by a prime mover such as a compressor with a V-belt takeoff from the flywheel to a jack shaft and then through a gear or V belt to the fan. Direct motor drive is generally limited to small-diameter fans.

V-belt drive assemblies are generally used with fans 3 m (10 ft) and less in diameter and motors of 22.4 kW (30 hp) and less.

Right-angle gear drive is preferred for fans over 3 m (10 ft) in diameter, for electric motors over 22.4 kW (30 hp), and with steam-turbine drives.

**Fan Ring and Plenum Chambers** The air must be distributed from the circular fan to the rectangular face of the tube bundle. The air velocity at the fan is between 3.8 and 10.2 m/s (750 and 2000 ft/in). The plenum-chamber depth ( from fan to tube bundle) is dependent upon the fan dispersion angle (Fig. 11-46), which should have a maximum value of 45°.

The fan ring is made to commercial tolerances for the relatively large-diameter fan. These tolerances are greater than those upon closely machined fan rings used for small-diameter laboratory-performance testing. Fan performance is directly affected by this increased clearance between the blade tip and the ring, and adequate provision in design must be made for the reduction in air flow. API Standard 661 requires that fan-tip clearance be a maximum of 0.5 percent of the fan diameter for diameters between 1.9 and 3.8 m (6.25 and 12.5 ft). Maximum clearance is 9.5 mm (⅜ in) for smaller fans and 19 mm (¾ in) for larger fans.

The depth of the fan ring is critical. Worsham (ASME Pap. 59-PET-27, Petroleum Mechanical Engineering Conference, Houston, 1959) reports an increase in flow varying from 5 to 15 percent with the same power consumption when the depth of a fan ring was doubled. The percentage increase was proportional to the volume of air and static pressure against which the fan was operating.

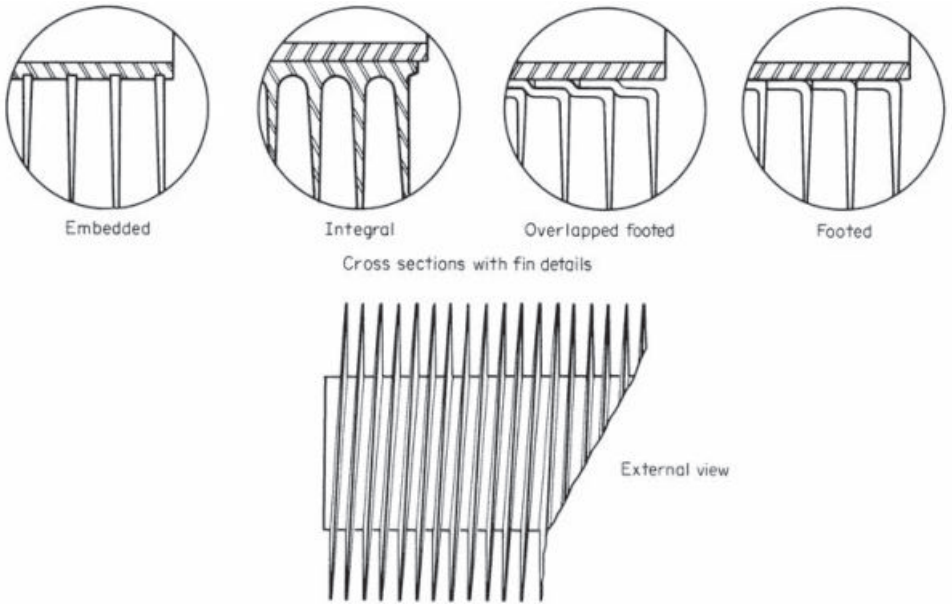

**FIG. 11-45** Finned-tube construction.

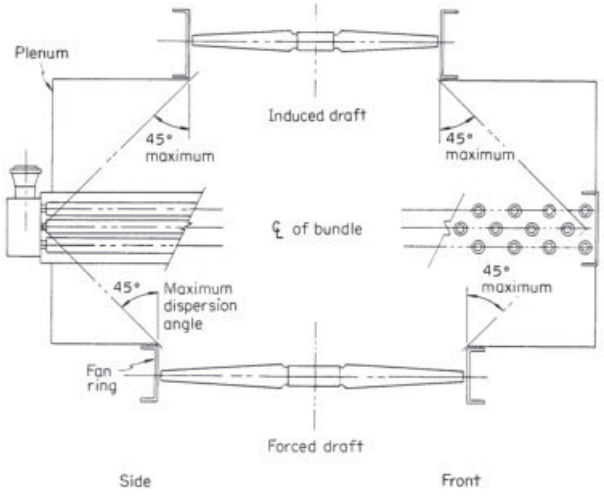

**FIG. 11-46** Fan dispersion angle. (*API Standard 661.*)

When a selection is made, the stall-out condition, which develops when the fan cannot produce any more air regardless of power input, should be considered.

**Air Flow Control** Process operating requirements and weather conditions are considered in determining the method of controlling air flow. The most common methods include simple on-off control, on-off step control (in the case of multiple-driver units), two-speed-motor control, variable-speed drivers, controllable fan pitch, manually or automatically adjustable louvers, and air recirculation.

Winterization is the provision of design features, procedures, or systems for air-cooled heat exchangers to avoid process-fluid operating problems resulting from low-temperature inlet air. These include fluid freezing, pour point, wax formation, hydrate formation, laminar flow, and condensation at the dew point (which may initiate corrosion). The freezing points for some commonly encountered fluids in refinery service are benzene, 5.6°C (42°F); *p*-xylene, 15.5°C (55.9°F); cyclohexane, 6.6°C (43.8°F); phenol, 40.9°C (105.6°F); monoethanolamine, 10.3°C (50.5°F); and diethanolamine, 25.1°C (77.2°F). Water solutions of these organic compounds are likely to freeze in air-cooled exchangers during winter service. Paraffinic and olefinic gases ($C_1$ through $C_4$) saturated with water vapor form hydrates when cooled. These hydrates are solid crystals which can collect and plug exchanger tubes.

Air flow control in some services can prevent these problems. Cocurrent flow of air and process fluid during winter may be adequate to prevent problems. (Normal design has countercurrent flow of air and process fluid.) In some services when the hottest process fluid is in the bottom tubes, which are exposed to the lowest-temperature air, winterization problems may be eliminated.

Following are references which deal with problems in low-temperature environments: Brown and Benkley, "Heat Exchangers in Cold Service—A Contractor's View," *Chem. Eng. Prog.* **70:** 59–62 (July 1974); Franklin and Munn, "Problems with Heat Exchangers in Low Temperature Environments," *Chem. Eng. Prog.* **70:** 63–67 (July 1974); Newell, "Air-Cooled Heat Exchangers in Low Temperature Environments: A Critique," *Chem. Eng. Prog.* **70:** 86–91 (October 1974); Rubin, "Winterizing Air Cooled Heat Exchangers," *Hydrocarbon Process* **59:** 147–149 (October 1980); Shipes, "Air-Cooled Heat Exchangers in Cold Climates," *Chem. Eng. Prog.* **70:** 53–58 (July 1974).

**Air Recirculation** Recirculation of air which has been heated as it crosses the tube bundle provides the best means of preventing operating problems due to low-temperature inlet air. Internal recirculation is the movement of air within a bay so that the heated air which has crossed the bundle is directed by a fan with reverse flow across another part of the bundle. Wind skirts and louvers are generally provided to minimize the entry of low-temperature air from the surroundings. Contained internal recirculation uses louvers within the bay to control the flow of warm air in the bay, as illustrated in Fig. 11-47. Note that low-temperature inlet air has access to the tube bundle.

External recirculation is the movement of the heated air within the bay to an external duct, where this air mixes with inlet air, and the mixture serves as the cooling fluid within the bay. Inlet air does not have direct access to the tube bundle; an adequate mixing chamber is essential. Recirculation over the end of the exchanger is illustrated in Fig. 11-48. Over-the-side recirculation also is used. External recirculation systems maintain the desired low temperature of the air crossing the tube bundle.

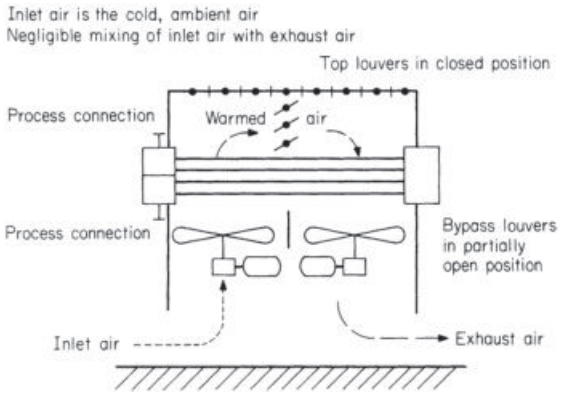

**FIG. 11-47** Contained internal recirculation (with internal louvers). [*Hydrocarbon Process* 59: 148–149 (October 1980).]

**Trim Coolers** Conventional air-cooled heat exchangers can cool the process fluid to within 8.3°C (15°F) of the design dry-bulb temperature. When a lower process outlet temperature is required, a trim cooler is installed in series with the air-cooled heat exchanger. The water-cooled trim cooler can be designed for a 5.6°C to 11.1°C (10°F to 20°F) approach to the wet-bulb temperature, which in the United States is about 8.3°C (15°F) less than the dry-bulb temperature. In arid areas the difference between dry- and wet-bulb temperatures is much greater.

**Humidification Chambers** The air-cooled heat exchanger is provided with humidification chambers in which the air is cooled to a close approach to the wet-bulb temperature before entering the finned-tube bundle of the heat exchanger.

**Evaporative Cooling** The process fluid can be cooled by using evaporative cooling with the sink temperature approaching the wet-bulb temperature.

**Steam Condensers** Air-cooled steam condensers have been fabricated with a single tube-side pass and several rows of tubes. The bottom row has a higher temperature difference than the top row, since the air has been heated as it crosses the rows of tubes. The bottom row condenses all the entering steam before the steam has traversed the length of the tube. The top row, with a lower-temperature driving force, does not condense all the entering steam. At the exit header, uncondensed steam flows from the top row into the bottom row. Since noncondensible gases are always present in steam, these accumulate within the bottom row because steam is entering from both ends of the tube. Performance suffers.

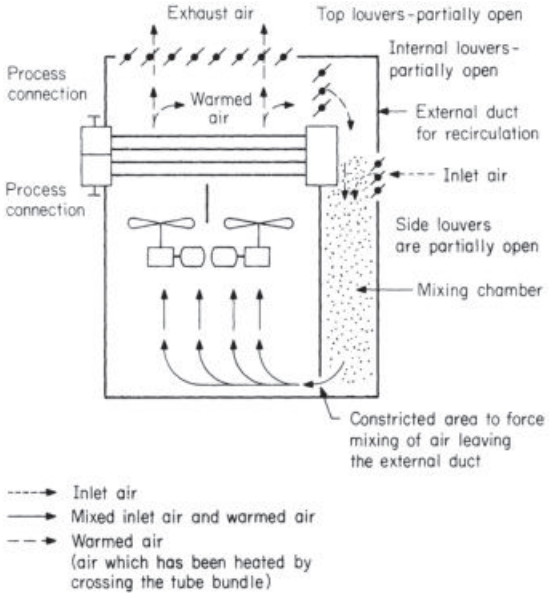

**FIG. 11-48** External recirculation with adequate mixing chamber. [*Hydrocarbon Process* 59: 148–149 (October 1980).]

**TABLE 11-18 Air-Cooled Heat-Exchanger Costs (1970)**

| Surface (bare tube), sq. ft. | 500 | 1000 | 2000 | 3000 | 5000 |
|---|---|---|---|---|---|
| Cost for 12-row-deep bundle, dollars/square foot | 9.0 | 7.6 | 6.8 | 5.7 | 5.3 |
| Factor for bundle depth: | | | | | |

| | 20 ft. tube length | 1.05 |
| | 30 ft. tube length | 0.95 |
| | 18 B.W.G. admiralty tube | 1.04 |
| | 16 B.W.G. admiralty tube | 1.12 |

NOTE: To convert feet to meters, multiply by 0.3048; to convert square feet to square meters, multiply by 0.0929; and to convert inches to millimeters, multiply by 25.4.

Various solutions have been used. These include orifices to regulate the flow into each tube, a "blow-through steam" technique with a vent condenser, complete separation of each row of tubes, and inclined tubes.

**Air-Cooled Overhead Condensers** *Air-cooled overhead condensers* (AOCs) have been designed and installed above distillation columns as integral parts of distillation systems. The condensers generally have inclined tubes, with air flow over the finned surfaces induced by a fan. Prevailing wind affects both structural design and performance.

AOCs provide the additional advantages of reducing ground-space requirements and piping and pumping requirements and of providing smoother column operation.

The downflow condenser is used mainly for nonisothermal condensation. Vapors enter through a header at the top and flow downward. The reflux condenser is used for isothermal and small-temperature-change conditions. Vapors enter at the bottom of the tubes.

AOC usage first developed in Europe but became more prevalent in the United States during the 1960s. A state-of-the-art article was published by Dehne [*Chem. Eng. Prog.* **64:** 51 (July 1969)].

**Air-Cooled Heat Exchanger Costs** The cost data in Table 11-18 are unchanged from those published in the 1963 edition of this text. In 1969 Guthrie [*Chem. Eng.* **75:** 114 (Mar. 24, 1969)] presented cost data for field-erected air-cooled exchangers. These costs are only 25 percent greater than those of Table 11-18 and include the costs of steel stairways, indirect subcontractor charges, and field erection charges. Since minimal field costs would be this high (i.e., 25 percent of purchase price), the basic costs appear to be unchanged. (Guthrie indicated a cost band of ±25 percent.) Preliminary design and the cost estimation of air-cooled heat exchangers have been discussed by J. E. Lerner ["Simplified Air Cooler Estimating," *Hydrocarbon Process* **52:** 93–100 (February 1972)].

**Design Considerations**

1. *Design dry-bulb temperature.* The typically selected value is the temperature which is equaled or exceeded 2½ percent of the time during the warmest consecutive 4 months. Since air temperatures at industrial sites are frequently higher than those used for these weather data reports, it is good practice to add 1°C to 3°C (2°F to 6°F) to the tabulated value.

2. *Air recirculation.* Prevailing winds and the locations and elevations of buildings, equipment, fired heaters, etc., require consideration. All air-cooled heat exchangers in a bank are of one type, i.e., all forced-draft or all induced-draft. Banks of air-cooled exchangers must be placed far enough apart to minimize air recirculation.

3. *Wintertime operations.* In addition to the previously discussed problems of winterization, provision must be made for heavy rain, strong winds, freezing of moisture upon the fins, etc.

4. *Noise.* Two identical fans have a noise level 3 dBa higher than one fan, while eight identical fans have a noise level 9 dBa higher than a single fan. Noise level at the plant site is affected by the exchanger position, reflective surfaces near the fan, hardness of these surfaces, and noise from adjacent equipment. The extensive use of air-cooled heat exchangers contributes significantly to plant noise level.

5. *Ground area and space requirements.* Comparisons of the overall space requirements for plants using air cooling versus water cooling are not consistent. Some air-cooled units are installed above other equipment—pipe racks, shell-and-tube exchangers, etc. Some plants avoid such installations because of safety considerations, as discussed later.

6. *Safety.* Leaks in air-cooled units are transmitted directly to the atmosphere and can cause fire hazards or toxic-fume hazards. However, the large air flow through an air-cooled exchanger greatly reduces any concentration of toxic fluids. Segal [*Pet. Refiner* **38:** 106 (April 1959)] reports that air-fin coolers "are not located over pumps, compressors, electrical switchgear, control houses and, in general, the amount of equipment such as drums and shell-and-tube exchangers located beneath them are minimized."

Pipe-rack-mounted air-cooled heat exchangers with flammable fluids generally have concrete fire decks which isolate the exchangers from the piping.

7. *Atmospheric corrosion.* Air-cooled heat exchangers should not be located where corrosive vapors and fumes from vent stacks will pass through them.

8. *Air-side fouling.* Air-side fouling is generally negligible.

9. *Process-side cleaning.* Either chemical or mechanical cleaning on the inside of the tubes can readily be accomplished.

10. *Process-side design pressure.* The high-pressure process fluid is always in the tubes. Tube-side headers are relatively small compared with water-cooled units when the high pressure is generally on the shell side. High-pressure design of rectangular headers is complicated. The plug-type header is normally used for design gauge pressures to 13,790 kPa (2000 lbf/in$^2$) and has been used to 62,000 kPa (9000 lbf/in$^2$). The use of threaded plugs at these pressures creates problems. Removable cover plate headers are generally limited to gauge pressures of 2068 kPa (300 lbf/in$^2$). The expensive billet-type header is used for high-pressure service.

11. *Bond resistance.* Vibration and thermal cycling affect the bond resistance of the various types of tubes in different manners and thus affect the amount of heat transfer through the fin tube.

12. *Approach temperature.* The approach temperature, which is the difference between the process-fluid outlet temperature and the design dry-bulb air temperature, has a practical minimum of 8°C to 14°C (15°F to 25°F). When a lower process-fluid outlet temperature is required, an air humidification chamber can be provided to reduce the inlet air temperature toward the wet-bulb temperature. A 5.6°C (10°F) approach is feasible. Since typical summer wet-bulb design temperatures in the United States are 8.3°C (15°F) lower than dry-bulb temperatures, the outlet process-fluid temperature can be 3°C (5°F) below the dry-bulb temperature.

13. *Mean-temperature-difference (MTD) correction factor.* When the outlet temperatures of both fluids are identical, the MTD correction factor for a 1:2 shell-and-tube exchanger (one pass shell side, two or more passes tube side) is approximately 0.8. For a single-pass, air-cooled heat exchanger the factor is 0.91. A two-pass exchanger has a factor of 0.96, while a three-pass exchanger has a factor of 0.99 when passes are arranged for counterflow.

14. *Maintenance cost.* Maintenance for air-cooled equipment as compared with shell-and-tube coolers (complete with cooling-tower costs) indicates that air-cooling maintenance costs are approximately 0.3 to 0.5 times those for water-cooled equipment.

15. *Operating costs.* Power requirements for air-cooled heat exchangers can be lower than at the summer design condition provided that an adequate means of air flow control is used. The annual power requirement for an exchanger is a function of the means of air flow control, the exchanger service, the air-temperature rise, and the approach temperature.

When the mean annual temperature is 16.7°C (30°F) lower than the design dry-bulb temperature and when both fans in a bay have automatically controllable pitch of fan blades, the annual power required has been found to be 22, 36, and 54 percent, respectively, of that needed at the design condition for three process services [Frank L. Rubin, "Power Requirements Are Lower for Air-Cooled Heat Exchangers with AV Fans," *Oil Gas J.,* pp. 165–167 (Oct. 11, 1982)]. Alternatively, when fans have two-speed motors, these deliver one-half of the design flow of air at half speed and use only one-eighth of the power of the full-speed condition.

# COMPACT AND NONTUBULAR HEAT EXCHANGERS

## COMPACT HEAT EXCHANGERS

With equipment costs rising and limited available plot space, compact heat exchangers are gaining a larger portion of the heat exchanger market. Numerous types use special enhancement techniques to achieve the required heat transfer in smaller plot areas and, in many cases, require lower initial investment. As with all items that afford a benefit, a series of restrictions limit the effectiveness or application of these special heat exchanger products. In most products discussed, some of these considerations are presented, but a thorough review with reputable suppliers of these products is the only positive way to select a compact heat exchanger. The following guidelines will assist in prequalifying one of these.

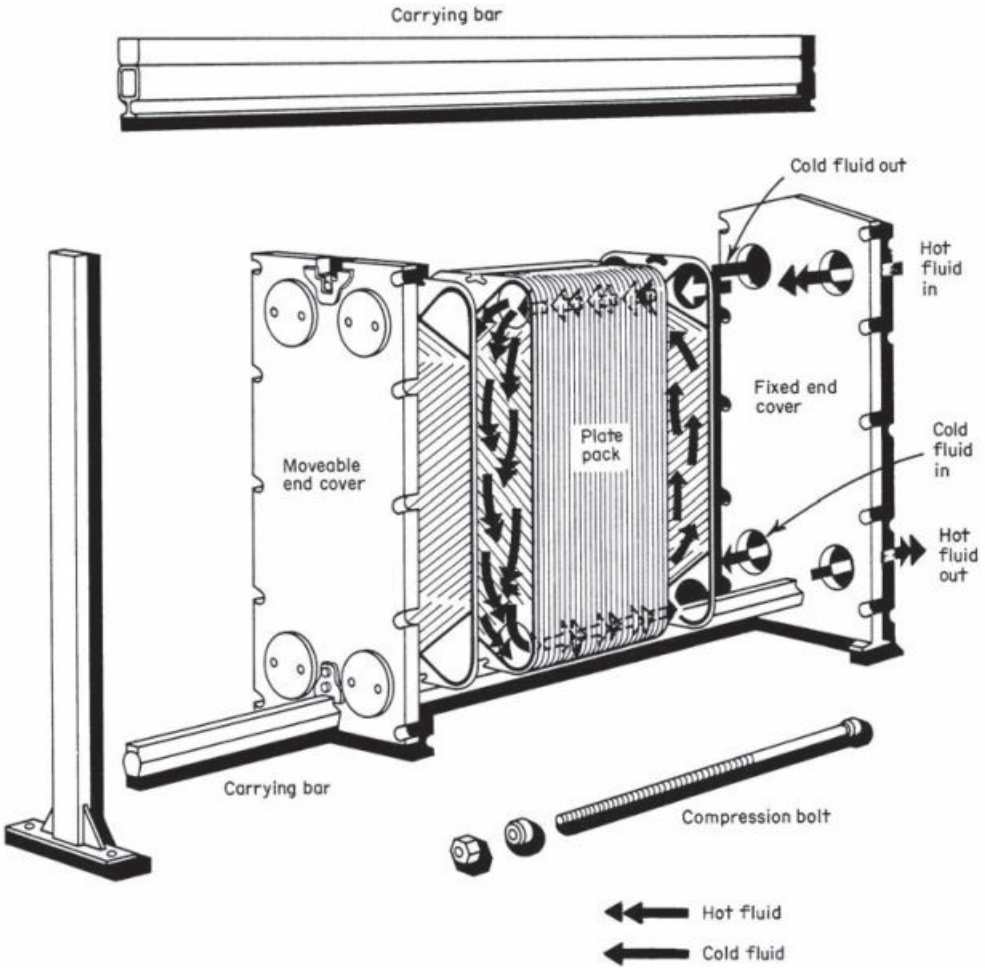

**FIG. 11-49** Plate-and-frame heat exchanger. Hot fluid flows down between alternate plates, and cold fluid flows up between alternate plates. (*Thermal Division, Alfa-Laval, Inc.*)

## PLATE-AND-FRAME EXCHANGERS

There are two major types: gasketed and welded-plate heat exchangers. Each is discussed individually.

## GASKETED-PLATE EXCHANGERS

**Description** This type is the fastest growing of the compact exchangers and the most recognized (see Fig. 11-49). A series of corrugated alloy material channel plates, bounded by elastomeric gaskets, are hung off and guided by longitudinal carrying bars, then compressed by large-diameter tightening bolts between two pressure-retaining frame plates (cover plates). The frame and channel plates have portholes which allow the process fluids to enter alternating flow passages (the space between two adjacent-channel plates). Gaskets around the periphery of the channel plate prevent leakage to the atmosphere and prevent process fluids from coming in contact with the frame plates. No interfluid leakage is possible in the port area because of a dual-gasket seal.

The frame plates are typically epoxy-painted carbon-steel material and can be designed per most pressure vessel codes. Design limitations are found in Table 11-19. The channel plates are always an alloy material with 304SS as a minimum (see Table 11-19 for other materials).

Channel plates are typically 0.4 to 0.8 mm thick and have corrugation depths of 2 to 10 mm. Special wide-gap (WG PHE) plates are available, in limited sizes, for slurry applications with depths of approximately 16 mm. The channel plates are compressed to achieve metal-to-metal contact for pressure-retaining integrity. These narrow gaps and the high number of contact points that change the fluid flow direction combine to create a very high turbulence between the plates. This means high individual heat-transfer coefficients (up to 14,200 $W/m^2 \cdot °C$), but very high pressure drops per length as well. To compensate, the channel plate lengths are usually short, most under 2 m and few over 3 m in length. In general, the same pressure drops as conventional exchangers are used without loss of the enhanced heat transfer.

Expansion of the initial unit is easily performed in the field without special considerations. The original frame length typically has an additional capacity of 15 to 20 percent more channel plates (i.e., surface area). In fact, if a known future capacity is available during fabrication stages, a longer carrying bar could be installed, and increasing the surface area would be easily handled later. When the expansion is needed, simply loosen the carrying bolts, pull back the frame plate, add the additional channel plates, and tighten the frame plate. API 662 Part I now covers the design of these types of heat exchangers.

**Applications** Most plate heat exchanger (PHE) applications historically have been liquid-liquid services, but there has been significant development in the use of PHE for vacuum condensing as well as evaporation and column reboiling. Industrial users typically have chevron-style channel plates while some food applications are washboard style.

Fine particulate slurries in concentrations up to 70 percent by weight are possible with standard channel spacings. Wide-gap units are used with larger particle sizes. Typical particle size should not exceed 75 percent of the *single* plate (not total channel) gap.

Close temperature approaches and tight temperature control possible with PHEs and the ability to sanitize the entire heat-transfer surface easily were a major benefit in the food industry.

Multiple services in a single frame are possible.

Gasket selection is one of the most critical and limiting factors in PHE use. Table 11-20 gives some guidelines for fluid compatibility. Even trace

The major applications are, but not limited to, the following:

| | |
|---|---|
| Temperature cross applications | (lean/rich solvent) |
| Close approaches | ( freshwater/seawater) |
| Viscous fluids | (emulsions) |
| Sterilized surface required | ( food, pharmaceutical) |
| Polished surface required | (latex, pharmaceutical) |
| Future expansion required | |
| Space restrictions | |
| Barrier coolant services | (closed-loop coolers) |
| Slurry applications | ($TiO_2$, Kaolin, precipitated calcium carbonate, and beet sugar raw juice) |

**Design** Plate exchangers are becoming so commonplace that there is now an API 662 document available for the specification of these products. In addition, commercial computer programs are available from HTRI among others. Standard channel-plate designs, unique to each manufacturer, are developed with limited modifications of each plate's corrugation depths and included angles. Manufacturers combine their different style plates to custom-fit each service. Due to the possible combinations, it is impossible to present a way to exactly size PHEs. However, it is possible to estimate areas for new units and to predict performance of existing units with different conditions (chevron-type channel plates are presented).

The fixed length and limited corrugation included angles on channel plates makes the NTU (number of heat transfer units) method of sizing practical. (Water-like fluids are assumed for the following examples.)

$$\text{NTU} = \frac{\Delta t \text{ of either side}}{\text{LMTD}} \tag{11-76}$$

Most plates have NTU values of 0.5 to 4.0, with 2.0 to 3.0 as the most common (multipass shell-and-tube exchangers are typically less than 0.75). The more closely the fluid profile matches that of the channel plate, the smaller the required surface area. Attempting to increase the service NTU beyond the plate's NTU capability causes oversurfacing (inefficiency).

True sizing from scratch is impractical since a pressure balance on a channel-to-channel basis, from channel closest to inlet to farthest, must be achieved and when mixed plate angles are used; this is quite a challenge. Computer sizing is not just a benefit, it is a necessity for supplier's selection. Averaging methods are recommended to perform any sizing calculations.

From the APV heat-transfer handbook *Design and Application of Paraflow-Plate Heat Exchangers* and J. Marriott's article "Where and How to Use Plate Heat Exchangers," *Chemical Engineering,* April 5, 1971, there are the equations for plate heat transfer.

$$\mathrm{Nu} = \frac{h\,\mathrm{De}}{k} = 0.28 \times (\mathrm{Re})^{0.65} \times (\mathrm{Pr})^{0.4} \tag{11-77}$$

where De = 2 × depth of single-plate corrugation. Also

$$G = \frac{W}{\mathrm{Np} \times w \times \mathrm{De}} \tag{11-78}$$

The width of the plate $w$ is measured from inside to inside of the channel gasket. If it is not available, use the tear-sheet drawing width and subtract 2 times the bolt diameter and subtract another 50 mm. For depth of corrugation ask the supplier, or take the compressed plate pack dimension, divide by the number of plates, and subtract the plate thickness from the result. The *number of passages* Np is the number of plates minus 1, then divided by 2.

Typical overall coefficients to start a rough sizing are listed below. Use these in conjunction with the NTU calculated for the process. The closer the NTU matches the plate (say, between 2.0 and 3.0), the higher the range of listed coefficients that can be used. The narrower (smaller) the depth of corrugation, the higher the coefficient (and pressure drop), but also the lower the ability to carry through any particulate.

| | |
|---|---|
| Water/water | 5700–7400 W/(m$^2$ · °C) |
| Steam/water | 5700–7400 W/(m$^2$ · °C) |
| Glycol/glycol | 2300–4000 W/(m$^2$ · °C) |
| Amine/amine | 3400–5000 W/(m$^2$ · °C) |
| Crude/emulsion | 400–1700 W/(m$^2$ · °C) |

Pressure drops typically can match conventional tubular exchangers. Again from the APV handbook, an average correlation is as follows:

$$\Delta P = \frac{2\,f G^2 L}{g \rho \mathrm{De}} \tag{11-79}$$

where $f = 2.5(G\,\mathrm{De}/\mu)^{-0.3}$
$g$ = gravitational constant

Fouling factors are typically one-tenth of TEMA values or an oversurfacing of 10 to 20 percent is used (J. Kerner, "Sizing Plate Exchangers," *Chemical Engineering,* November 1993).

LMTD is calculated as a 1 pass-1 pass shell and tube with no $F$ correction factor required in most cases.

Overall coefficients are determined as for shell-and-tube exchangers; that is, sum all the resistances, then invert. The resistances include the hot-side coefficient, the cold-side coefficient, the fouling factor (usually only a total value, not individual values per fluid side), and the wall resistance.

## WELDED- AND BRAZED-PLATE EXCHANGERS

The title of this group of plate exchangers has been used for a great variety of designs for various applications from normal gasketed-plate exchanger services to air-preheater services on fired heaters or boilers. The intent here is to discuss more traditional heat exchanger designs, not the heat recovery designs on fired equipment flue-gas streams. Many similarities exist between these products, but the manufacturing techniques are quite different due to the normal operating conditions these units experience.

To overcome the gasket limitations, PHE manufacturers have developed welded-plate exchangers. There are numerous approaches to this solution: weld plate pairs together with the other fluid side conventionally gasketed; weld up both sides but use a horizonal stacking-of-plates method of assembly; entirely braze the plates together with copper or nickel brazing; diffusion bond and then pressure-form plates and bond-etched passage plates. The act of welding the plates together removed one of the largest limitations of the plate-and-frame: the many gaskets and their compatibility limitations to process fluids.

Most methods of welded-plate manufacturing do not allow for inspection of the heat-transfer surface or mechanical cleaning of that surface, and they have limited ability to repair or plug off damaged channels. Consider these limitations when the fluid is heavily fouling, has solids, or in general, the need for repair or the potential of plugging for severe services.

One of the previous types has an additional issue of the brazing material to consider for fluid compatibility. The brazing compound entirely coats both fluids' heat-transfer surfaces.

The second type, a Compabloc (CP) from Alfa-Laval AB, has the advantage of removable cover plates, similar to air-cooled exchanger headers, to observe both fluids' surface areas. The fluids flow at 90° angles to each other on a horizontal plane. LMTD correction factors approach 1.0 for Compabloc just as for the other welded and gasketed PHEs. Hydroblast cleaning of Compabloc surfaces is also possible. The Compabloc has higher operating conditions than PHEs or W-PHE.

The performances and estimating methods of welded PHEs match those of gasketed PHEs in most cases, but normally the Compabloc, with larger depth of corrugations, can be lower in overall coefficient. Some extensions of the design operating conditions are possible with welded PHEs; most notable is that cryogenic applications are possible. Pressure vessel code acceptance is available on most units.

Applications of welded plate exchangers, especially the Compabloc type, are increasingly being accepted in the chemical industry as a reliable process heat exchanger. Typical applications include, but not limited to, these:

1. Crude oil preheat trains
2. Oil and gas facilities, crude and gas sweetening applications
3. Process condensers and reboilers on chemical industry distillation columns
4. Refined product coolers and primary petrochemical manufacturing heat exchangers
5. Pharmaceutical condensers
6. Other areas where space and weight are primary concerns

## COMBINATION WELDED-PLATE EXCHANGERS

Plate exchangers are well known for their high efficiency but suffer from limitations on operating pressure. Several companies have rectified this limitation by placing the welded plate exchanger inside a pressure vessel to withstand the pressure, such as Alfa Laval's Packinox design. One popular application is the feed effluent exchange in a catalytic reforming plant for oil refineries. Large volumes of gases with some liquids require cross-exchange to feed a reactor system. Close temperature approaches and lower pressure drops are required as well as a very clean service. These combined units provide an economic alternative to shell-and-tube exchangers.

## SPIRAL-PLATE HEAT EXCHANGER (SHE)

**Description** The *spiral-plate heat exchanger* (SHE) may be one exchanger selected primarily for its virtues and not for its initial cost. SHEs offer high reliability and on-line performance in many severely fouling services such as slurries.

The SHE is formed by rolling two strips of plate, with welded-on spacer studs, upon each other into clock-spring shape. This forms two passages. Passages are sealed off on one end of the SHE by welding a bar to the plates; hot and cold fluid passages are sealed off on opposite ends of the SHE. A single rectangular flow passage is now formed for each fluid, producing very high shear rates compared to tubular designs. Removable covers are provided on each end to access and clean the entire heat-transfer surface. Pure countercurrent flow is achieved, and the LMTD correction factor is essentially = 1.0.

Since there are no dead spaces in a SHE, the helical flow pattern combines to entrain any solids and create high turbulence, creating a self-cleaning flow passage.

There are no thermal expansion problems in spirals. Since the center of the unit is not fixed, it can torque to relieve stress.

The SHE can be expensive when only one fluid requires a high-alloy material. Since the heat-transfer plate contacts both fluids, it is required to be fabricated out of the higher alloy. SHEs can be fabricated out of any material that can be cold-worked and welded.

The channel spacings can be different on each side to match the flow rates and pressure drops of the process design. The spacer studs are also adjusted in their pitch to match the fluid characteristics.

As the operating pressure or design conditions require, the plate thickness increases from a minimum of 2 mm to a maximum (as required by pressure) up to 10 mm if the shell is integrally rolled. For high pressures, the SHE is inserted in a standard pressure vessel with cover flanges. This means relatively thick material separates the two fluids compared to the tubing of conventional exchangers. Pressure vessel code conformance is a common request. API 664 was recently issued covering this type of heat exchanger and its use.

**Applications** The most common applications that fit SHE are slurries. The single rectangular channel provides an ideal geometry to sweep the surface clear of blockage and causes none of the distribution problems associated with other exchanger types. A localized restriction causes an increase in local velocity which aids in keeping the unit free-flowing, eliminating plugging problems that plague other heat exchanger types. Only fibers that are long and stringy cause SHE to have a blockage it cannot clear itself.

As an additional antifoulant measure, SHEs have been coated with a phenolic lining. This provides some degree of corrosion protection as well, but this is not guaranteed due to pinholes in the lining process.

There are three types of SHE to fit different applications:

*Type I* is the spiral-spiral flow pattern. It is used for all heating and cooling services and can accommodate temperature crosses such as lean/rich services in one unit. The removable covers on each end enable access to one side at a time to perform maintenance on that fluid side. Never remove a cover with one side under pressure as the unit will telescope out like a collapsible cup.

*Type II* units are the condenser and reboiler designs. One side is spiral flow, and the other side is in cross-flow. These SHEs provide very stable designs for vacuum condensing and reboiling services. A SHE can be fitted with special mounting connections for reflux-type vent-condenser applications. The vertically mounted SHE directly attaches onto the column or tank.

*Type III* units are a combination of the type I and type II where part is in spiral flow and part is in cross-flow. This SHE can condense and subcool in a single unit.

The unique channel arrangement has been used to provide on-line cleaning, by switching fluid sides to clean the fouling (caused by the fluid that previously flowed there) off the surface. Phosphoric acid coolers use pond water for cooling and both sides foul; water, as you expect, and phosphoric acid deposit crystals. By reversing the flow sides, the water dissolves the acid crystals and the acid clears up the organic fouling. SHEs are also used as oleum coolers, sludge coolers/heaters, slop oil heaters, and in other services where multiple-flow-passage designs have not performed well.

**Design** A thorough article by P. E. Minton of Union Carbide called "Designing Spiral-Plate Heat Exchangers" appeared in *Chemical Engineering* on May 4, 1970. It covers the design in detail. Also an article in *Chemical Engineering Progress* titled "Applications of Spiral Plate Heat Exchangers" by A. Hargis, A. Beckman, and J. Loicano appeared in July 1967 and provides formulas for heat-transfer and pressure-drop calculations.

Spacings are from 6.35 to 31.75 mm (in 6.35-mm increments) with 9.5 mm the most common. Stud densities are 60 × 60 to 110 × 110 mm, with the former the most common. The width (measured to the spiral flow passage) is from 150 to 2500 mm (in 150-mm increments). By varying the spacing and the width, separately for each fluid, velocities can be maintained at optimum rates to reduce fouling tendencies or utilize the allowable pressure drop most effectively. Diameters can reach 2500 mm. The total surface areas exceed 465 $m^2$. Materials that work harder are not suitable for spirals since hot-forming is not possible and heat treatment after forming is impractical.

$$\mathrm{Nu} = \frac{H\,\mathrm{De}}{k} = 0.0315\ (\mathrm{Re})^{0.8}(\mathrm{Pr})^{0.25}(\mu/\mu_w)^{0.17} \qquad (11\text{-}80)$$

where De = 2 × spacing and flow area = width × spacing

$$\Delta P = \frac{LV^2\rho}{1.705\mathrm{E}03} \times 1.45 \quad (1.45 \text{ for } 60\text{-}\times 60\text{-mm studs}) \qquad (11\text{-}81)$$

The LMTD and overall coefficient are calculated as in the PHE section above.

## BRAZED-PLATE-FIN HEAT EXCHANGERS

Brazed-aluminum-plate-fin heat exchangers (or *core exchangers* or *cold boxes*, as they are sometimes called) were first manufactured for the aircraft industry during World War II. In 1950, the first tonnage air-separation plant with these compact, lightweight, reversing heat exchangers began producing oxygen for a steel mill. Aluminum-plate-fin exchangers are used in the process and gas-separation industries, particularly for services below −45°C.

Core exchangers are made up of a stack of rectangular sheets of aluminum separated by a wavy, usually perforated, aluminum fin. Two ends are sealed off to form a passage (see Fig. 11-50). The layers have the wavy fins and sealed ends alternating at 90° to each. Aluminum half-pipe-type headers are attached to the open ends to route the fluids into the alternating passages. Fluids usually flow at this same 90° angle to one another. Variations in the fin height, number of passages, and length and width of the prime sheet allow for the core exchanger to match the needs of the intended service.

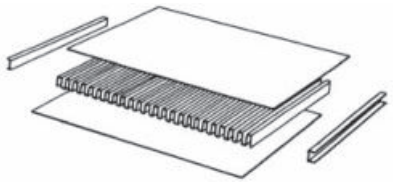

**FIG. 11-50** Exploded view of a typical plate-fin arrangement. (*Trane Co.*)

Design conditions range in pressures from full vacuum to 96.5 bar g and in temperatures from −269°C to 200°C. This is accomplished while meeting the quality standards of most pressure vessel codes. API 662 Part 2 has been developed for this type of heat exchanger.

**Design and Application** Brazed plate heat exchangers have two design standards available. One is ALPEMA, the Aluminum Plate-Fin Heat Exchanger Manufacturers' Association, and the other is the API 662 document for plate heat exchangers.

Applications are varied for this highly efficient, compact exchanger. Mainly it is seen in the cryogenic fluid services of air-separation plants, in refrigeration trains as in ethylene plants, and in natural-gas processing plants. Fluids can be all vapor, liquid, condensing, or vaporizing. Multifluid exchangers and multiservice cores, that is, one exchanger with up to 10 different fluids, are common for this type of product. Cold boxes are a group of cores assembled into a single structure or module, prepiped for minimum field connections. (Data were obtained from ALTEC International, now Chart Industries. For detailed information refer to *GPSA Engineering Handbook,* Sec. 9.)

## PLATE-FIN TUBULAR EXCHANGER (PFE)

**Description** These shell-and-tube exchangers are designed to use a group of tightly spaced plate fins to increase the shell-side heat-transfer performance as fins do on double-pipe exchangers. In this design, a series of very thin plates ( fins), usually of copper or aluminum, are punched to the same pattern as the tube layout, spaced very close together, and mechanically bonded to the tube. Fin spacing is 315 to 785 FPM ( fins per meter) with 550 FPM most common. The fin thicknesses are 0.24 mm for aluminum and 0.19 mm for copper. Surface-area ratios over bare prime-tube units can be 20:1 to 30:1. The cost of the additional plate-fin material, without a reduction in shell diameter in many cases, and increased fabrication has to be offset by the total reduction of plot space and prime tube surface area. The more costly the prime tube or plot space, the better the payout for this design. A rectangular tube layout is normally used with *no tubes in the window* (NTIW). The window area (where no tubes are) of the plate fins is cut out. This causes a larger shell diameter for a given tube count compared to conventional tubular units. A dome area on the top and bottom of the inside of the shell has been created for the fluid to flow along the tube length. To exit the unit, the fluid must flow across the plate-finned tube bundle with extremely low pressure loss. The units from the outside and from the tube side appear as in any conventional shell-and-tube exchanger.

**Applications** Two principal applications are rotating equipment oil coolers and compressor intercoolers and after-coolers. Although seemingly different applications, both rely on the shell-side finning to enhance the heat transfer of low heat-transfer characteristic fluids, viscous oils, and gases. By the nature of the fluids and their applications, both are clean servicing. The tightly spaced fins would be a maintenance problem otherwise.

**Design** The economics usually work out in the favor of gas coolers when the centrifugal machine's flow rate reaches about 5000 scfm. The pressure loss can be kept to 7.0 kPa in most cases. When the ratio of $A_f h_t$ to $A_s h_s$ is 20:1, this is another point to consider in these plate-fin designs. Vibration is practically impossible with this design, and uses in reciprocating compressors are possible because of this.

Marine and hydraulic-oil coolers use these characteristics to enhance the coefficient of otherwise poorly performing fluids. The higher metallurgies in marine applications such as 90/10 Cu-Ni allow the higher cost of plate-fin design to be offset by the reduced amount of alloy material being used. On small hydraulic coolers, these fins usually allow one to two size smaller coolers for the package and save skid space and initial cost.

Always check on metallurgy compatibility and cleanliness of the shell-side fluid! (Data are provided by Bos-Hatten and ITT-Standard.)

## PRINTED-CIRCUIT HEAT EXCHANGERS

These are a variation of the welded or brazed plate heat exchangers that uses a chemical etching process to form the flow channels and diffusion bonding

technique to secure the plates together. These units have the high heat-transfer characteristics and extended operating conditions that welded or brazed units have, but the diffusion process makes the bond the same strength as that of the prime plate material. The chemical etching, similar to that used in printed circuitry, allows greater flexibility in flow channel patterns than any other heat exchanger. This type of heat exchanger is perhaps the most compact design of all due to the infinite variations in passage size, layout, and direction.

Headers are welded on the core block to direct the fluids into the appropriate passages. The all-metal design allows very high operating conditions for both temperature and pressure. The diffusion bonding provides a near-homogeneous material for fluids that are corrosive or require high purity.

These exchangers can handle gases, liquids, and two-phase applications. They have the greatest potential in cryogenic, refrigeration, gas processing, and corrosive chemical applications. Other applications are possible with the exception of fluids containing solids: the narrow passages, as in most plate exchangers, are conducive to plugging.

## SPIRAL-TUBE EXCHANGER (STE)

**Description** These exchangers are typically a series of stacked helical-coil tubes connected to manifolds, then inserted into a casing or shell. They have many advantages similar to those of spiral-plate designs, such as avoiding differential expansion problems, acceleration effects of the helical flow increasing the heat-transfer coefficient, and compactness of plot area. They are typically selected because of their economical design.

The most common form has both sides in helical flow patterns, pure countercurrent flow is followed, and the LMTD correction factor approaches 1.0. Temperature crosses are possible in single units. As with the spiral-plate unit, different configurations are possible for special applications.

Tube material includes any that can be formed into a coil, but usually copper, copper alloys, and stainless steel are most common. The casing or shell material can be cast iron, cast steel, cast bronze, fabricated steel, stainless steel, and other high-alloy materials. Units are available with pressure vessel code conformance.

The data provided here have been supplied by Graham Mfg. for their units called Heliflow.

**Applications** The common Heliflow applications are tank-vent condensers, sample coolers, pump-seal coolers, and steam-jet vacuum condensers. Instant water heaters, glycol/water services, and cryogenic vaporizers use the spiral tube's ability to reduce thermally induced stresses caused in these applications.

Many other applications are well suited for spiral tube units, but many believe only small surface areas are possible with these units. Graham Mfg. states that units are available to 60 $m^2$. Their ability to polish the surfaces, double-wall the coil, use finned coil, and insert static mixers, among other configurations in design, make them quite flexible. Tube-side design pressures can be up to 69,000 kPa. A cross-flow design on the external surface of the coil is particularly useful in steam-jet ejector condensing service. These Heliflow units can be made very cost-effective, especially in small units. The main difference, compared to spiral plate, is that the tube side cannot be cleaned except chemically and that multiple flow passages make tube-side slurry applications (or fouling) impractical.

**Design** The fluid flow is similar to that of the spiral-plate exchangers, but through parallel tube passages. Graham Mfg. has a liquid-liquid sizing pamphlet available from its local distributor. An article by M. A. Noble, J. S. Kamlani, and J. J. McKetta ("Heat Transfer in Spiral Coils," *Petroleum Engineer,* April 1952, p. 723) discusses sizing techniques.

The tube-side fluid must be clean or at least chemically cleanable. With a large number of tubes in the coil, cleaning of inside surfaces is not totally reliable. Fluids that attack stressed materials such as chlorides should be reviewed as to proper coil-material selection. Fluids that contain solids can be a problem due to erosion of relatively thin coil materials, unlike for the thick plates in spiral-plate units and multiple, parallel fluid passages compared to a single passage in spiral-plate units.

## GRAPHITE HEAT EXCHANGERS

Impervious graphite exchangers now come in a variety of geometries to suit the particular requirements of the service. They include cubic block form, drilled cylinder block, shell-and-tube, and plate-and-frame.

**Description** Graphite is one of three crystalline forms of carbon. The other two are diamond and charcoal. Graphite has a hexagonal crystal structure, diamond is cubic, and charcoal is amorphous. Graphite is inert to most chemicals and resists corrosion attack. It is, however, porous and it must be impregnated with a resin sealer to be used. Two main resins used are phenolic and PTFE with furan (one currently being phased out of production). Selection of resins includes chemical compatibility, operating temperatures, and type of unit to be used. For proper selection, consult with a graphite supplier.

Shell-and-tube units in graphite were started by Karbate in 1939. The European market started using block design in the 1940s. Both technologies utilize the high thermal conductivity of the graphite material to compensate for the poor mechanical strength. The thicker materials needed to sustain pressure do not adversely impede the heat transfer. Maximum design pressures range from 0.35 to 1.0 kPa depending on the type and size of exchanger. Design temperature is dependent on the fluid and resin selection, the maximum is 230°C.

In all situations, the graphite heat-transfer surface is contained within a metal structure or a shell (graphite-lined on process side) to maintain the design pressure. For shell-and-tube units, the design is a packed floating tubesheet at both ends within a shell and channel. For stacked block design, the standardize blocks are glued together with special adhesives and compressed within a framework that includes manifold connections for each fluid. The cylindrical block unit is a combination of the above two with blocks glued together and surrounded by a pressure-retaining shell. Pressure vessel code conformance of the units is possible due to the metallic components of these designs. Since welding of graphite is not possible, the selection and application of the adhesives used are critical to the proper operation of these units. Tube–tubesheet joints are glued since rolling of tubes into tubesheet is not possible. The packed channels and gasketed manifold connections are two areas of additional concern when one is selecting sealants for these units.

**Applications and Design** The major applications for these units are in the acid-related industries. Sulfuric, phosphoric, and hydrochloric acids require either very costly metals or impervious graphite. Usually graphite is the more cost-effective material used. Applications are increasing in the herbicide and pharmaceutical industries as new products with chlorine and fluorine compounds expand. Services are coolers, condensers, and evaporators, basically all services requiring this material. Types of units are shell-and-tube, block-type (circular and rectangular), and plate-and-frame type of exchangers. The designs of the shell-and-tube units are the same as any others, but the design characteristics of tubes, spacing, and thickness are unique to the graphite design. The block and plate and frame also can be evaluated by using techniques previously addressed; but again the unique characteristics of the graphite materials require input from a reputable supplier. Most designs will need the supplier to provide the most cost-effective design for the immediate and future operation of the exchangers. Also consider the entire system design as some condensers and/or evaporators can be integral with their associated column.

## CASCADE COOLERS

Cascade coolers are a series of standard pipes, usually manifolded in parallel and connected in series by vertically or horizontally oriented U bends. Process fluid flows inside the pipe entering at the bottom, and water trickles from the top downward over the external pipe surface. The water is collected from a trough under the pipe sections, cooled, and recirculated over the pipe sections. The pipe material can be any of the metallics and also glass, impervious graphite, and ceramics. The tube-side coefficient and pressure drop are as in any circular duct. The water coefficient (with Re number less than 2100) is calculated from the following equation by W. H. McAdams, T. B. Drew, and G. S. Bays, Jr., from *ASME Trans.* **62:** 627–631 (1940).

$$h = 218 \times (G'/D_o)^{1/3} \quad (\mathrm{W/m^2 \cdot °C}) \tag{11-82}$$

where $G' = m/(2L)$
$m$ = water rate, kg/h
$L$ = length of each pipe section, m
$D_o$ = outside diameter of pipe, m
LMTD corrections are per Fig. 11-4*i* or *j* depending on U-bend orientation.

## BAYONET-TUBE EXCHANGERS

This type of exchanger gets its name from its design, which is similar to a bayonet sword and its associated scabbard or sheath. The bayonet tube is a smaller-diameter tube inserted into a larger-diameter tube that has been capped at one end. The fluid flow typically enters the inner tube, exiting, hitting the cap of the larger tube, and returning to the opposite direction in the annular area. The design eliminates any thermal expansion problems. It also creates a unique nonfreeze-type tube side for steam heating of cryogenic fluids; the inner tube steam keeps the annulus condensate from freezing against the cold shell-side fluid. This design can be expensive on a surface-area basis due to the need for a double-channel design, and only the outer tube surface is used to transfer heat. LMTD calculations for nonisothermal fluid are quite extensive, and those applications are far too few to attempt

to define it. The heat transfer is like the annular calculation of a double-pipe unit. The shell side is a conventional baffled shell-and-tube design. A rigorous treatment of the design of bayonet exchangers, "Understanding Bayonet Heat Exchangers" by Richard L. Shilling, is available through Heat Transfer Research, Inc.

### ATMOSPHERIC SECTIONS

These consist of a rectangular bundle of tubes in similar fashion to air cooler bundles, placed just under the cooled water distribution section of a cooling tower. It, in essence, combines the exchanger and cooling tower into a single piece of equipment. This design is practical only for single-service cooler/condenser applications, and expansion capabilities are not provided. The process fluid flows inside the tubes, and the cooling tower provides cool water that flows over the outside of the tube bundle. Water quality is critical for these applications to prevent fouling or corrosive attack on the outside of the tube surfaces and to prevent blockage of the spray nozzles. The initial and operating costs are lower than those for a separate cooling tower and exchanger. Principal applications now are in the HVAC, refrigeration, and industrial systems. Sometimes these are called *wet surface air coolers.*

$$h = 1729\ [(m^2/h)/\text{face area } m^2]^{1/3} \qquad (11\text{-}83)$$

### NONMETALLIC HEAT EXCHANGERS

Another growing field is that of nonmetallic heat exchanger designs which typically are of the shell-and-tube or coiled-tubing type. The graphite units were previously discussed, but numerous other materials are available. The materials include Teflon, PVDF, glass, ceramic, and others as the need arises.

When using these types of products, one should consider the following topics and discuss the application openly with experienced suppliers.

1. The tube-to-tubesheet joint, how is it made? Many use O-rings to add another material to the selection process. Preference should be given to a fusing technique of similar material.
2. What size tube or flow passage is available? Small tubes plug unless filtration is installed. The size of filtering is needed from the supplier.
3. These materials are very sensitive to temperature and pressure. Thermal or pressure shocks must be avoided.
4. Thermal conductivity of these materials is very low and affects the overall coefficient. When several materials are compatible, explore all of them, as final cost is not always the same as raw material costs.

## HEAT EXCHANGERS FOR SOLIDS

This section describes equipment for heat transfer to or from solids by the indirect mode. Such equipment is constructed so that the solids load (burden) is separated from the heat-carrier medium by a wall; the two phases are never in direct contact. Heat transfer is by conduction based on diffusion laws. Equipment in which the phases are in direct contact is covered in other sections of this text, principally in Sec. 20.

Some of the devices covered here handle the solids burden in a static or laminar-flow bed. Other devices can be considered as continuously agitated kettles in their heat-transfer aspect. For the latter, unit-area performance rates are higher.

Computational and graphical methods for predicting performance are given for both major heat-transfer aspects in Sec. 10. In solids heat processing with indirect equipment, the engineer should remember that the heat-transfer capability of the wall is many times that of the solids burden. Hence the solids properties and bed geometry govern the rate of heat transfer. This is more fully explained earlier in this section. Only limited resultant (not predictive) and "experience" data are given here.

### EQUIPMENT FOR SOLIDIFICATION

A frequent operation in the chemical field is the removal of heat from a material in a molten state to effect its conversion to the solid state. When the operation is carried on batchwise, it is termed *casting,* but when done continuously, it is termed *flaking.* Because of rapid heat transfer and temperature variations, jacketed types are limited to an initial melt temperature of 232°C (450°F). Higher temperatures [to 316°C (600°F)] require extreme care in jacket design and cooling-liquid flow pattern. Best performance and greatest capacity are obtained by (1) holding precooling to the minimum and (2) optimizing the cake thickness. The latter cannot always be done from the heat-transfer standpoint, as size specifications for the end product may dictate thickness.

**Table Type** This is a simple flat metal sheet with slightly upturned edges and jacketed on the underside for coolant flow. For many years this was the mainstay of food processors. Table types are still widely used when production is done in small batches, when considerable batch-to-batch variation occurs, for pilot investigation, and when the cost of continuous devices is unjustifiable. Slab thicknesses are usually in the range of 13 to 25 mm (½ to 1 in). These units are homemade, with no standards available. Initial cost is low, but operating labor is high.

**Agitated-Pan Type** A natural evolution from the table type is a circular flat surface with jacketing on the underside for coolant flow and the added feature of a stirring means to sweep over the heat-transfer surface. This device is the agitated-pan type (Fig. 11-51). It is a batch-operation device. Because of its age and versatility, it still serves a variety of heat-transfer operations for the chemical-process industries. While the most prevalent designation is agitated-pan dryer (in this mode, the burden is heated rather than cooled), considerable use is made of it for solidification applications. In this field, it is particularly suitable for processing burdens that change phase (1) slowly, by "thickening," (2) over a wide temperature range, (3) to an amorphous solid form, or (4) to a soft semigummy form (versus the usual hard crystalline structure).

The stirring produces the end product in the desired divided-solids form. Hence, it is frequently termed a *granulator* or a *crystallizer*. A variety of factory-made sizes in various materials of construction are available. Initial cost is modest, while operating cost is rather high (as is true of all batch devices), but the ability to process "gummy" burdens and/or simultaneously effect two unit operations often yields an economical application.

**Vibratory Type** This construction (Fig. 11-52) takes advantage of the burden's special needs and the characteristic of vibratory actuation. A flammable burden requires the use of an inert atmosphere over it and a suitable nonhazardous fluid in the jacket. The vibratory action permits construction of rigid self-cleaning chambers with simple flexible connections. When solidification has been completed and vibrators started, the intense vibratory motion of the whole deck structure (as a rigid unit) breaks free the friable cake [up to 76 mm (3 in) thick], shatters it into lumps, and conveys it up over the dam to discharge. Heat-transfer performance is good, with overall coefficient $U$ of about 68 W/(m$^2$ · °C) [12 Btu/(h · ft$^2$ · °F)] and values of heat flux $q$ on the order of 11,670 W/m$^2$ [3700 Btu/(h · ft$^2$)]. Application of timing-cycle controls and a surge hopper for the discharge solids facilitates automatic operation of the caster and continuous operation of subsequent equipment.

**Belt Types** The patented metal-belt type (Fig. 11-53*a*), termed the "water-bed" conveyor, features a thin wall, a well-agitated fluid side for a thin water film (there are no rigid welded jackets to fail), a stainless-steel or Swedish-iron conveyor belt "floated" on the water with the aid of guides, no removal knife, and cleanability. It is mostly used for cake thicknesses of 3.2 to 15.9 mm (⅛ to ⅝ in) at speeds up to 15 m/min (50 ft/min), with

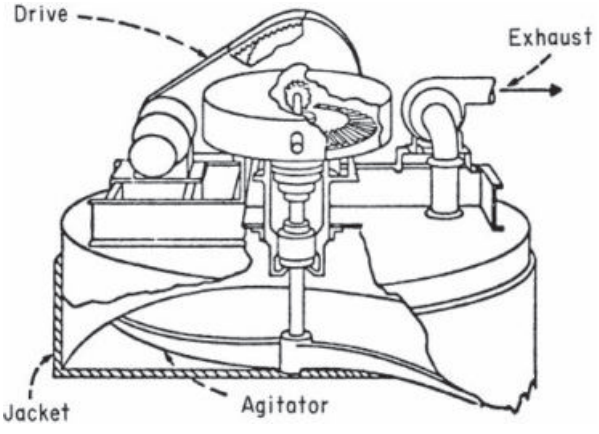

**FIG. 11-51** Heat-transfer equipment for solidification (with agitation); agitated-pan type.

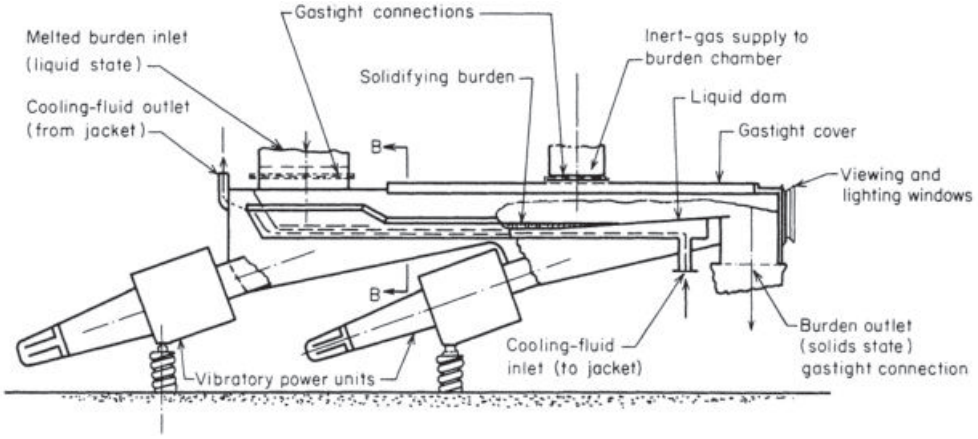

**FIG. 11-52** Heat-transfer equipment for batch solidification; vibrating-conveyor type. (*Courtesy of Jeffrey Mfg. Co.*)

45.7-m (150-ft) pulley centers common. For 25- to 32-mm (1- to 1¼-in) cake, another belt on top to give two-sided cooling is frequently used. Applications are in food operations for cooling to harden candies, cheeses, gelatins, margarines, gums, etc.; and in chemical operations for solidification of sulfur, greases, resins, soaps, waxes, chloride salts, and some insecticides. Heat transfer is good, with sulfur solidification showing values of $q = 5800$ W/m$^2$ [1850 Btu/(h · ft$^2$)] and $U = 96$ W/(m$^2$ · °C) [17 Btu/(h · ft$^2$ · °F)] for a 7.9-mm ($^5/_{16}$-in) cake.

The submerged metal belt (Fig. 11-53*b*) is a special version of the metal belt to meet the peculiar handling properties of pitch in its solidification process. Although adhesive to a dry metal wall, pitch will not stick to the submerged wetted belt or rubber edge strips. Submergence helps to offset the very poor thermal conductivity through two-sided heat transfer.

A fairly recent application of the water-cooled metal belt to solidification duty is shown in Fig. 11-54. The operation is termed *pastillizing* from the form of the solidified end product, termed *pastilles.* The novel feature is a one-step operation from the molten liquid to a fairly uniformly sized and shaped product without intermediate operations on the solid phase.

Another development features a nonmetallic belt [*Plast. Des. Process* **13** (July 1968)]. When rapid heat transfer is the objective, a glass-fiber, Teflon-coated construction in a thickness as little as 0.08 mm (0.003 in) is selected for use. No performance data are available, but presumably the thin belt permits rapid heat transfer while taking advantage of the nonsticking property of Teflon. Another development [*Food Process. Mark.* **69** (March 1969)] is extending the capability of belt solidification by providing use of subzero temperatures.

**Rotating-Drum Type** This type (Fig. 11-55*a* and *b*) is not an adaptation of a material-handling device (though volumetric material throughput is a first consideration) but is designed specifically for heat-transfer service. It is well engineered, established, and widely used. The twin-drum type (Fig. 11-55*b*) is best suited to thin [0.4- to 6-mm (1/64- to ¼-in)] cake production. For temperatures to 149°C (300°F) the coolant water is piped in and siphoned out. Spray application of coolant water to the inside is employed for high-temperature work, permitting feed temperatures to at least 538°C (1000°F), or double those values for jacketed equipment. Vaporizing refrigerants are readily applicable for very low temperature work.

The burden must have a definite solidification temperature to ensure proper pickup from the feed pan. This limitation can be overcome by side feeding through an auxiliary rotating spreader roll. Application limits are further extended by special feed devices for burdens having oxidation-sensitive and/or supercooling characteristics. The standard double-drum model turns downward, with adjustable roll spacing to control sheet thickness. The newer twin-drum model (Fig. 11-55*b*) turns upward and, though subject to variable cake thickness, handles viscous and indefinite solidification temperature-point burden materials well.

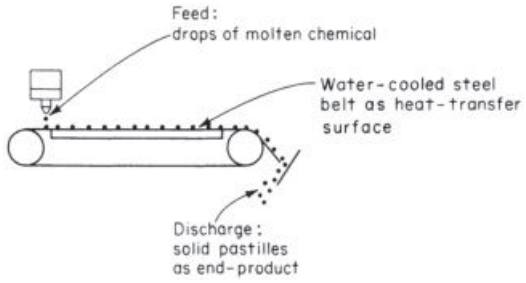

**FIG. 11-54** Heat-transfer equipment for solidification; belt type for the operation of pastillization. (*Courtesy of Sandvik, Inc.*)

Drums have been successfully applied to a wide range of chemical products, both inorganic and organic, pharmaceutical compounds, waxes, soaps, insecticides, food products to a limited extent (including lard cooling), and even flake-ice production. A novel application is that of using a water-cooled roll to pick up from a molten-lead bath and turn out a 1.2-m- (4-ft-) wide continuous sheet, weighing 4.9 kg/m$^2$ (1 lb/ft$^2$), which is ideal for a sound barrier. This technique is more economical than other sheeting methods [*Mech. Eng.* **631** (March 1968)].

*Heat-transfer performance* of drums, in terms of reported heat flux, is: for an 80°C (176°F) melting-point wax, 7880 W/m$^2$ [2500 Btu/(h·ft$^2$)]; for a 130°C (266°F) melting-point organic chemical, 20,000 W/m$^2$ [6500 Btu/(h·ft$^2$)]; and for high-melting-point [318°C (604°F)] caustic soda (water-sprayed in drum), 95,000 to 125,000 W/m$^2$ [30,000 to 40,000 Btu/(h·ft$^2$)], with overall coefficients of 340 to 450 W/(m$^2$·°C) [60 to 80 Btu/(h·ft$^2$·°F)]. An innovation that is claimed often to increase these performance values by as much as 300 percent is the addition of hoods to apply impinging streams of heated air to the solidifying and drying solids surface as the drums carry it upward [*Chem. Eng.* **74:** 152 (June 19, 1967)]. Similar rotating-drum indirect heat-transfer equipment is also extensively used for drying duty on liquids and thick slurries of solids (see Sec. 20).

**Rotating-Shelf Type** The patented Roto-shelf type (Fig. 11-55*c*) features (1) a large heat-transfer surface provided over a small floor space and in a small building volume, (2) easy floor cleaning, (3) nonhazardous machinery, (4) stainless-steel surfaces, (5) good control range, and (6) substantial capacity by providing as needed 1 to 10 shelves operated in parallel. It is best suited for thick-cake production and burden materials having an indefinite solidification temperature. Solidification of liquid sulfur into 13- to 19-mm- (½- to ¾-in-) thick lumps is a successful application. Heat transfer, by liquid-coolant circulation through jackets, limits feed temperatures to 204°C (400°F). Heat-transfer rate, controlled by the thick cake rather than by equipment construction, should be equivalent to the belt type. Thermal performance is aided by applying water sprayed directly to the burden top to obtain two-sided cooling.

## EQUIPMENT FOR FUSION OF SOLIDS

The thermal duty here is the opposite of solidification operations. The indirect heat-transfer equipment suitable for one operation is not suitable for the other because of the material-handling aspects rather than the thermal aspects. Whether the temperature of transformation is a definite or ranging one is of little importance in the selection of equipment for fusion. The burden is much agitated, but the beds are deep. Only fair overall coefficient values may be expected, although heat flux values are good.

**Horizontal-Tank Type** This type (Fig. 11-56*a*) is used to transfer heat for melting or cooking dry powdered solids, rendering lard from meat-scrap solids, and drying divided solids. Heat-transfer coefficients are 17 to 85 W/(m$^2$·°C) [3 to 15 Btu/(h·ft$^2$·°F)] for drying and 28 to 140 W/(m$^2$·°C) [5 to 25 Btu/(h·ft$^2$·°F)] for vacuum and/or solvent recovery.

**Vertical Agitated-Kettle Type** Shown in Fig. 11-56*b,* this type is used to cook, melt to the liquid state, and provide or remove reaction heat for solids that vary greatly in "body" during the process so that material handling is a real problem. The virtues are simplicity and 100 percent cleanability. These often outweigh the poor heat-transfer aspect. These devices are available from the small jacketed type illustrated to huge cast-iron direct-underfired bowls for calcining gypsum. Temperature limits vary with construction; the simpler jackets allow temperatures to 371°C (700°F) (as with Dowtherm), which is not true of all jacketed equipment.

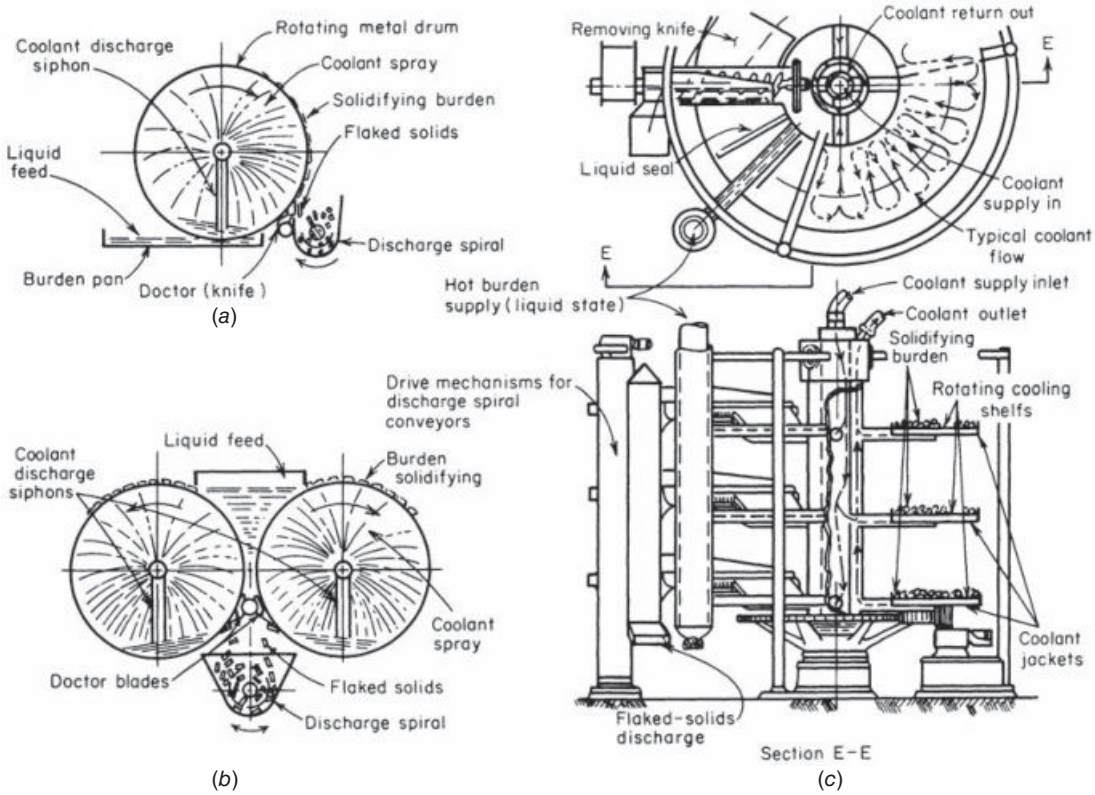

**FIG. 11-55** Heat-transfer equipment for continuous solidification. (*a*) Single drum. (*b*) Twin drum. (*c*) Roto shelf. (*Courtesy of Buflovak Division, Blaw-Knox Food & Chemical Equipment, Inc.*)

**Mill Type** Figure 11-56*c* shows one model of roll construction used. Note the ruggedness, as it is a *power device* as well as one for *indirect* heat transfer, employed to knead and heat a mixture of dry powdered-solid ingredients with the objective of reacting and reforming via fusion to a consolidated product. In this compounding operation, frictional heat generated by the kneading may require heat-flow reversal (by cooling). Heat-flow control and temperature-level considerations often predominate over heat-transfer performance. Power and mixing considerations, rather than heat transfer, govern. The two-roll mill shown is employed in compounding raw plastic, rubber, and rubberlike elastomer stocks. Multiple-roll mills less knives (termed *calenders*) are used for continuous sheet or film production in widths up to 2.3 m (7.7 ft). Similar equipment is employed in the chemical compounding of inks, dyes, paint pigments, and the like.

## HEAT-TRANSFER EQUIPMENT FOR SHEETED SOLIDS

**Cylinder Heat-Transfer Units** Sometimes called "can" dryers or drying rolls, these devices are differentiated from drum dryers in that they are used for solids in flexible continuous-sheet form, whereas drum dryers are used for liquid or paste forms. The construction of the individual cylinders, or drums, is similar in most respects to that of drum dryers. Special designs are used to obtain uniform distribution of steam within large drums when uniform heating across the drum surface is critical.

A cylinder dryer may consist of one large cylindrical drum, such as the so-called Yankee dryer, but more often it comprises a number of drums arranged so that a continuous sheet of material may pass over them in series. Typical of this arrangement are Fourdrinier paper machine dryers, cellophane dryers, slashers for textile piece goods and fibers, etc. The multiple cylinders are arranged in various ways. Generally, they are staggered in two horizontal rows. In any one row, the cylinders are placed close together. The sheet material contacts the undersurface of the lower rolls and passes over the upper rolls, contacting 60 to 70 percent of the cylinder surface. The cylinders may also be arranged in a single horizontal row, in more than two horizontal rows, or in one or more vertical rows. When it is desired to contact only one side of the sheet with the cylinder surface, unheated guide rolls are used to conduct the sheeting from one cylinder to the next. For sheet materials that shrink on processing, it is frequently necessary to drive the cylinders at progressively slower speeds through the dryer. This requires elaborate individual electric drives on each cylinder.

Cylinder dryers usually operate at atmospheric pressure. However, the Minton paper dryer is designed for operation under vacuum. The drying cylinders are usually heated by steam, but occasionally single cylinders may be gas-heated, as in the case of the Pease blueprinting machine. Upon contacting the cylinder surface, wet sheet material is first heated to an equilibrium temperature somewhere between the wet-bulb temperature of the surrounding air and the boiling point of the liquid under the prevailing total pressure. The heat-transfer resistance of the vapor layer between the sheet and the cylinder surface may be significant.

These cylinder units are applicable to almost any form of sheet material that is not injuriously affected by contact with steam-heated metal surfaces. They are used chiefly when the sheet possesses certain properties such as a tendency to shrink or lacks the mechanical strength necessary for most types of continuous-sheeting air dryers. Applications are to dry films of various sorts, paper pulp in sheet form, paper sheets, paperboard, textile piece goods and fibers, etc. In some cases, imparting a special finish to the surface of the sheet may be an objective.

The *heat-transfer performance capacity* of cylinder dryers is not easy to estimate without a knowledge of the sheet temperature, which, in turn, is difficult to predict. According to published data, steam temperature is the largest single factor affecting capacity. Overall evaporation rates based on the total surface area of the dryers cover a range of 3.4 to 23 kg water/($h \cdot m^2$) [0.7 to 4.8 lb water/($h \cdot ft^2$)].

The value of the *coefficient of heat transfer* from steam to sheet is determined by the conditions prevailing on the inside and on the surface of the dryers. Low coefficients may be caused by (1) poor removal of air or other noncondensibles from the steam in the cylinders, (2) poor removal of condensate, (3) accumulation of oil or rust on the interior of the drums, and (4) accumulation of a fiber lint on the outer surface of the drums. In a test reported by Lewis et al. [*Pulp Pap. Mag. Can.* **22** (February 1927)] on a sulfite-paper dryer, in which the actual sheet temperatures were measured, a value of 187 W/($m^2 \cdot °C$) [33 Btu/($h \cdot ft^2 \cdot °F$)] was obtained for the coefficient of heat flow between the steam and the paper sheet.

Operating-cost data for these units are meager. Power costs may be estimated by assuming 1 hp per cylinder for diameters of 1.2 to 1.8 m (4 to 6 ft). Data on labor and maintenance costs are also lacking.

The size of commercial cylinder dryers covers a wide range. The individual rolls may vary in diameter from 0.6 to 1.8 m (2 to 6 ft) and up to 8.5 m (28 ft) in width. In some cases, the width of rolls decreases throughout the dryer in order to conform to the shrinkage of the sheet. A single-cylinder dryer,

such as the Yankee dryer, generally has a diameter between 2.7 and 4.6 m (9 and 15 ft).

## HEAT-TRANSFER EQUIPMENT FOR DIVIDED SOLIDS

Most equipment for this service is some adaptation of a *material-handling* device whether or not the transport ability is desired. The old vertical tube and the vertical shell (fluidizer) are exceptions. Material-handling problems, plant transport needs, power, and maintenance are prime considerations in equipment selection and frequently overshadow heat-transfer and capital-cost considerations. Material handling is generally the most important aspect. Material-handling characteristics of the divided solids may vary during heat processing. The body changes are usually important in drying, occasionally significant for heating, and only on occasion important for cooling. The ability to minimize the effects of changes is a major consideration in equipment selection. Dehydration operations are better performed on contactive apparatus (see Sec. 12) that provides air to carry off released water vapor before a semiliquid form develops.

Some types of equipment are convertible from heat removal to heat supply by simply changing the temperature level of the fluid or air. Other types require an auxiliary change. Still others require constructional changes. Temperature limits for the equipment generally vary with the thermal operation. The kind of thermal operation has a major effect on heat-transfer values. For drying, overall coefficients are substantially higher in the presence of substantial moisture for the constant-rate period than in finishing. However, a stiff "body" occurrence due to moisture can prevent a normal "mixing" with an adverse effect on the coefficient.

**Fluidized-Bed Type** Known as the *cylindrical fluidizer*, this operates with a bed of *fluidized solids* (Fig. 11-57). It is an indirect heat-transfer version of the contactive type in Sec. 17. An application disadvantage is the need for batch operation unless some short circuiting can be tolerated. Solids-cooling applications are few, as they can be more effectively accomplished by the fluidizing gas via the contactive mechanism that is referred to in Sec. 11. Heating applications are many and varied. These are subject to one shortcoming, which is the dissipation of the heat input by carry-off in the fluidizing gas. Heat-transfer performance for the indirect mode to solids has been outstanding, with overall coefficients in the range of 570 to 850 $W/(m^2 \cdot °C)$ [100 to 150 $Btu/(h \cdot ft^2 \cdot °F)$]. This device with its thin film does for solids what the falling-film and other thin-film techniques do for fluids, as shown by Holt (Pap. 11, 4th National Heat-Transfer Conference, August 1960). In a design innovation with high heat-transfer capability, heat is supplied indirectly to the fluidized solids through the walls of in-bed, horizontally placed, finned tubes [Petrie, Freeby, and Buckham, *Chem. Eng. Prog.* **64**(7): 45 (1968)].

**Moving-Bed Type** This concept uses a single-pass tube bundle in a vertical shell with the divided solids flowing by gravity in the tubes. It is little used for solids. A major difficulty in divided-solids applications is the problem of charging and discharging with uniformity. A second is poor heat-transfer rates. Because of these limitations, this tube bundle type is not the workhorse for solids that it is for liquid- and gas-phase heat exchange.

However, there are applications in which the nature of a specific chemical reactor system requires indirect heating or cooling of a moving bed of divided solids. One of these is the segregation process which through a gaseous reaction frees chemically combined copper in an ore to a free copper form which permits easy, efficient subsequent recovery [Pinkey and Plint, *Miner. Process.* pp. 17–30 (June 1968)]. The apparatus construction and principle of operation are shown in Fig. 11-58. The functioning is abetted by a novel heat-exchange provision of a fluidized sand bed in the jacket. This provides a much higher unit heat-input rate (coefficient value) than would the usual low-density hot-combustion-gas flow.

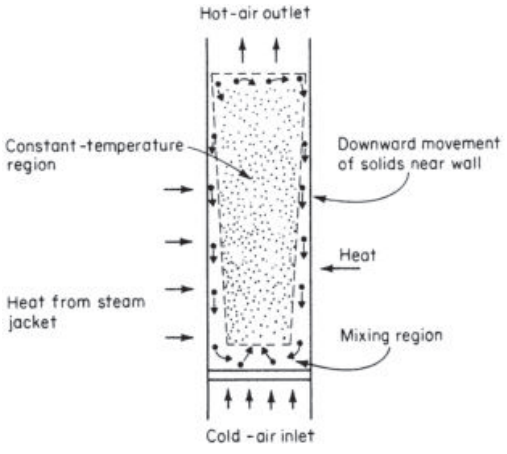

**FIG. 11-57** Heat-transfer equipment for divided solids; stationary vertical-shell type. The indirect fluidizer.

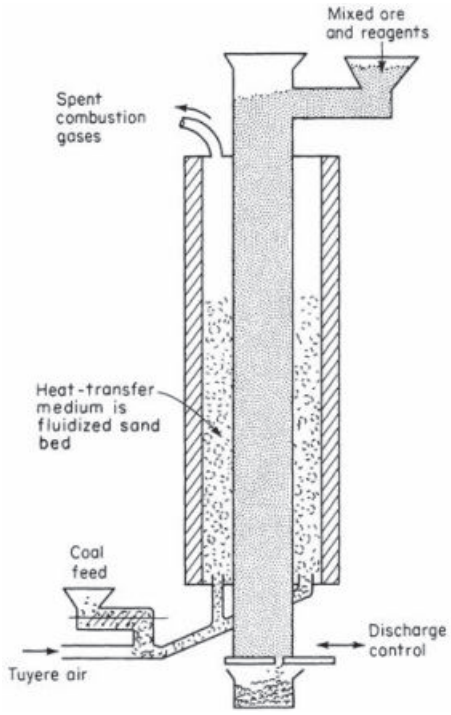

**FIG. 11-58** Stationary vertical-tube type of indirect heat-transfer equipment with divided solids inside tubes, laminar solids flow, and steady-state heat conditions.

**Agitated-Pan Type** This device (Fig. 11-52) is not an adaptation of a material-handling device but was developed many years ago primarily for heat-transfer purposes. As such, it has found wide application. In spite of its batch operation with high attendant labor costs, it is still used for processing divided solids when no phase change is occurring. Simplicity and easy cleanout make the unit a wise selection for handling small, experimental, and even some production runs when quite a variety of burden materials are heat-processed. Both heating and cooling are feasible with it, but greatest use has been for drying [see Sec. 12 and Uhl and Root, *Chem. Eng. Prog.* **63**(7): 8 (1967)]. Because it can be readily covered (as shown in the illustration) and a vacuum drawn or special atmosphere provided, this device features versatility to widen its use. For drying granular solids, the heat-transfer rate ranges from 28 to 227 $W/(m^2 \cdot °C)$ [5 to 40 $Btu/(h \cdot ft^2 \cdot °F)$]. For atmospheric applications, thermal efficiency ranges from 65 to 75 percent. For vacuum applications, it is about 70 to 80 percent. These devices are available from several sources, fabricated of various metals used in chemical processes.

**Kneading Devices** These are closely related to the agitated pan but differ as being primarily mixing devices with heat transfer a secondary consideration. Heat transfer is provided by jacketed construction of the main body and is effected by a coolant, hot water, or steam. These devices are applicable for the compounding of divided solids by mechanical rather than chemical action. Application is largely in the pharmaceutical and food processing industries. For a more complete description, illustrations, performance, and power requirements, refer to Sec. 19.

**Shelf Devices** Equipment having heated and/or cooled shelves is available but is little used for divided-solids heat processing. Most extensive use of stationary shelves is for freezing of packaged solids for food industries and for freeze drying by sublimation (see Sec. 22).

**Rotating-Shell Devices** These (see Fig. 11-59) are installed horizontally, whereas stationary-shell installations are vertical. Material-handling aspects are of greater importance than thermal performance. Thermal results are customarily given in terms of overall coefficient on the basis of the total area provided, which varies greatly with the design. The effective use, chiefly percent fill factor, varies widely, affecting the reliability of

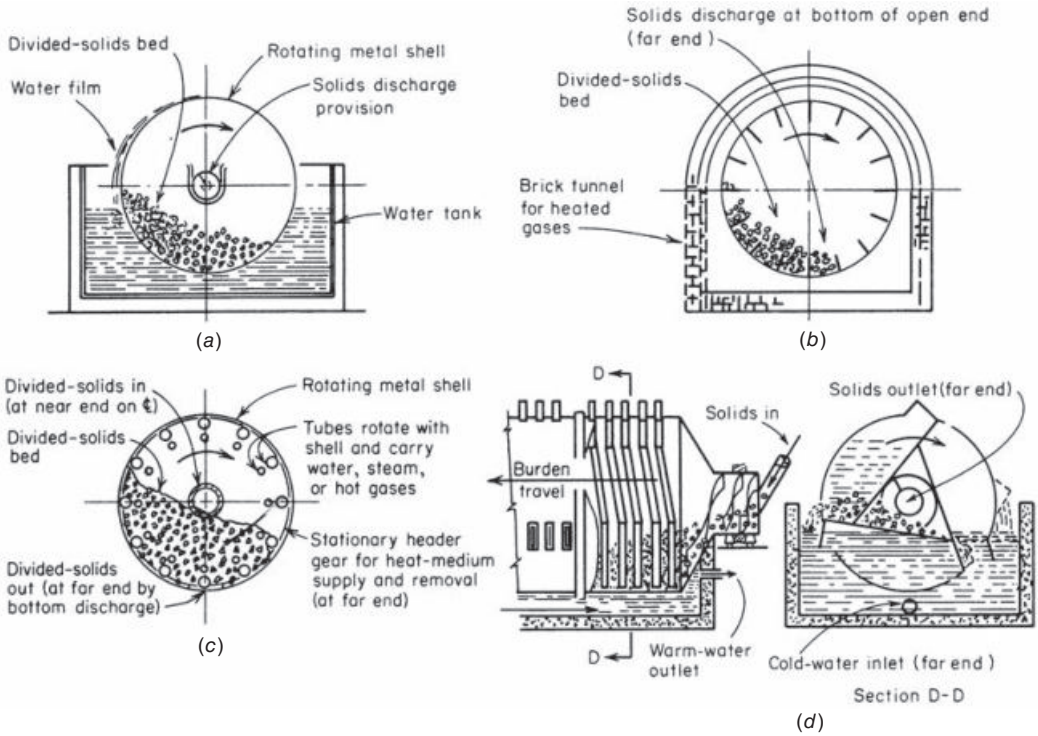

**FIG. 11-59** Rotating shells as indirect heat-transfer equipment. (*a*) Plain. (*Courtesy of BSP Corp.*) (*b*) Flighted. (*Courtesy of BSP Corp.*) (*c*) Tubed. (*d*) Deep-finned type. (*Courtesy of Link-Belt Co.*)

stated coefficient values. For performance calculations see Sec. 10 on heat-processing theory for solids. These devices are variously used for cooling, heating, and drying and are the workhorses for heat-processing divided solids in the large-capacity range. Different modifications are used for each of the three operations.

The *plain* type (Fig. 11-59*a*) features simplicity and yet versatility through various end-construction modifications enabling wide and varied applications. Thermal performance is strongly affected by the "body" characteristics of the burden because of its dependency for material handling on frictional contact. Hence, performance ranges from well-agitated beds with good thin-film heat-transfer rates to poorly agitated beds with poor thick-film heat-transfer rates. Temperature limits in application are (1) low-range cooling with shell dipped in water, 400°C (750°F) and less; (2) intermediate cooling with forced circulation of tank water, to 760°C (1400°F); (3) primary cooling, above 760°C (1400°F), water copiously sprayed and loading kept light; (4) low-range heating, below steam temperature, hot-water dip; and (5) high-range heating by tempered combustion gases or ribbon radiant-gas burners.

The *flighted* type (Fig. 11-59*b*) is a first-step modification of the plain type. The simple flight addition improves heat-transfer performance. This type is most effective on semifluid burdens which slide readily. Flighted models are restricted from applications in which soft-cake sticking occurs, breakage must be minimized, and abrasion is severe. A special flighting is one having the cross section compartmented into four lesser areas with ducts between. Hot gases are drawn through the ducts en route from the outer oven to the stack to provide about 75 percent more heating surface, improving efficiency and capacity with a modest cost increase. Another similar unit has the flights made in a triangular-duct cross section with hot gases drawn through.

The *tubed-shell* type (Fig. 11-59*c*) is basically the same device more commonly known as a *steam-tube rotary dryer* (see Sec. 20). The rotation, combined with slight inclination from the horizontal, moves the shell-side solids through it continuously. This type features good mixing with the objective of increased heat-transfer performance. Tube-side fluid may be water, steam, or combustion gas. Bottom discharge slots in the shell are used so that heat-transfer-medium supply and removal can be made through the ends; these restrict wide-range loading and make the tubed type inapplicable for floody materials. These units are seldom applicable for sticky, soft-caking, scaling, or heat-sensitive burdens. They are not recommended for abrasive materials. This type has high thermal efficiency because heat loss is minimized. *Heat-transfer coefficient* values are as follows: water, 34 W/(m$^2$·°C) [6 Btu/(h·ft$^2$·°F)]; steam, same, with heat flux reliably constant at 3800 W/m$^2$ [1200 Btu/(h·ft$^2$)]; and gas, 17 W/(m$^2$·°C) [3 Btu/(h·ft$^2$·°F)], with a high temperature difference. Although from the preceding discussion the device may seem rather limited, it is nevertheless widely used for drying, with condensing steam predominating as the heat-carrying fluid. But with water or refrigerants flowing in the tubes, it is also effective for cooling operations. The units are custom-built by several manufacturers in a wide range of sizes and materials. A few fabricators that specialize in this type of equipment have accumulated a vast store of data for determining application sizing.

The patented *deep-finned* type in Fig. 11-59*d* is named the *Rotofin cooler*. It features loading with a small layer thickness, excellent mixing to give a good effective diffusivity value, and a thin fluid-side film. Unlike other rotating-shell types, it is installed horizontally, and the burden is moved positively by the fins acting as an Archimedes spiral. Rotational speed and spiral pitch determine travel time. For cooling, this type is applicable to both secondary and intermediate cooling duties. Applications include solids in small lumps [9 mm (¾ in)] and granular size [6 mm and less (¼ to 0 in)] with no larger pieces to plug the fins, solids that have a free-flowing body characteristic with no sticking or caking tendencies, and drying of solids that have a low moisture and powder content unless special modifications are made for substantial vapor and dust handling. Thermal performance is very good, with overall coefficients to 110 W/(m$^2$·°C) [20 Btu/(h·ft$^2$·°F)], with one-half of these coefficients nominal for cooling based on the total area provided (nearly double those reported for other indirect rotaries).

**Conveyor-Belt Devices** The metal-belt type (Fig. 11-55) is the only device in this classification of material-handling equipment that has had serious effort expended on it to adapt it to indirect heat-transfer service with divided solids. It features a lightweight construction of a large area with a thin metal wall. Indirect-cooling applications have been made with poor thermal performance, as could be expected with a static layer. Auxiliary plowlike mixing devices, which are considered an absolute necessity to secure any worthwhile results for this service, restrict applications.

**Spiral-Conveyor Devices** Figure 11-60 illustrates the major adaptations of this widely used class of material-handling equipment to indirect heat-transfer purposes. These conveyors can be considered for heat-transfer purposes as continuously agitated kettles. The adaptation of Fig. 11-60*d* offers a batch-operated version for evaporation duty. For this service, all are package-priced and package-shipped items requiring few, if any, auxiliaries.

The *jacketed solid-flight* type (Fig. 11-60*a*) is the standard low-cost (parts-basis-priced) material-handling device, with a simple jacket added and employed for secondary-range heat transfer of an incidental nature. Heat-transfer coefficients are as low as 11 to 34 W/(m$^2$ · °C) [2 to 6 Btu/(h · ft$^2$ · °F)] on sensible heat transfer and 11 to 68 W/(m$^2$ · °C) [2 to 12 Btu/(h · ft$^2$ · °F)] on drying because of substantial static solids-side film.

The *small-spiral–large-shaft* type (Fig. 11-60*b*) is inserted in a solids-product line as pipe banks are in a fluid line, solely as a heat-transfer device. It features a thin burden ring carried at a high rotative speed and subjected to two-sided conductance to yield an estimated heat-transfer coefficient of 285 W/(m$^2$ · °C) [50 Btu/(h · ft$^2$ · °F)], thereby ranking thermally next to the shell-fluidizer type. This device for powdered solids is comparable with the Votator of the fluid field.

Figure 11-60*c* shows a fairly new spiral device with a medium-heavy annular solids bed and having the combination of a jacketed, stationary outer shell with moving paddles that carry the heat-transfer fluid. A unique feature of this device to increase volumetric throughput, by providing an overall greater temperature drop, is that the heat medium is supplied to and withdrawn from the rotor paddles by a parallel piping arrangement in the rotor shaft. This is a unique flow arrangement compared with the usual series flow. In addition, the rotor carries burden-agitating spikes which give it the trade name of Porcupine Heat-Processor (*Chem. Equip. News,* April 1966; and Uhl and Root, *AIChE Prepr*. **21,** 11th National Heat-Transfer Conference, August 1967).

The *large-spiral hollow-flight* type (Fig. 11-60*d*) is an adaptation, with external bearings, full fill, and salient construction points as shown, that is highly versatile in application. Heat-transfer coefficients are 34 to 57 W/(m$^2$ · °C) [6 to 10 Btu/(h · ft$^2$ · °F)] for poor, 45 to 85 W/(m$^2$ · °C) [8 to 15 Btu/(h · ft$^2$ · °F)] for fair, and 57 to 114 W/(m$^2$ · °C) [10 to 20 Btu/(h · ft$^2$ · °F)] for wet conductors. A popular version of this employs two such spirals in one material-handling chamber for a pugmill agitation of the deep solids bed. The spirals are seldom heated. The shaft and shell are heated.

Another deep-bed spiral-activated solids-transport device is shown by Fig. 11-60*e.* The flights carry a heat-transfer medium as well as the jacket. A unique feature of this device, which is purported to increase heat-transfer capability in a given equipment space and cost, is the dense-phase fluidization of the deep bed that promotes agitation and moisture removal on drying operations.

**Double-Cone Blending Devices** The original purpose of these devices was mixing (see Sec. 19). Adaptations have been made; so many models now are primarily for indirect heat-transfer processing. A jacket on the shell carries the heat-transfer medium. The mixing action, which breaks up agglomerates (but also causes some degradation), provides very effective burden exposure to the heat-transfer surface. On drying operations, the vapor release (which in a static bed is a slow diffusional process) takes place relatively quickly. To provide vapor removal from the burden chamber, a hollow shaft is used. Many of these devices carry the hollow-shaft feature a step further by adding a rotating seal and drawing a vacuum. This increases thermal performance notably and makes the device a natural for solvent-recovery operations.

These devices are replacing the older tank and spiral-conveyor devices. Better provisions for speed and ease of fill and discharge (without powered

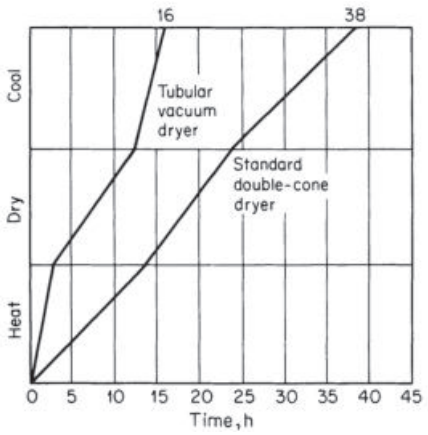

**FIG. 11-61** Performance of tubed blender heat-transfer device.

rotation) minimize downtime to make this batch-operated device attractive. Heat-transfer coefficients ranging from 28 to 200 W/(m$^2$ · °C) [5 to 35 Btu/(h · ft$^2$ · °F)] are obtained. However, if caking on the heat-transfer walls is serious, then values may drop to 5.5 or 11 W/(m$^2$ · °C) [1 or 2 Btu/(h · ft$^2$ · °F)], constituting a misapplication. The double cone is available in a fairly wide range of sizes and construction materials. The users are the fine-chemical, pharmaceutical, and biological-preparation industries.

A novel variation is a cylindrical model equipped with a tube bundle to resemble a shell-and-tube heat exchanger with a bloated shell [*Chem. Process.* **20** (Nov. 15, 1968)]. Conical ends provide for redistribution of burden between passes. The improved heat-transfer performance is shown by Fig. 11-61.

**Vibratory-Conveyor Devices** Figure 11-62 shows the various adaptations of vibratory material-handling equipment for indirect heat-transfer service on divided solids. The basic vibratory-equipment data are given in Sec. 21. These indirect heat-transfer adaptations feature simplicity, nonhazardous construction, nondegradation, nondusting, no wear, ready conveying-rate variation [1.5 to 4.5 m/min (5 to 15 ft/min)], and good heat-transfer coefficient—115 W/(m$^2$ · °C) [20 Btu/(h · ft$^2$ · °F)] for sand. They usually require feed rate and distribution auxiliaries. They are suited for heating and cooling of divided solids in powdered, granular, or moist forms but no sticky, liquefying, or floody ones. Terminal-temperature differences less than 11°C (20°F) on cooling and 17°C (30°F) on heating or drying operations are seldom practical. These devices are for medium and light capacities.

The *heavy-duty jacketed* type (Fig. 11-62*a*) is a special custom-built adaptation of a heavy-duty vibratory conveyor shown in Fig. 11-60. Its application is to continuously cool the crushed material [from about 177°C (350°F)] produced by the vibratory-type "caster" of Fig. 11-53. It does not have the liquid dam and is made in longer lengths that employ L, switchback, and S arrangements on one floor. The capacity rate is 27,200 to 31,700 kg/h (30 to 35 ton/h) with heat-transfer coefficients in the order of 142 to 170 W/(m$^2$ · °C) [25 to 30 Btu/(h · ft$^2$ · °F)]. For heating or drying applications, it employs steam to 414 kPa (60 lbf/in$^2$).

The *jacketed* or *coolant-spraying* type (Fig. 11-62*b*) is designed to ensure a very thin, highly agitated liquid-side film and the same initial coolant temperature over the entire length. It is frequently employed for transporting substantial quantities of hot solids, with cooling as an incidental consideration. For heating or drying applications, hot water or steam at a gauge pressure of 7 kPa (1 lbf/in$^2$) may be employed. This type is widely used because of its versatility, simplicity, cleanability, and good thermal performance.

The *light-duty jacketed* type (Fig. 11-62*c*) is designed for use of air as a heat carrier. The flow through the jacket is highly turbulent and is usually counterflow. On long installations, the air flow is parallel to every two sections for greater heat-carrying capacity and a fairly uniform surface temperature. The outstanding feature is that a wide range of temperature control is obtained by merely changing the heat-carrier temperature level from as low as atmospheric moisture condensation will allow to 204°C (400°F). On heating operations, a very good thermal efficiency can be obtained by insulating the machine and recycling the air. While the heat-transfer rating is good, the heat-removal capacity is limited. Cooler units are often used in series with like units operated as dryers or when clean water is unavailable. Drying applications are for heat-sensitive [49°C to 132°C (120°F to 270°F)] products; when temperatures higher than steam at a gauge pressure of 7 kPa (1 lbf/in$^2$) can provide are wanted but heavy-duty equipment is too costly; when the

jacket corrosion hazard of steam is unwanted; when headroom space is at a premium; and for highly abrasive burden materials such as fritted or crushed glasses and porcelains.

The *tiered arrangement* (Fig. 11-62*d*) employs the units of Fig. 11-62 with either air or steam at a gauge pressure of 7 kPa (1 lbf/in$^2$) as a heat medium. These are custom-designed and built to provide a large amount of heat-transfer surface in a small space with the minimum of transport and to provide a complete processing system. These receive a damp material, resize while in process by granulators or rolls, finish dry, cool, and deliver to packaging or tableting. The applications are primarily in the fine chemical, food, and pharmaceutical manufacturing fields.

The *Mix-R-Step* type in Fig. 11-62*e* is an adaptation of a vibratory conveyor. It features better heat-transfer rates, practically doubling the coefficient values of the standard flat surface and trebling heat-flux values, as the layer depth can be increased from the normal 13 to 25 and 32 mm (½ to 1 and 1¼ in). It may be provided on decks jacketed for air, steam, or water spray. It is also often applicable when an infrared heat source is mounted overhead to supplement the indirect or as the sole heat source.

**Elevator Devices** The *vibratory elevating-spiral* type (Fig. 11-63) adapts divided-solids-elevating material-handling equipment to heat-transfer service. It features a large heat-transfer area over a small floor space and employs a reciprocating shaker motion to effect transport. Applications, layer depth, and capacities are restricted, as burdens must be of such "body" character as to convey uphill by the microhopping transport principle. The type lacks self-emptying ability. Complete washdown and cleaning is a feature not inherent in any other elevating device. A typical application is the cooling of a low-density plastic powder at the rate of 544 kg/h (1200 lb/h).

Another elevator adaptation is that for a *spiral-type elevating* device developed for ground cement and thus limited to fine powdery burdens. The spiral operates inside a cylindrical shell, which is externally cooled by a falling film of water. The spiral not only elevates the material in a thin layer against the wall but keeps it agitated to achieve high heat-transfer rates. Specific operating data are not available [*Chem. Eng. Prog.* **68**(7): 113 (1968)]. The falling-water film, besides being ideal thermally, by virtue of no jacket pressure very greatly reduces the hazard that the cooling water may contact the water-sensitive burden in process. Surfaces wet by water are accessible for cleaning. A fair range of sizes are available, with material-handling capacities to 60 ton/h.

**Pneumatic Conveying Devices** See Sec. 21 for descriptions, ratings, and design factors of these devices. Use is primarily for transport purposes, and heat transfer is a very secondary consideration. Applications have largely been for plastics in powder and pellet forms.

By modifications, needed cooling operations have been simultaneously effected with transport to stock storage [*Plast. Des. Process* **28** (December 1968)].

Heat-transfer aspects and performance were studied and reported on by Depew and Farbar (ASME Pap. 62-HT-14, September 1962). Heat-transfer coefficient characteristics are similar to those shown in Sec. 11 for the indirectly heated fluid bed. Another frequent application on plastics is a small, rather incidental but necessary amount of drying required for plastic pellets and powders on receipt when shipped in bulk to the users. Pneumatic conveyors modified for heat transfer can handle this readily.

A pneumatic transport device designed primarily for heat-sensitive products is shown in Fig. 11-64. This was introduced into the United States after 5 years' use in Europe [*Chem. Eng.* **76:** 54 (June 16, 1969)].

Both the shell and the rotor carry steam as a heating medium to effect indirect transfer as the burden briefly contacts those surfaces rather than from the transport air, as is normally the case. The rotor turns slowly (1 to 10 r/min) to control, by deflectors, product distribution and prevent caking on walls. The carrier gas can be inert, as nitrogen, and also recycled through appropriate auxiliaries for solvent recovery. Application is limited to burdens that (1) are fine and uniformly grained for the pneumatic transport, (2) dry very fast, and (3) have very little, if any, sticking or decomposition characteristics. Feeds can carry 5 to 100 percent moisture (dry basis) and discharge at 0.1 to 2 percent. Wall temperatures range from 100 to 170°C (212 to 340°F) for steam and lower for a hot-water heat source. Pressure drops are on the order of 500 to 1500 mm$H_2O$ (20 to 60 in$H_2O$). Steam consumption approaches that of a contractive-mechanism dryer down to a low value of 2.9 kg steam/kg water (2.9 lb steam/lb water). Available burden capacities are 91 to 5900 kg/h (200 to 13,000 lb/h).

**Vacuum-Shelf Types** These are very old devices, being a version of the table type. Early-day use was for drying (see Sec. 12). Heat transfer is slow even when supplemented by vacuum, which is 90 percent or more of present-day use. The newer vacuum blender and cone devices are taking over many applications. The slow heat-transfer rate is quite satisfactory in a major application, freeze drying, which is a sublimation operation (see Sec. 22 for description) in which the water must be retained in the solid state during its removal. Then slow diffusional processes govern. Another extensive application is in freezing packaged foods for preservation purposes.

Available sizes range from shelf areas of 0.4 to 67 m$^2$ (4 to 726 ft$^2$). These are available in several manufacturers' standards, either as system components or with auxiliary gear as packaged systems.

## THERMAL INSULATION

Materials or combinations of materials which have air- or gas-filled pockets or void spaces that retard the transfer of heat with reasonable effectiveness are thermal insulators. Such materials may be particulate and/or fibrous, with or without binders, or may be assembled, such as multiple heat-reflecting surfaces that incorporate air- or gas-filled void spaces.

The ability of a material to retard the flow of heat is expressed by its thermal *conductivity* (for unit thickness) or *conductance* (for a specific thickness). Low values for thermal conductivity or conductance (or high thermal resistivity or resistance value) are characteristics of thermal insulation.

**TABLE 11-21 Thicknesses of Piping Insulation**

| | Insulation, nominal thickness | | | | | | | | | | | | | | | |

Heat is transferred by radiation, conduction, and convection. Radiation is the primary mode and can occur even in a vacuum. The amount of heat transferred for a given area is relative to the temperature differential and emissivity from the radiating to the absorbing surface. Conduction is due to molecular motion and occurs within gases, liquids, and solids. The tighter the molecular structure, the higher the rate of transfer. As an example, steel conducts heat at a rate approximately 600 times that of typical thermal insulation materials. Convection is due to mass motion and occurs only in fluids. The prime purpose of a thermal insulation system is to minimize the amount of heat transferred.

## INSULATION MATERIALS

**Materials** Thermal insulations are produced from many materials or combinations of materials in various forms, sizes, shapes, and thicknesses. The most commonly available materials fall within the following categories:

*Fibrous or cellular—mineral:* Alumina, asbestos, glass, perlite, rock, silica, slag, or vermiculite

*Fibrous or cellular—organic:* Cane, cotton, wood, and wood bark (cork)

*Cellular organic plastics.* Elastomer, polystyrene, polyisocyanate, polyisocyanurate, and polyvinyl acetate

*Cements:* Insulating and/or finishing

*Heat-reflecting metals (reflective):* Aluminum, nickel, stainless steel

*Available forms.* Blanket ( felt and batt), block, cements, loose fill, foil and sheet, formed or foamed in place, flexible, rigid, and semirigid.

The actual thicknesses of piping insulation differ from the nominal values. Dimensional data of ASTM Standard C585 appear in Table 11-21.

**Thermal Conductivity (*K* Factor)** Depending on the type of insulation, the thermal conductivity (*K* factor) can vary with age, manufacturer, moisture content, and temperature. Typical published values are shown in Fig. 11-65. Mean temperature is equal to the arithmetic average of the temperatures on both sides of the insulating material.

*Actual system heat loss* (or gain) will normally exceed calculated values because of projections, axial and longitudinal seams, expansion-contraction openings, moisture, workers' skill, and physical abuse.

**Finishes** Thermal insulations require an external covering ( finish) to provide protection against entry of water or process fluids, mechanical damage, and ultraviolet degradation of foamed materials. In some cases the finish can reduce the flame-spread rating and/or provide fire protection.

The finish may be a coating (paint, asphaltic, resinous, or polymeric), a membrane (coated felt or paper, metal foil, or laminate of plastic, paper, foil, or coatings), or sheet material ( fabric, metal, or plastic).

Finishes for systems operating below 2°C (35°F) must be sealed and retard vapor transmission. Those from 2°C (35°F) through 27°C (80°F) should retard vapor transmission (to prevent surface condensation), and those above 27°C (80°F) should prevent water entry and allow moisture to escape.

Metal finishes are more durable, require less maintenance, reduce heat loss, and, if uncoated, increase the surface temperature on hot systems.

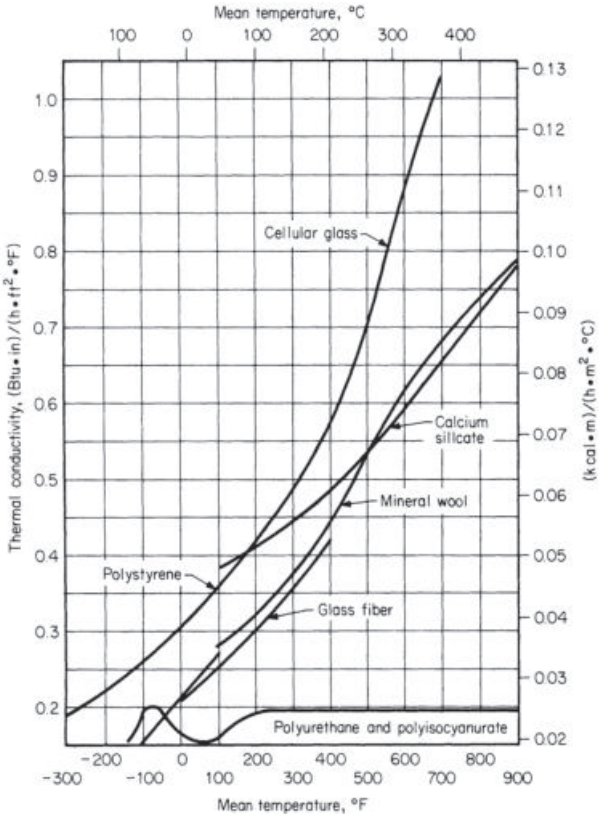

**FIG. 11-65** Thermal conductivity of insulating materials.

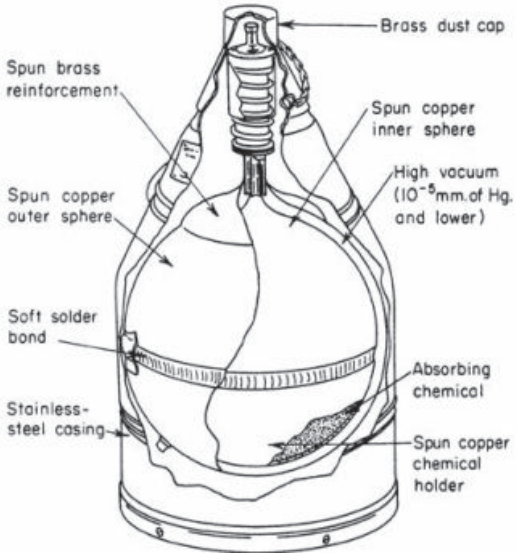

**FIG. 11-66** Dewar flask.

## SYSTEM SELECTION

A combination of insulation and finish produces the thermal insulation system. Selection of these components depends on the purpose for which the system is to be used. No single system performs satisfactorily from the cryogenic through the elevated-temperature range. Systems operating below freezing have a low vapor pressure, and atmospheric moisture is pushed into the insulation system, while the reverse is true for hot systems. Some general guidelines for system selection follow.

**Cryogenic [−273 to −101°C (−459 to −150°F)] High Vacuum** This technique is based on the Dewar flask, which is a double-walled vessel with reflective surfaces on the evacuated side to reduce radiation losses. Figure 11-66 shows a typical laboratory-size Dewar. Figure 11-67 shows a

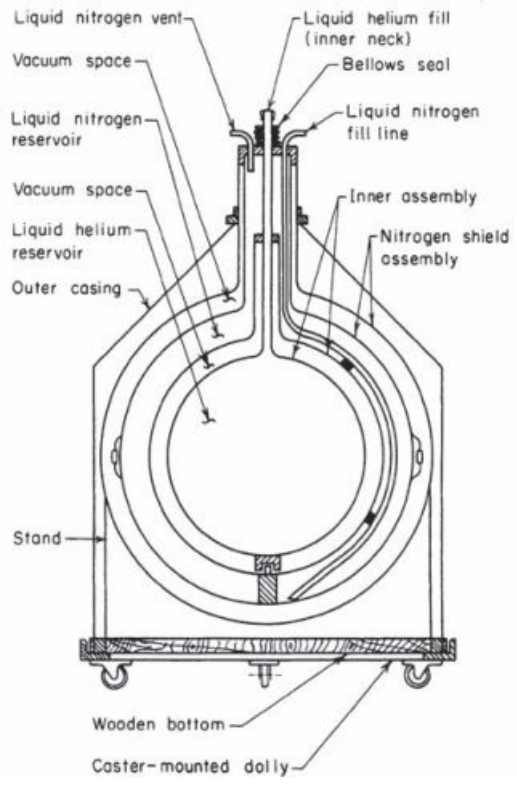

**FIG. 11-67** Hydrogen bottle.

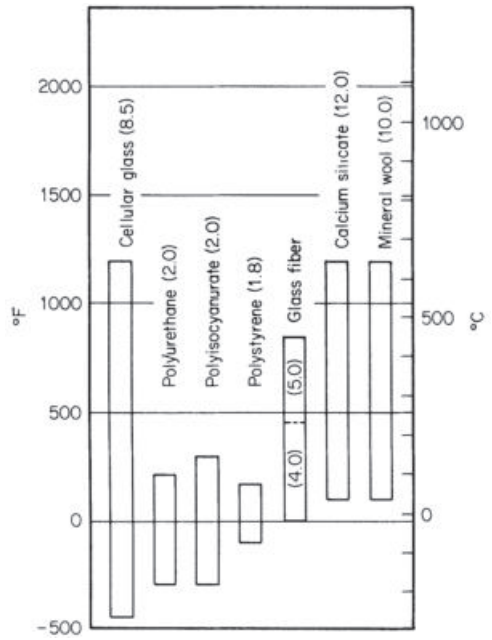

**FIG. 11-68** Insulating materials and applicable temperature ranges.

semiportable type. Radiation losses can be further reduced by filling the cavity with powders such as perlite or silica prior to pulling the vacuum.

***Multilayer*** Multilayer systems consist of series of radiation-reflective shields of low emittance separated by fillers or spacers of very low conductance and exposed to a high vacuum.

***Foamed or Cellular*** Cellular plastics such as polyurethane and polystyrene do not hold up or perform well in the cryogenic temperature range because of permeation of the cell structure by water vapor, which in turn increases the heat-transfer rate. Cellular glass holds up better and is less permeable.

**Low Temperature [−101 to −1°C (−150 to +30°F)]** Cellular glass, glass fiber, polyurethane foam, and polystyrene foam are frequently used for this service range. A vapor-retarder finish with a perm rating less than 0.02 is required. In addition, it is good practice to coat all contact surfaces of the insulation with a vapor-retardant mastic to prevent moisture migration when the finish is damaged or is not properly maintained. Closed-cell insulation should not be relied on as the vapor retarder. Hairline cracks can develop, cells can break down, glass-fiber binders are absorbent, and moisture can enter at joints between all materials.

**Moderate and High Temperature [over 2°C (36°F)]** Cellular or fibrous materials are normally used. See Fig. 11-68 for nominal temperature range. Nonwicking insulation is desirable for systems operating below 100°C (212°F).

***Other Considerations*** *Autoignition* can occur if combustible fluids are absorbed by wicking-type insulations. *Chloride stress corrosion* of austenitic stainless steel can occur when chlorides are concentrated on metal surfaces at or above approximately 60°C (140°F). The chlorides can come from sources other than the insulation. Some calcium silicates are formulated to exceed the requirements of the MIL-I-24244A specification. *Fire resistance* of insulations varies widely. Calcium silicate, cellular glass, glass fiber, and mineral wool are fire-resistant but do not perform equally under actual fire conditions. A steel jacket provides protection, but aluminum does not.

Traced pipe performs better with a nonwicking insulation which has low thermal conductivity. Underground systems are very difficult to keep dry permanently. Methods of insulation include factory-preinsulated pouring types and conventionally applied types. Corrosion can occur under wet insulation. A protective coating, applied directly to the metal surface, may be required.

## ECONOMIC THICKNESS OF INSULATION

Optimal economic insulation thickness may be determined by various methods. Two of these are the minimum total cost method and the incremental cost method (or marginal cost method). The minimum total cost method involves actual calculations of lost energy and insulation costs for each insulation thickness. The thickness producing the lowest total cost is the

optimal economic solution. The optimum thickness is determined to be the point where the last dollar invested in insulation results in exactly $1 in energy cost savings ("ETI—Economic Thickness for Industrial Insulation," Conservation Pap. 46, Federal Energy Administration, August 1976). The incremental cost method provides a simplified and direct solution for the least-cost thickness.

The total cost method does *not* in general provide a satisfactory means for making most insulation investment decisions, since an economic return on investment is required by investors and the method does not properly consider this factor. Return on investment is considered by Rubin ("Piping Insulation—Economics and Profits," in *Practical Considerations in Piping Analysis,* ASME Symposium, vol. 69, 1982, pp. 27–46). The incremental method used in this reference requires that each incremental ½ in of insulation provide the predetermined return on investment. The minimum thickness of installed insulation is used as a base for calculations. The incremental installed capital cost for each additional ½ in of insulation is determined. The energy saved for each increment is then found. The value of this energy varies directly with the temperature level [e.g., steam at 538°C (1000°F) has a greater value than condensate at 100°C (212°F)]. The final increment selected for use is required either to provide a satisfactory return on investment or to have a suitable payback period.

**Recommended Thickness of Insulation** Indoor insulation thickness appears in Table 11-22, and outdoor thickness appears in Table 11-23. These selections were based upon calcium silicate insulation with a suitable aluminum jacket. However, the variation in thickness for fiberglass, cellular glass, and rock wool is minimal. Fiberglass is available for maximum temperatures of 260, 343, and 454°C (500, 650, and 850°F). Rock wool, cellular glass, and calcium silicate are used up to 649°C (1200°F).

The tables were based upon the cost of energy at the end of the first year, a 10 percent inflation rate on energy costs, a 15 percent interest cost, and a present-worth pretax profit of 40 percent per annum on the last increment of insulation thickness. Dual-layer insulation was used for 3½-in and greater

*Aluminum-jacketed calcium silicate insulation with an emissivity factor of 0.05. To convert inches to millimeters, multiply by 25.4; to convert miles per hour to kilometers per hour, multiply by 1.609; and to convert dollars per 1 million British thermal units to dollars per 1 million kilojoules, multiply by 0.948; °C = 5/9 (°F − 32).

thicknesses. The tables and a full explanation of their derivation appear in a paper by F. L. Rubin ("Piping Insulation—Economics and Profits," in *Practical Considerations in Piping Analysis,* ASME Symposium, vol. 69, 1982, pp. 27–46). Alternatively, the selected thicknesses have a payback period on the last nominal ½-in increment of 1.44 years as presented in a later paper by Rubin ["Can You Justify More Piping Insulation?" *Hydrocarbon Process* 152–155 (July 1982)].

***Example 11-1*** For 24-in pipe at 371°C (700°F) with an energy cost of $4/million Btu, select 2-in thickness for indoor and 2½-in thickness for outdoor locations. [A 2½-in thickness would be chosen at 399°C (750°F) indoors and 3½-in outdoors.]

***Example 11-2*** For 16-in pipe at 343°C (650°F) with energy valued at $5/million Btu, select 2½-in insulation indoors [use 3-in thickness at 371°C (700°F)]. Outdoors choose 3-in insulation [use 3½-in dual-layer insulation at 538°C (1000°F)].

***Example 11-3*** For 12-in pipe at 593°C (1100°F) with an energy cost of $6/million Btu, select 3½-in thickness for an indoor installation and 4½-in thickness for an outdoor installation.

## INSTALLATION PRACTICE

**Pipe** Depending on the diameter, pipe is insulated with cylindrical half, third, or quarter sections or with flat segmental insulation. Fittings and

valves are insulated with preformed insulation covers or with individual pieces cut from sectional straight pipe insulation.

**Method of Securing** Insulation with factory-applied jacketing may be secured with adhesive on the overlap, staples, tape, or wire, depending on the type of jacket and the outside diameter. Insulation which has a separate jacket is wired or banded in place before the jacket ( finish) is applied.

**Double Layer** Pipe expansion is a significant factor at temperatures above 600°F (316°C). Above this temperature, insulation should be applied in a double layer with all joints staggered to prevent excessive heat loss and high surface temperature at joints opened by pipe expansion. This procedure also minimizes thermal stresses in the insulation.

**Finish** Covering for cylindrical surfaces ranges from asphalt-saturated or saturated and coated organic and asbestos paper, through laminates of such papers and plastic films or aluminum foil, to medium-gauge aluminum, galvanized steel, or stainless steel. Fittings and irregular surfaces may be covered with fabric-reinforced mastics or preformed metal or plastic covers. Finish selection depends on function and location. Vapor-barrier finishes may be in sheet form or a mastic, which may or may not require reinforcing, depending on the method of application; and additional protection may be required to prevent mechanical abuse and/or provide fire resistance. Criteria for selecting other finishes should include protection of insulation against water entry, mechanical abuse, or chemical attack. Appearance, life-cycle cost, and fire resistance may also be determining factors. Finish may be secured with tape, adhesive, bands, or screws. Fasteners which will penetrate vapor-retarder finishes should not be used.

**Tanks, Vessels, and Equipment** Flat, curved, and irregular surfaces such as tanks, vessels, boilers, and breechings are normally insulated with flat blocks, beveled lags, curved segments, blankets, or spray-applied insulation. Since no general procedure can apply to all materials and conditions, it is important that manufacturers' specifications and instructions be followed for specific insulation applications.

**Method of Securing** On small-diameter cylindrical vessels, the insulation may be secured by banding around the circumference. On larger cylindrical vessels, banding may be supplemented with angle-iron ledges to support the insulation and prevent slipping. On large flat and cylindrical surfaces, banding or wiring may be supplemented with various types of welded studs or pins. Breather springs may be required with bands to accommodate expansion and contraction.

**Finish** The materials are the same as for pipe and should satisfy the same criteria. Breather springs may be required with bands.

# AIR CONDITIONING

## INTRODUCTION

Air conditioning is the process of treating air to simultaneously control its temperature, humidity, cleanliness, and distribution to meet the requirements of the conditioned spaces. Detailed discussions of various air cleaning and air distribution systems can be found in the *HVAC Applications* volume of the ASHRAE Handbook (American Society of Heating, Refrigerating, and Air-Conditioning Engineers Inc., 1791 Tullie Circle NE, Atlanta, Ga.). Air conditioning applications may include human comfort as well as the maintenance of proper conditions for manufacturing, processing, or preserving a wide variety of material and equipment. Industrial environments may use localized air conditioning to maintain safe working conditions for the health and efficiency of workers, even when overall space conditions cannot be made entirely comfortable for economical or other practical reasons.

## COMFORT AIR CONDITIONING

Human comfort is influenced primarily by air temperature and humidity, local air velocity, radiant heat exchange, clothing insulation value, and metabolic rate. Chapter 48 of the 2012 ASHRAE Handbook *HVAC Applications* has an extensive discussion of noise control, another important consideration in air conditioning system design. Chapter 9 of the 2013 ASHRAE Handbook *HVAC Fundamentals* relates ambient air temperature and moisture content to human comfort, accounting for a wide variety of clothing and activity levels. It also provides results from extensive research efforts that address the impact of air velocity, radiative exchange, vertical temperature variations, age, gender, and a variety of other factors. The standard that addresses human comfort design criteria is ASHRAE Standard 55, *Thermal Environmental Conditions for Human Occupancy*. Because of the differences typically found in a given conditioned space regarding occupant manner of dress, age, gender, activity levels, and personal preferences, an 80 percent occupant comfort satisfaction rate is about the maximum that can realistically be obtained.

## INDUSTRIAL AIR CONDITIONING

Industrial buildings should be designed according to their intended use. For instance, the manufacture or processing of hygroscopic materials (e.g., paper, textiles, and foods) will require tight control of humidity. The production of many electronic components often requires clean rooms with stringent limitations on particulate matter in the air. The processing of many fresh foods requires low temperatures, while the ambient in a facility for manufacturing refractories or forged metal products might be acceptable at much higher temperatures. Chapter 14 of the 2011 ASHRAE Handbook *HVAC Applications* provides extensive tables of suggested temperature and humidity conditions for many industrial air conditioning applications as well as special space conditioning considerations that may be needed for a wide variety of industrial processes.

## VENTILATION

Odors or pollutants arising from occupants, cooking, or building material outgassing in residential or commercial buildings must be controlled to maintain a pleasant and safe living or working environment. Acceptable air quality can be maintained by localized exhaust of pollutants at their source, dilution with outdoor air that is free of such pollutants, or a combination of the two processes. Recommended outdoor air requirements for different types of nonresidential buildings are given in ASHRAE Standard 62.1, *Ventilation for Acceptable Indoor Air Quality*. Ventilation air requirements will vary because of the amounts of pollutant produced by different occupant activities and structural materials, but the ventilation rates are typically between 15 and 25 cfm of outdoor air per person for non-manufacturing commercial environments. Outdoor ventilation air requires much more energy to condition than the recirculated air from the nearly constant temperature conditioned space. Occupancy sensors (which typically detect $CO_2$ levels) are often used to reduce space conditioning costs by regulating the amount of outdoor air when space occupancy may be highly variable, such as in schools, theaters, or office complexes occupied less than 50 h per week. Local or state building codes may restrict how ventilation systems must be designed for fire or smoke control.

Industrial air conditioning systems must often address harmful gases, vapors, dusts, or fumes that are released into the work environment. These contaminants are best controlled by exhaust systems located near the source before they can enter the working environment. Dilution ventilation may be acceptable where nontoxic contaminants come from widely dispersed points. Combinations of local exhaust and dilution ventilation may provide the least expensive installation. Dilution alone may not be appropriate for cases involving toxic materials or large volumes of contaminants, or where the employees must work near the contaminant source. Chapter 32 of the ASHRAE Handbook *HVAC Applications* provides extensive information on the design and efficacy of a variety of exhaust systems. Safety codes from OSHA or local government bodies may have requirements that must take priority.

## AIR CONDITIONING EQUIPMENT

Basically, an air conditioning system consists of a fan unit that forces air through a series of devices which act upon the air to clean it, increase or decrease its temperature, and increase or decrease its water vapor content. Air conditioning equipment can generally be classified into two broad types: central (also called field-erected) and unitary.

## CENTRAL COOLING AND HEATING SYSTEMS

At least a dozen types of central air conditioning and air distribution systems are commonly used in commercial and industrial applications. They usually have large cooling and heating equipment located in a central location from which many different spaces or zones are served. Chilled-water

coils or direct-expansion refrigerant coils are most commonly used for cooling the airstream. Spray washers using chilled water are sometimes used where continuous humidity control and air cleaning are especially important. Steam or hot-water coils usually provide the heating effect where the steam or hot water is generated in a boiler. Humidification may be provided by steam injection into the airstream, target-type water nozzles, pan humidifiers, air washers, or sprayed coils. Air cleaning is most commonly provided by cleanable or throwaway filters. Electronic air cleaners may be used when a low air pressure drop is important. Air handling units are available in capacities up to 50,000 $ft^3$/min with the cooling/heating coils, filters, and humidity control systems in a prefabricated package. These units can be located on a rooftop of a low-rise structure and connected to the chiller and boiler for fast field installation with minimal design of components.

The principal types of refrigeration equipment used in central systems are reciprocating (up to 300 tons); helical rotary (up to 750 tons); absorption (up to 2000 tons); and centrifugal (up to 10,000 tons). The mechanical drives are most commonly electric motors, but larger systems may use turbines or engines depending on the system size and the availability or cost of various fuels. The heat rejected from the condensers usually calls for wet cooling towers for larger systems or air-cooled condensers for smaller units. Modular condensing units with the compressor(s), direct expansion condensers with fans, and chilled-water heat exchangers are available in capacities up to several hundred tons.

## UNITARY REFRIGERANT-BASED AIR CONDITIONING SYSTEMS

Unitary systems range from window-mounted air conditioners and heat pumps to residential and small commercial systems to commercial self-contained systems. The various types of unitary systems are described in detail in the *HVAC Systems and Equipment* volume of the ASHRAE Handbook. A detailed analysis of the proposed installation is necessary to select the type of air conditioning equipment that is best for an application. Each type of system has its own particular advantages and disadvantages. Important factors to be considered in the selection of air conditioning equipment are the required precision of temperature and humidity control; investment, owning, and operating costs; and space requirements. Building characteristics are also important, such as whether it is new or existing, multiple-story, size, available space for ducts, etc. For example, rooftop air conditioners or low-profile water source units may offer advantages for existing buildings where extensive air ducts would be difficult to install. A central system would usually be employed for large industrial processes where precise temperature and humidity control may be required.

## LOAD CALCULATION

The first step in the design of most air conditioning systems is to determine the peak load at suitably severe design operating conditions. Since both outdoor and indoor temperatures influence the size of the equipment, the designer must exercise good judgment in selecting appropriate conditions for sizing the system. The efficiency of most systems is highest at full-load conditions, so oversizing cooling equipment will increase the first cost as well as operating costs. The most severe historical local outdoor conditions should almost never be used for sizing a system, or it will operate at a small fraction of its full capacity almost all the time. ASHRAE has compiled extensive weather data for over 6000 locations around the world based on 30 years of hourly recordings at each site. Data are presented in statistical format, such as dry-bulb temperatures exceeded 2.0, 1.0, or 0.4 percent of the time; the mean coincident wet-bulb temperature at those dry-bulb conditions; wind speeds exceeded 5, 2.5, and 1.0 percent of the time, and similarly compiled dew point temperatures. These data provide a good understanding of the number of hours per year that the capacity of the system may be exceeded. The statistical data permit loads to be computed for peak sensible or latent conditions, as well as for sizing cooling towers or other humidity-sensitive equipment. Due to the size of this weather data set, an abbreviated data set is included in the ASHRAE Handbook *Fundamentals*, with the complete data set available on the CD that comes with the Handbook. In addition, the weather data have been standardized in ANSI/ASHRAE Standard 169. These data allow for different design conditions to be used for critical applications (such as a hospital) or for much less critical applications (such as an exercise gym).

After appropriate design temperature and humidity conditions are selected, the next step is to calculate the space cooling load. The sensible heat load consists of (1) transmission through the building exterior envelope; (2) solar and sky radiation through windows and skylights; (3) heat gains from infiltration of outside air; (4) heat gains from people, lights, appliances, and power equipment (including the A/C fan motors); and (5) heat from materials brought in at higher than room temperature. The latent heat load accounts for moisture (1) given off from people, appliances, and products and (2) from infiltration of outside air. The total space load is the sum of the sensible and latent loads. The total cooling equipment load consists of the total space load plus the sensible and latent loads from the outside ventilation air.

The procedure for load calculation in nonresidential buildings should account for thermal storage in the mass of the structure, occupancy patterns, and other uses of energy that affect the load. The load can be strongly dependent on the use of the building. For example, lighting, computers, and copy equipment might be major load components for an office building that will require cooling even in winter. Load calculations are now performed almost exclusively with computer software. Basic loads for simple buildings can be determined using spreadsheet software, while large buildings with variable occupancy, large internal loads, and extensive window areas usually require much more elaborate computer models. Most computer models incorporate hourly weather data so load variations and changes in equipment performance with outdoor conditions can both be properly accounted for. Chapter 19 of the ASHRAE Handbook *Fundamentals* presents a summary of the various types of computerized load models that are currently available.

# REFRIGERATION

## INTRODUCTION

Refrigeration is a process in which heat is transferred from a lower- to a higher-temperature level by doing work on a system. In some systems heat transfer is used to provide the energy to drive the refrigeration cycle. All refrigeration systems are heat pumps ("pump energy from a lower to a higher potential"). The term *heat pump* is mostly used to describe refrigeration system applications where heat rejected to the condenser is of primary interest.

There are many means to obtain the refrigerating effect, but here three are discussed: mechanical vapor refrigeration cycles, absorption, and steam-jet cycles due to their significance for industry.

**Basic Principles** Since refrigeration is the practical application of the thermodynamics, comprehending the basic principles of thermodynamics is crucial for a full understanding of refrigeration. Section 4 includes a through approach to the theory of thermodynamics. Since our goal is to understand refrigeration processes, cycles are of crucial interest.

The Carnot refrigeration cycle is reversible and consists of adiabatic (isentropic due to reversible character) compression (1-2), isothermal rejection of heat (2-3), adiabatic expansion (3-4), and isothermal addition of heat (4-1). The temperature-entropy diagram is shown in Fig. 11-69. The Carnot cycle is an unattainable ideal which serves as a standard of comparison, and it provides a convenient guide to the temperatures that should be maintained to achieve maximum effectiveness.

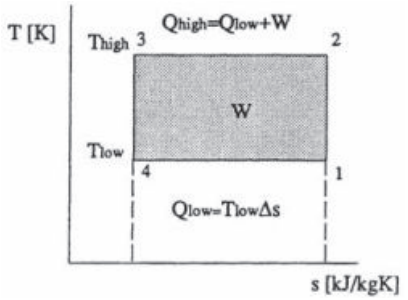

**FIG. 11-69** Temperature–entropy diagram of the Carnot cycle.

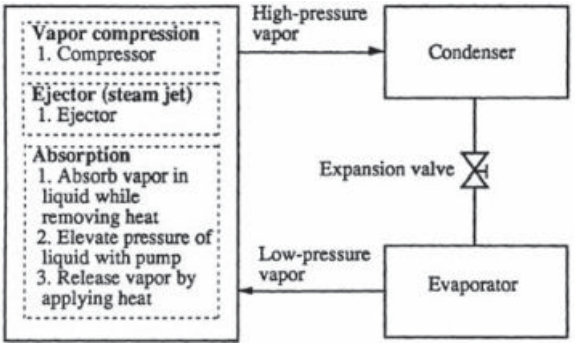

**FIG. 11-70** Methods of transforming low-pressure vapor into high-pressure vapor in refrigeration systems (*Stoecker, Refrigeration, and Air-Conditioning.*)

The measure of the system performance is the *coefficient of performance* (COP). For refrigeration applications $\text{COP}_R$ is the ratio of heat removed from the low-temperature level ($Q_{\text{low}}$) to the energy input ($W$):

$$\text{COP}_R = \frac{Q_{\text{low}}}{W} \tag{11-84}$$

For the heat pump (HP) operation, heat rejected at the high temperature $Q_{\text{high}}$ is the objective, thus

$$\text{COP}_{\text{HP}} = \frac{Q_{\text{high}}}{W} = \frac{Q+W}{W} = \text{COP}_R + 1 \tag{11-85}$$

For a Carnot cycle (where $\Delta Q = T\,\Delta s$), the COP for the refrigeration application becomes (note that $T$ is absolute temperature [K])

$$\text{COP}_R = \frac{T_{\text{low}}}{T_{\text{high}} - T_{\text{low}}} \tag{11-86}$$

and for heat pump application

$$\text{COP}_{\text{HP}} = \frac{T_{\text{high}}}{T_{\text{high}} - T_{\text{low}}} \tag{11-87}$$

The COP in real refrigeration cycles is always less than that for the ideal (Carnot) cycle, and there is constant effort to achieve this ideal value.

**Basic Refrigeration Methods** Three basic methods of refrigeration (mentioned above) use similar processes for obtaining the refrigeration effect: evaporation in the evaporator, condensation in the condenser where heat is rejected to the environment, and expansion in a flow restrictor. The main difference lies in the way compression is being done (Fig. 11-70): using mechanical work (in compressor), thermal energy (for absorption and desorption), or pressure difference (in ejector).

In Fig. 11-71 basic refrigeration systems are displayed in greater detail. A more elaborate approach is presented in the text.

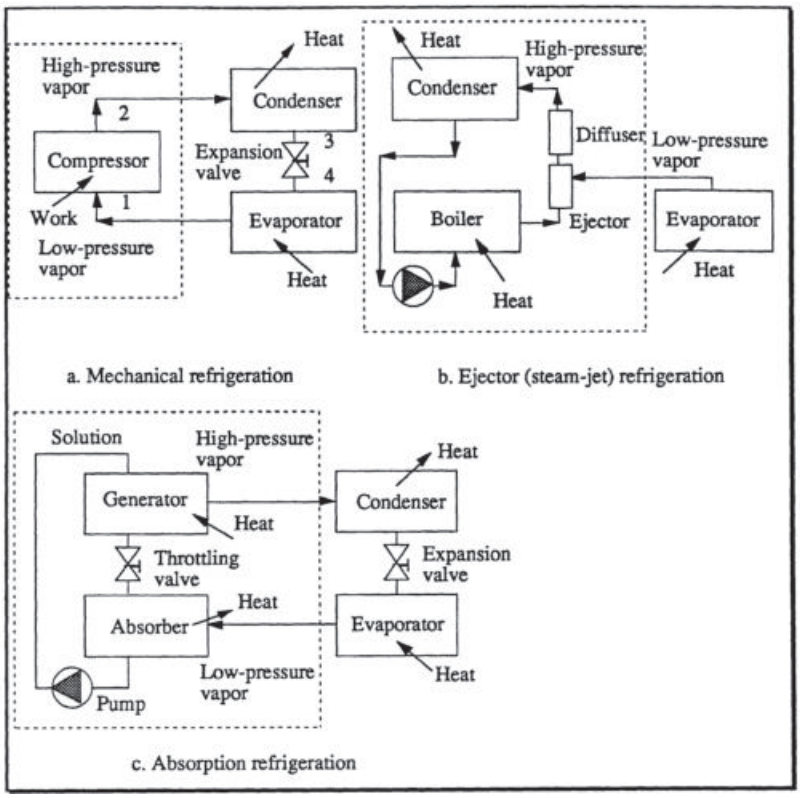

**FIG. 11-71** Basic refrigeration systems.

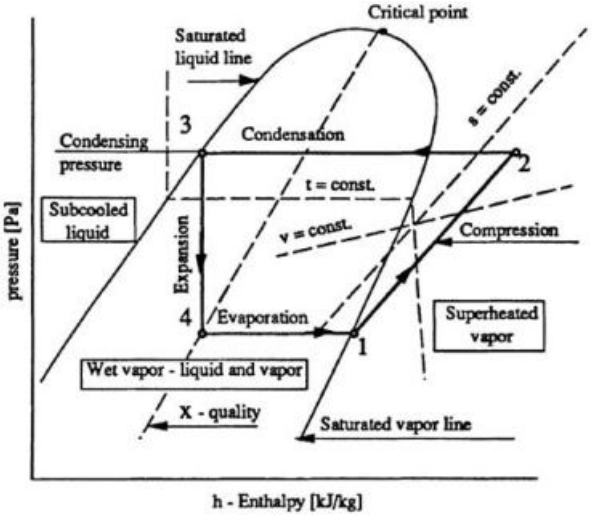

**FIG. 11-72** The pressure-enthalpy diagram for the vapor compression cycle.

## MECHANICAL REFRIGERATION (VAPOR COMPRESSION SYSTEMS)

**Vapor Compression Cycles** The most widely used refrigeration principle is vapor compression. Isothermal processes are realized through isobaric evaporation and condensation in the tubes. The standard vapor compression refrigeration cycle (counterclockwise Rankine cycle) is marked in Fig. 11-71*a* by 1, 2, 3, 4.

Work that could be obtained in a turbine is small, and a turbine is substituted for an expansion valve. For reasons of proper compressor function, wet compression is substituted for compression of dry vapor.

Although the *T–s* diagram is very useful for thermodynamic analysis, the pressure enthalpy diagram is used much more in refrigeration practice because both evaporation and condensation are isobaric processes so that the heat exchanged is equal to the enthalpy difference $\Delta Q = \Delta h$. For the ideal, isentropic compression, the work could be also presented as enthalpy difference $\Delta W = \Delta h$. The vapor compression cycle (Rankine) is presented in Fig. 11-72 in *p-h* coordinates.

Figure 11-73 presents the actual versus standard vapor-compression cycle. In reality, flow through the condenser and evaporator must be accompanied by a pressure drop. There is always some subcooling in the condenser and superheating of the vapor entering the compressor-suction line, both due to continuing process in the heat exchangers and the influence of the

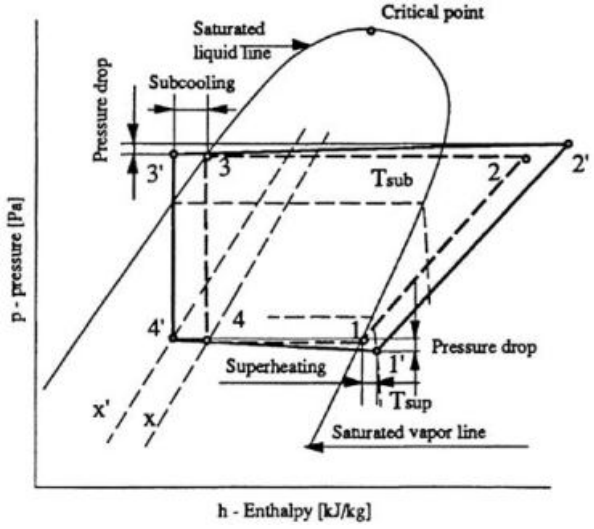

**FIG. 11-73** Actual vapor compression cycle compared with standard cycle.

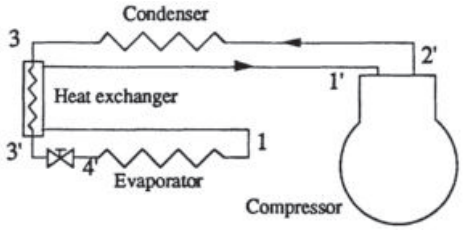

**FIG. 11-74** Refrigeration system with a heat exchanger to subcool the liquid from the condenser.

environment. Subcooling and superheating are usually desirable to ensure only liquid enters the expansion device. Superheating is recommended as a precaution against droplets of liquid being carried over into the compressor.

There are many ways to increase cycle efficiency (COP). Some of them are better suited to one, but not for the other refrigerant. Sometimes, for the same refrigerant, the impact on COP could be different for various temperatures. One typical example is the use of a liquid-to-suction heat exchanger (Fig. 11-74).

The suction vapor coming from the evaporator could be used to subcool the liquid from the condenser. Graphic interpretation in the *T–s* diagram for such a process is shown in Fig. 11-75. The result of the use of suction line heat exchanger is to increase the refrigeration effect $\Delta Q$ and to increase the work by $\Delta W$. The change in COP is then

$$\Delta\text{COP} = \text{COP}' - \text{COP} = \frac{Q + \Delta Q}{P + \Delta P - Q/P} \tag{11-88}$$

When dry, or superheated, vapor is used to subcool the liquid, the COP in R12 systems will increase, and the COP in $NH_3$ systems will decrease. For R22 systems it could have both effects, depending on the operating regime. Generally, this measure is advantageous (COP is improved) for fluids with high specific heat of liquid (less inclined saturated-liquid line on the *p-h* diagram), small heat of evaporation $h_{fg}$ when vapor-specific heat is low (isobars in superheated regions are steep) and when the difference between evaporation and condensation temperatures is high. Measures to increase COP should be studied for every refrigerant. Sometimes the purpose of the suction-line heat exchanger is not only to improve the COP, but also to ensure that only the vapor reaches the compressor, particularly in the case of a malfunctioning expansion valve.

The system shown in Fig. 11-74 is direct expansion where dry or slightly superheated vapor leaves the evaporator. Such systems are predominantly used in small applications because of their simplicity and light weight. For the systems where efficiency is crucial (large industrial systems), recirculating systems (Fig. 11-76) are more appropriate.

Ammonia refrigeration plants are almost exclusively built as recirculating systems. The main advantage of recirculating versus direct expansion systems is better utilization of evaporator surface area. The diagram reflecting the influence of quality on the local heat-transfer coefficients is shown

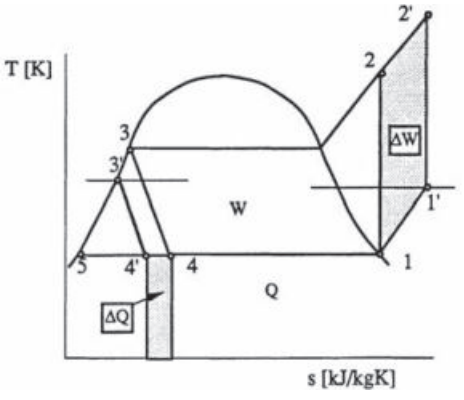

**FIG. 11-75** Refrigeration system with a heat exchanger to subcool the liquid from the condenser.

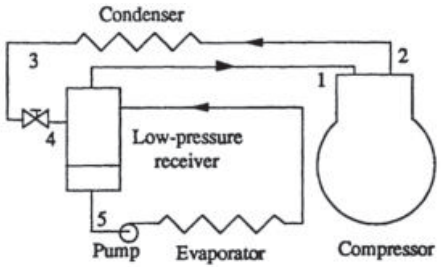

**FIG. 11-76** Recirculation system.

in Fig. 11-89. It is clear that heat-transfer characteristics will be better if the outlet quality is lower than 1. Circulation could be achieved either by pumping (mechanical or gas) or by using gravity (thermosyphon effect: density of pure liquid at the evaporator entrance is higher than density of the vapor-liquid mixture leaving the evaporator). The circulation ratio (ratio of actual mass flow rate to the evaporated mass flow rate) is higher than 1 and up to 5. Higher values are not recommended due to a small increase in heat-transfer rate for a significant increase in pumping costs.

**Multistage Systems** When the evaporation and condensing pressure (or temperature) difference is large, it is prudent to separate compression into two stages. The use of multistage systems opens up the opportunity to use flash-gas removal and intercooling as measures to improve system performance. One typical two-stage system with two evaporating temperatures and both flash-gas removal and intercooling is shown in Fig. 11-77. The purpose of the flash-tank intercooler is to (1) separate vapor created in the expansion process, (2) cool superheated vapor from compressor discharge, and (3) eventually separate existing droplets at the exit of the medium-temperature evaporator. The first measure will decrease the size of the low-stage compressor because it will not wastefully compress the portion of flow which cannot perform the refrigeration, and the second measure will decrease the size of the high-stage compressor due to lowering the specific volume of the vapor from the low-stage compressor discharge, positively affecting operating temperatures of the high-stage compressor due to the cooling effect.

If the refrigerating requirement at a low-evaporating temperature is $Q_l$ and at the medium level is $Q_m$, then the mass flow rates ($m_1$ and $m_m$, respectively) needed are

$$m_1 = \frac{Q_l}{h_1 - h_8} = \frac{Q_l}{h_1 - h_7} \tag{11-89}$$

$$m_m = \frac{Q_m}{h_3 - h_6} \tag{11-90}$$

The mass flow rate at the flash-tank inlet $m_i$ consists of three components ($m_i = m_1 + m_{sup} + m_{flash}$):

$m_1$ = liquid at $p_m$ feeding low-temperature evaporator

$m_{sup}$ = liquid at $p_m$ to evaporate in flash tank to cool superheated discharge

$m_{flash}$ = flashed refrigerant, used to cool remaining liquid

The vapor component is

$$m_{flash} = x_m \times m_i \tag{11-91}$$

and the liquid component is

$$(1 - x_m) \times m_i = m_1 + m_{sup} \tag{11-92}$$

The liquid part of flow to cool superheated compressor discharge is determined by

$$m_{sup} = \frac{Q_l}{h_1 - h_8} \times \frac{h_2 - h_3}{h_3 - h_7} = m_1 \times \frac{h_2 - h_3}{h_{fgm}} \tag{11-93}$$

Since the quality $x_m$ is

$$x_m = \frac{h_6 - h_7}{h_3 - h_7} \tag{11-94}$$

The mass flow rate through the condenser and high-stage compressor $m_h$ is finally

$$m_h = m_m + m_i \tag{11-94a}$$

The optimum intermediate pressure for the two-stage refrigeration cycle is determined as the geometric mean between evaporation pressure $p_l$ and condensing pressure $p_h$ (Fig. 11-78):

$$p_m = \sqrt{p_h p_l} \tag{11-95}$$

based on equal pressure ratios for low- and high-stage compressors. The optimum interstage pressure is slightly higher than the geometric mean of the suction and the discharge pressures, but, due to the very flat optimum of power versus interstage pressure relation geometric mean, it is widely accepted for determining the intermediate pressure. The required pressure of the intermediate-level evaporator may dictate interstage pressure other than determined as optimal.

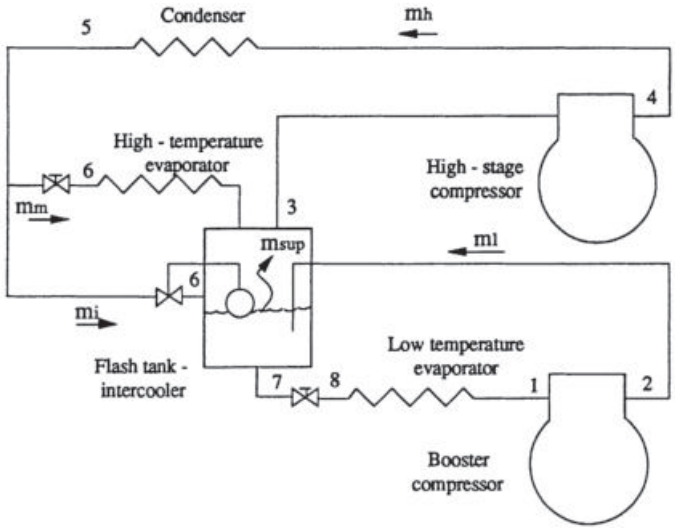

**FIG. 11-77** Typical two-stage system with two evaporating temperatures, flash-gas removal, and intercooling.

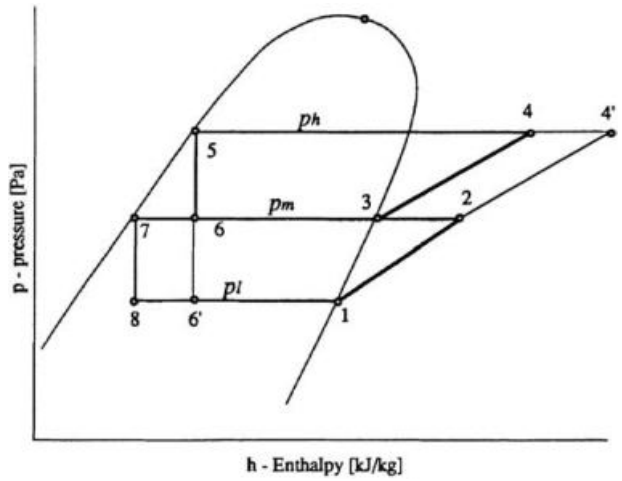

**FIG. 11-78** Pressure–enthalpy diagram for typical two-stage system with two evaporating temperatures, flash-gas removal, and intercooling.

Two-stage systems should be seriously considered when the evaporating temperature is below −20°C. Such designs will save on power and reduce compressor discharge temperatures, but will increase the initial cost.

**Cascade System** This is a reasonable choice in cases where the evaporating temperature is very low (below −60°C). When condensing pressures are to be in the rational limits, the same refrigerant has a high specific volume at very low temperatures, requiring a large compressor. The evaporating pressure may be below atmospheric, which could cause moisture and air infiltration into the system if there is a leak. In other words, when the temperature difference between the medium that must be cooled and the environment is too high to be served with one refrigerant, it is wise to use different refrigerants in the high and low stages. Figure 11-79 shows a cascade system schematic diagram. There are basically two independent systems linked via a heat exchanger: the evaporator of the high-stage system and the condenser of the low-stage system.

## EQUIPMENT

**Compressors** These could be classified by one criterion (the way the increase in pressure is obtained) as positive-displacement and dynamic types, as shown in Fig. 11-80 (see Sec. 10 for drawings and mechanical description of the various types of compressors). *Positive-displacement compressors* (PDCs) are the machines that increase the pressure of the vapor by reducing the volume of the chamber. Typical PDCs are reciprocating (in a variety of types) or rotary as screw (with one and two rotors), vane, scroll, and so on. Centrifugal compressors or turbocompressors are machines where the pressure is raised, converting some of the kinetic energy obtained by a rotating mechanical element which continuously adds angular momentum to a steadily flowing fluid, similar to a fan or pump.

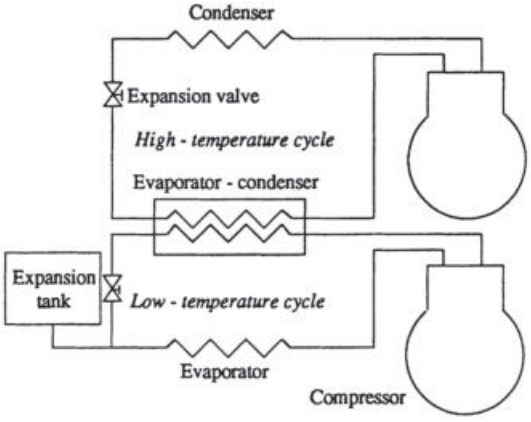

**FIG. 11-79** Cascade system.

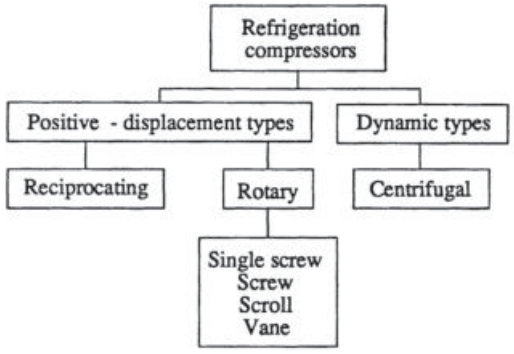

**FIG. 11-80** Types of refrigeration compressors.

Generally, reciprocating compressors dominate in the range up to 300-kW refrigeration capacity. Centrifugal compressors are more accepted for the range over 500 kW, while screw compressors are in between with a tendency to go toward smaller capacities. The vane and the scroll compressors are finding their places primarily in very low-capacity range (domestic refrigerators and air conditioners), although vane compressors could be found in industrial compressors. Frequently, screw compressors operate as boosters, for the base load, while reciprocating compressors accommodate the variation of capacity in the high stage. The major reason for such design is the advantageous operation of screw compressors near full load and in design conditions, while reciprocating compressors seem to have better efficiencies at part-load operation than screw compressors.

Using other criteria, compressors are classified as *open, semihermetic* (*accessible*), or *hermetic.* Open type is characterized by shaft extension out of the compressor, where it is coupled to the driving motor. When the electric motor is in the same housing with the compressor mechanism, it could be either hermetic or accessible (semihermetic). Hermetic compressors have welded enclosures, not designed to be repaired, and are generally manufactured for smaller capacities (seldom over 30 kW), while semihermetic or an accessible type is located in the housing which is tightened by screws. Semihermetic compressors have all the advantages of hermetic (no sealing of moving parts, e.g., no refrigerant leakage at the seal shaft, no external motor mounting, no coupling alignment) and could be serviced, but it is more expensive.

Compared to other applications, refrigeration capacities in the chemical industry are usually high. That leads to wide use of centrifugal, screw, or high-capacity rotary compressors. Most centrifugal and screw compressors use economizers to minimize power and suction volume requirements. Generally, there is far greater use of open-drive type of compressors in the chemical plants than in air conditioning, commercial, or food refrigeration. Very frequently, compressor lube oil systems are provided with auxiliary oil pumps, filters, coolers, and other equipment to permit maintenance and repair without shutdown.

**Positive-Displacement Compressors** *Reciprocating compressors* are built in different sizes (up to about 1-MW refrigeration capacity per unit). Modern compressors are high-speed, mostly direct-coupled, single-acting, from 1 to mostly 8, and occasionally up to 16 cylinders.

Two characteristics of compressors for refrigeration are the most important: refrigerating capacity and power. Typical characteristics are as presented in Fig. 11-81.

Refrigerating capacity $Q_e$ is the product of the mass flow rate of refrigerant $m$ and the refrigerating effect $R$ which is (for isobaric evaporation) $R = h_{\text{evaporator outlet}} - h_{\text{evaporator inlet}}$. Power $P$ required for the compression, necessary for the motor selection, is the product of mass flow rate $m$ and work of compression $W$. The latter is, for the isentropic compression, $W = h_{\text{discharge}} - h_{\text{suction}}$. Both of these characteristics could be calculated for the ideal (without losses) and for the actual compressor. Ideally, the mass flow rate is equal to the product of the compressor displacement $V_i$ per unit time and the gas density $\rho$: $m = V_i \times \rho$. The compressor displacement rate is the volume swept through by the pistons (product of the cylinder number $n$ and volume of cylinder $V$ = stroke $\times\ d^2\pi/4$) per second. In reality, the actual compressor delivers less refrigerant.

The ratio of the actual flow rate (entering compressor) to the displacement rate is the volumetric efficiency $\eta_{va}$. The volumetric efficiency is less than unity due to reexpansion of the compressed vapor in clearance volume, pressure drop (through suction and discharge valves, strainers, manifolds, etc.), internal gas leakage (through the clearance between piston rings and cylinder walls, etc.), valve inefficiencies, and expansion of the vapor in the suction cycle caused by the heat exchanged (hot cylinder walls, oil, motor, etc.).

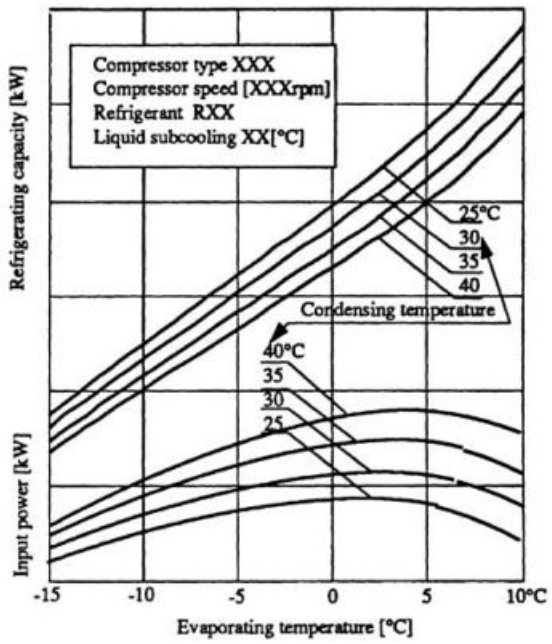

**FIG. 11-81** Typical capacity and power-input curves for reciprocating compressor.

Similar to volumetric efficiency, isentropic (adiabatic) efficiency $\eta_a$ is the ratio of the work required for isentropic compression of the gas to work input to the compressor shaft. The adiabatic efficiency is less than 1 mainly due to pressure drop through the valve ports and other restricted passages and the heating of the gas during compression.

Figure 11-82 presents the compression on a pressure-volume diagram for an ideal compressor with clearance volume (thin lines) and actual compressor (thick lines). Compression in an ideal compressor without clearance is extended using dashed lines to the points $I_d$ (end of discharge), line $I_d - I_s$ (suction), and $I_s$ (beginning of suction). The area surrounded by the lines of compression, discharge, reexpansion, and intake presents the work needed for compression. The actual compressor only appears to demand less work for compression due to smaller area in the $p$-$V$ diagram. The mass flow rate for an ideal compressor is higher, which cannot be seen in the diagram. In reality, an actual compressor will have adiabatic compression and reexpansion and higher discharge and lower suction pressures due to pressure drops in valves and lines. The slight increase in the pressure at the beginning of the discharge and suction is due to forces needed to initially open valves.

When the suction pressure is lowered, the influence of the clearance will increase, causing in the extreme cases the entire volume to be used for reexpansion, which drives the volumetric efficiency to zero.

There are various options for capacity control of reciprocating refrigeration compressors:

1. Open the suction valves by some external force (oil from the lubricating system, discharge gas, electromagnets, ...).
2. Gas bypass: return the discharge gas to suction (within the compressor or outside the compressor).
3. Control the suction pressure by throttling in the suction line.
4. Control the discharge pressure.
5. Add reexpansion volume.
6. Change the stroke.
7. Change the compressor speed.

The first method is used most frequently. The next preference is for the last method, mostly used in small compressors due to problems with speed control of electric motors. Other means of capacity control are very seldom utilized due to thermodynamic inefficiencies and design difficulties. Energy losses in a compressor, when capacity regulation is provided by lifting the suction valves, are due to friction of gas flowing into and out of the unloaded cylinder. This is shown in Fig. 11-83 where the comparison is made for ideal partial-load operation, reciprocating, and screw compressors.

Rotary compressors are also PDC types, but where refrigerant flow rotates during compression. Unlike the reciprocating type, rotary compressors have a built-in volume ratio which is defined as the volume in the cavity when the suction port is closed ($V_s = m \times \upsilon_s$) over the volume in the cavity when the discharge port is uncovered ($V_d = m \times \upsilon_d$). The built-in volume ratio determines for a given refrigerant and conditions the pressure ratio, which is

$$\frac{p_d}{p_s} = \left(\frac{\upsilon_s}{\upsilon_d}\right)^n \tag{11-96}$$

where $n$ represents the politropic exponent of compression.

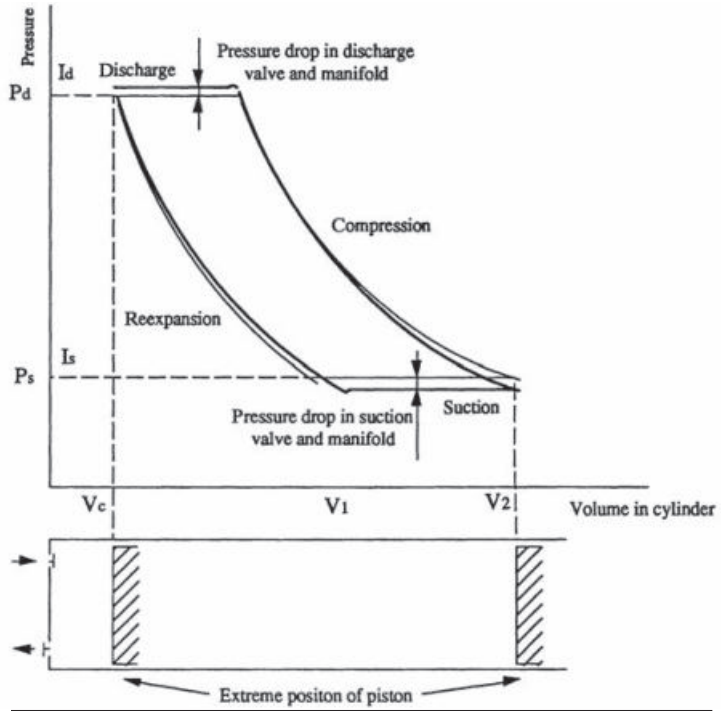

**FIG. 11-82** Pressure–volume diagram of an ideal (thin line) and actual (thick line) reciprocating compressor.

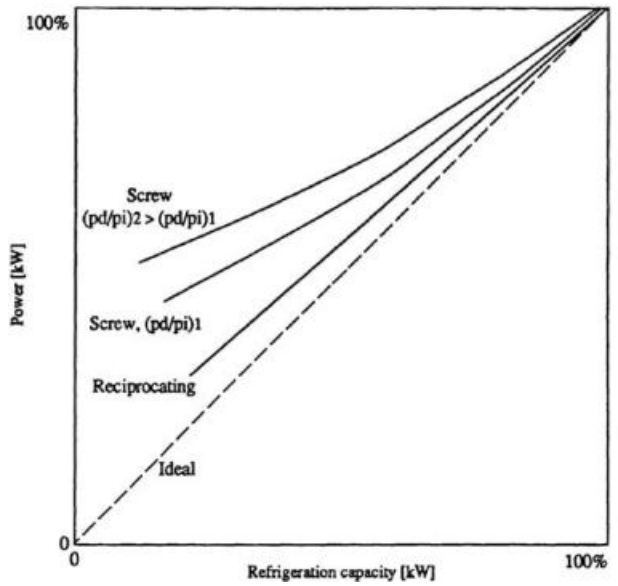

**FIG. 11-83** Typical power-refrigeration capacity data for different types of compressors during partial unloaded operation.

In other words, in a reciprocating compressor the discharge valve opens when the pressure in the cylinder is slightly higher than the pressure in the high-pressure side of the system, while in rotary compressors the discharge pressure will be established only by inlet conditions ($p_s$, $V_s$) and the built-in volume ratio regardless of the system discharge pressure. Very seldom are the discharge and system (condensing) pressures equal, causing the situation shown in Fig. 11-84. When condensing pressure $p$ is lower than discharge $p_d$, shown as case (*a*), "overcompression" will cause energy losses presented by the horn on the diagram. If the condensing pressure is higher, in the moment when the discharge port uncovers there will be flow of refrigerant backward into the compressor, causing losses shown in Fig. 11-84*b*; and the last stage will be only discharge without compression. The case when the compressor discharge pressure is equal to the condensing pressure is shown in Fig. 11-84*c*.

*Double helical rotary (twin) screw compressors* consist of two mating, helically grooved rotors (male and female) with asymmetric profile, in a housing formed by two overlapped cylinders, with inlet and outlet ports. Developed relatively recently (in the 1930s), the first twin-screw compressors were used for air, and later (in the 1950s) became popular for refrigeration. Screw compressors have some advantages over reciprocating compressors ( fewer moving parts and greater compactness) but also some drawbacks (lower efficiency at off-design conditions, as discussed above, higher manufacturing cost due to complicated screw geometry, large separators and coolers for oil which is important as a sealant). Figure 11-85 shows the oil circuit of a screw compressor. Oil cooling could be provided by water, glycol, or refrigerant either in the heat exchanger utilizing thermosyphon effect or using the direct expansion concept.

To overcome some inherent disadvantages, screw compressors have been initially used predominantly as booster (low-stage) compressors, and following development in capacity control and decreasing prices, they are now widely used for high-stage applications. There are several methods for capacity regulation of screw compressors. One is variable-speed drive, but a more economical first-cost concept is a slide valve that is used in some form by practically all screw compressors.

The slide is located in the compressor casting below the rotors, allowing internal gas recirculation without compression. The slide valve is operated by a piston located in a hydraulic cylinder and actuated by high-pressure oil from both sides. When the compressor is started, the slide valve is fully open and the compressor is unloaded. To increase capacity, a solenoid valve on the hydraulic line opens, moving the piston in the direction of increasing capacity. To increase part-load efficiency, the slide valve is designed to consist of two parts, one traditional slide valve for capacity regulation and other for built-in volume adjustment.

*Single-screw compressors* are a newer design (early 1960s) compared to twin-screw compressors, and are manufactured in the range of capacity from 100 kW to 4 MW. The compressor screw is cylindrical with helical grooves mated with two star wheels (gate rotors) rotating in opposite direction from each other. Each tooth acts as the piston in the rotating "cylinder" formed by the screw flute and cylindrical main-rotor casting.

As compression occurs concurrently in both halves of the compressor, radial forces are oppositely directed, resulting in negligible net-radial loads on the rotor bearings (unlike twin-screw compressors), but there are some loads on the star wheel shafts.

*Scroll compressors* are currently used in relatively small-size installations, predominantly for residential air conditioning (up to 50 kW). They are recognized for low-noise operation. Two scrolls ( freestanding, involute spirals bounded on one side by a flat plate) facing each other form a closed volume while one moves in a controlled orbit around a fixed point on the other fixed scroll.

The suction gas which enters from the periphery is trapped by the scrolls. The closed volumes move radially inward until the discharge port is reached, when vapor is pressed out. The orbiting scroll is driven by a short-throw crank mechanism. As in screw compressors, internal leakage should be kept low, and it occurs in gaps between cylindrical surfaces and between the tips of the involute and the opposing scroll baseplate.

Similar to the screw compressor, the scroll compressor is a constant-volume-ratio machine. Losses occur when operating conditions of the compressor do not match the built-in volume ratio (see Fig. 11-84).

*Vane compressors* are used in small, hermetic units, but sometimes as booster compressors in industrial applications. Two basic types are the *fixed* (roller) or single-vane type and the *rotating* or multiple-vane type. In the single-vane type, the rotor (called *roller*) is eccentrically placed in the cylinder so these two are always in contact. The contact line makes the first separation between the suction and discharge chambers while the vane (spring-loaded divider) makes the second. In the multiple-vane compressors, the rotor and the cylinder are not in the contact. The rotor has two or more sliding vanes which are held against the cylinder by centrifugal force. In the vane rotary compressors, no suction valves are needed. Since the gas enters the compressor continuously, gas pulsations are at a minimum. Vane compressors have a high volumetric efficiency because of the small clearance volume and consequent low reexpansion losses. Rotary vane compressors have a low weight-to-displacement ratio, which makes them suitable for transport applications.

**Centrifugal Compressors** These are sometimes called *turbocompressors* and mostly serve refrigeration systems in the capacity range of 200 to 10,000 kW. The main component is a spinning impeller wheel, backward-curved, which imparts energy to the gas being compressed. Some of the kinetic energy converts into pressure in a volute. Refrigerating centrifugal compressors are predominantly multistage, compared to other turbocompressors, which produce high-pressure ratios.

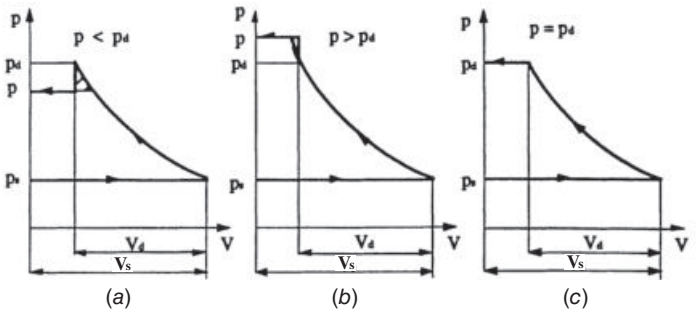

**FIG. 11-84** Matching compressor built-in pressure ratio with actual pressure difference.

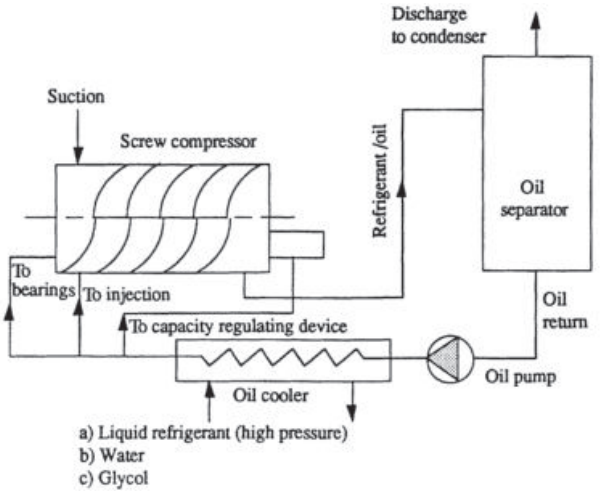

**FIG. 11-85** Oil cooling in a screw compressor.

The torque $T$ (N·m) the impeller ideally imparts to the gas is

$$T = m\,(u_{\text{tang.out}}\,r_{\text{out}} - u_{\text{tang.in}}\,r_{\text{in}}) \tag{11-97}$$

where $m$ (kg/s) = mass flow rate
$r_{\text{out}}$ (m) = radius of exit of impeller
$r_{\text{in}}$ (m) = radius of entrance of impeller
$u_{\text{tang.out}}$ (m/s) = tangential velocity of refrigerant leaving impeller
$u_{\text{tang.in}}$ (m/s) = tangential velocity of refrigerant entering impeller

When refrigerant enters essentially radially, $u_{\text{tang.in}} = 0$ and torque becomes

$$T = m \times u_{\text{tang.out}} \times r_{\text{out}} \tag{11-98}$$

The power $P$ (in watts) is the product of torque and rotative speed ω [l/s] and so is

$$P = T \times \omega = m \times u_{\text{tang.out}} \times r_{\text{out}} \times \omega \tag{11-99}$$

which for $u_{\text{tang.ou}} = r_{\text{out}} \times \omega$ becomes

$$P = m \times u^2_{\text{tang.out}} \tag{11-100}$$

or for isentropic compression

$$P = m \times \Delta h \tag{11-101}$$

The performance of a centrifugal compressor (discharge to suction-pressure ratio versus the flow rate) for different speeds is shown in Fig. 11-86.

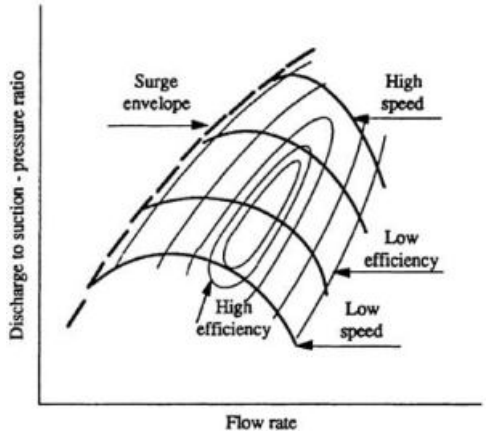

**FIG. 11-86** Performance of the centrifugal compressor.

Lines of constant efficiencies show the maximum efficiency. Unstable operation sequence, called *surging*, occurs when compressors fail to operate in the range left of the surge envelope. It is characterized by noise and wide fluctuations of load on the compressor and the motor. The period of the cycle is usually 2 to 5 s, depending upon the size of the installation.

The capacity could be controlled by (1) adjusting the prerotation vanes at the impeller inlet, (2) varying the speed, (3) varying the condenser pressure, and (4) bypassing discharge gas. The first two methods are predominantly used.

**Condensers** These are heat exchangers that convert refrigerant vapor to a liquid. Heat is transferred in three main phases: (1) desuperheating, (2) condensing, and (3) subcooling. In reality condensation occurs even in the superheated region, and subcooling occurs in the condensation region. Three main types of refrigeration condensers are air-cooled, water-cooled, and evaporative.

Air-cooled condensers are used mostly in air conditioning and for smaller refrigeration capacities. The main advantage is the availability of cooling medium (air), but heat-transfer rates for the air side are far below values when water is used as a cooling medium. Condensation always occurs inside tubes, while the air side uses extended surface (fins).

The most common types of water-cooled refrigerant condensers are (1) shell-and-tube, (2) shell-and-coil, (3) tube-in-tube, and (4) brazed-plate. *Shell-and-tube* condensers are built up to 30-MW capacity. Cooling water flows through the tubes in a single-pass or multipass circuit. Fixed-tubesheet and straight-tube construction are common. Horizontal layout is typical, but sometimes vertical is used. Heat-transfer coefficients for the vertical types are lower due to poor condensate drainage, but less water of lower purity can be utilized. Condensation always occurs on the tubes, and often the lower portion of the shell is used as a receiver. In *shell-and-coil* condensers, water circulates through one or more continuous or assembled coils contained within the shell while refrigerant condenses outside. The tubes cannot be mechanically cleaned or replaced. *Tube-in-tube* condensers could be found in versions where condensation occurs either in the inner tube or in the annulus. Condensing coefficients are more difficult to predict, especially in the cases where tubes are formed in spiral. Mechanical cleaning is more complicated, sometimes impossible, and tubes are not replaceable. *Brazed-plate* condensers are constructed of plates brazed together to make up an assembly of separate channels. The plates are typically stainless steel, wave-style corrugated, enabling high heat-transfer rates. Performance calculation is difficult, with very few correlations available. The main advantage is the highest performance/volume (mass) ratio and the lowest refrigerant charge. The last mentioned advantage seems to be the most important feature for many applications where minimization of charge inventory is crucial.

*Evaporative condensers* (Fig. 11-87) are widely used due to lower condensing temperatures than in the air-cooled condensers and also lower than the water-cooled condenser combined with the cooling tower. Water demands are far lower than for water-cooled condensers. The chemical industry uses shell-and-tube condensers widely, although the use of air-cooled condensing equipment and evaporative condensers is on the increase.

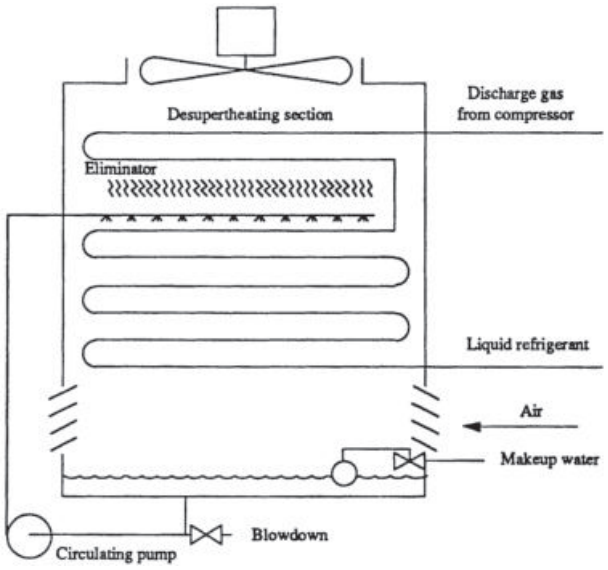

**FIG. 11-87** Evaporative condenser with desuperheating coil.

Generally, cooling water is of a lower quality than normal, having also higher mud and silt content. Sometimes even replaceable copper tubes in shell-and-tube heat exchangers are required. It is advisable to use cupronickel instead of copper tubes (when water is high in chlorides) and to use conservative water-side velocities (less than 2 m/s for copper tubes).

Evaporative condensers are used quite extensively. In most cases, commercial evaporative condensers are not totally suitable for chemical plants due to the hostile atmosphere, which usually abounds in vapor and dusts that can cause either chemical (corrosion) or mechanical problems (plugging of spray nozzles).

Air-cooled condensers are similar to evaporative ones in that the service dictates the use of either more expensive alloys in the tube construction or conventional materials of greater wall thickness.

Heat rejected in the condenser $Q_{Cd}$ consists of heat absorbed in the evaporator $Q_{Eevap}$ and energy $W$ supplied by the compressor:

$$Q_{Cd} = Q_{Eevap} + W \tag{11-102}$$

For the actual systems, compressor work will be higher than for ideal systems for the isentropic efficiency and other losses. In the case of hermetic or accessible compressors where an electric motor is cooled by the refrigerant, condenser capacity should be

$$Q_{Cd} = Q_{Eevap} + P_{EM} \tag{11-103}$$

It is common that compressor manufacturers provide data for the ratio of the heat rejected at the condenser to the refrigeration capacity, as shown in Fig. 11-88. The solid line represents data for the open compressors while the dotted line represents the hermetic and accessible compressors. The difference between solid and dotted line is due to all losses (mechanical and electrical in the electric motor). Condenser design is based on the value

$$Q_{Cd} = Q_{Eevap} \times \text{heat rejection ratio} \tag{11-104}$$

Thermal and mechanical design of heat exchangers (condensers and evaporators) is presented earlier in this section.

**Evaporators** These are heat exchangers where refrigerant is evaporated while cooling the product, fluid, or body. Refrigerant could be in direct contact with the body that is being cooled, or some other medium could be used as secondary fluid. Mostly air, water, and antifreeze are fluids that are cooled. Design is strongly influenced by the application. Evaporators for air cooling will have in-tube evaporation of the refrigerant, while liquid chillers could have refrigerant evaporation inside or outside the tube. The heat-transfer coefficient for evaporation inside the tube (versus length or quality) is shown in Fig. 11-89. Fundamentals of the heat transfer in evaporators, as well as design aspects, are presented in Sec. 11. We point out only some specific aspects of refrigeration applications.

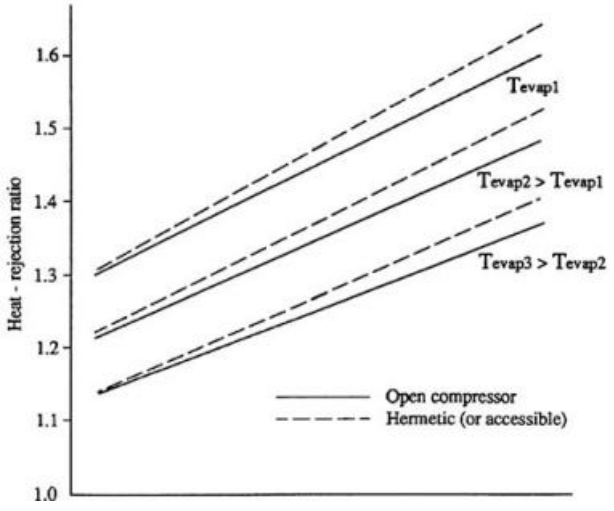

**FIG. 11-88** Typical values of the heat rejection ratio of the heat rejected at the condenser to the refrigerating capacity.

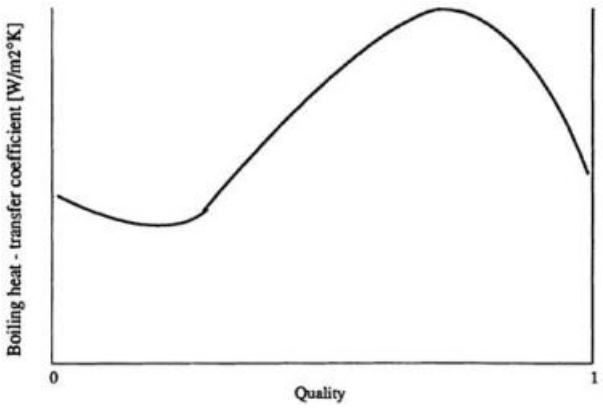

**FIG. 11-89** Heat-transfer coefficient for boiling inside the tube.

Refrigeration evaporators could be classified according to the method of feed as either direct (dry) expansion or flooded (liquid overfeed). In dry expansion the evaporator's outlet is dry or slightly superheated vapor. This limits the liquid feed to the amount that can be completely vaporized by the time it reaches the end of the evaporator. In the liquid overfeed evaporator, the amount of liquid refrigerant circulating exceeds the amount evaporated by the circulation number. Decision on the type of the system to be used is one of the first in the design process. A direct-expansion evaporator is generally applied in smaller systems where compact design and low first costs are crucial. Control of the refrigerant mass flow is then obtained by either a thermoexpansion valve or a capillary tube. Figure 11-89 suggests that the evaporator surface is the most effective in the regions with quality that is neither low nor high. In dry-expansion evaporators, inlet qualities are 10 to 20 percent, but when controlled by the thermoexpansion valve, vapor at the outlet is not only dry, but even superheated.

In recirculating systems, saturated liquid ($x = 0$) is entering the evaporator. Either the pump or gravity will deliver more refrigerant liquid than will evaporate, so outlet quality could be lower than 1. The ratio of refrigerant flow rate supplied to the evaporator overflow rate of refrigerant vaporized is the circulation ratio $n$. When $n$ increases, the coefficient of heat transfer will increase due to the wetted outlet of the evaporator and the increased velocity at the inlet (Fig. 11-90). In the range of $n = 2$ to 4, the overall $U$ value for air cooler increases roughly by 20 to 30 percent compared to the direct-expansion case. Circulation rates higher than 4 are not efficient.

The price for an increase in heat-transfer characteristics is a more complex system with more auxiliary equipment: low-pressure receivers, refrigerant pumps, valves, and controls. Liquid refrigerant is predominantly pumped by mechanical pumps; however, sometimes gas at condensing pressure is used for pumping, in the variety of concepts.

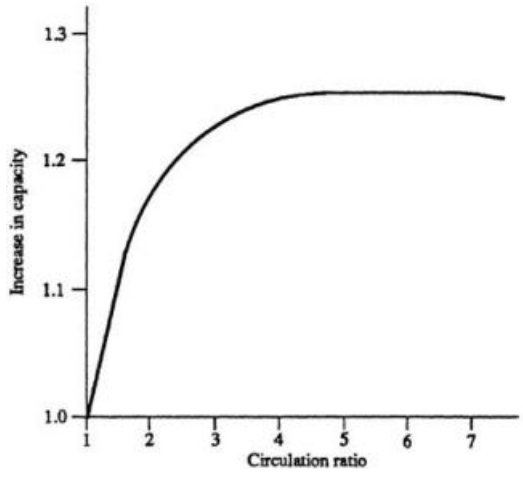

**FIG. 11-90** Effect of circulation ratio on the overall heat-transfer coefficient of an air-cooling coil.

The important characteristics of the refrigeration evaporators is the presence of the oil. The system is contaminated with oil in the compressor, in spite of reasonably efficient oil separators. Some systems will recirculate oil, when miscible with refrigerant, returning it to the compressor crankcase. This is found mostly in the systems using halocarbon refrigerants. Although oils that are miscible with ammonia exist, immiscible oils are predominantly used. This inhibits the ammonia systems from recirculating the oil. In systems with oil recirculation when halocarbons are used, special consideration should be given to proper sizing and layout of the pipes. Proper pipeline configuration, slopes, and velocities (to ensure oil circulation under all operating loads) are essential for good system operation. When refrigerant is lighter than the oil in systems with no oil recirculation, oil will be at the bottom of every volume with a top outlet. Then oil must be drained periodically to avoid decreasing the performance of the equipment.

It is essential for proper design to have the data for refrigerant–oil miscibility under all operating conditions. Some refrigerant–oil combinations will always be miscible, others always immiscible, but still others will have both characteristics, depending on the temperatures and pressures applied. Defrosting is the important issue for evaporators which are cooling air below freezing. Defrosting is done periodically, actuated predominantly by time relays, but other frost indicators are used (temperature, visual, or pressure-drop sensors). Defrost technique is determined mostly by fluids available and tolerable complexity of the system. Defrosting is done by the following mechanisms when the system is off:

- Hot (or cool) refrigerant gas (the predominant method in industrial applications)
- Water (defrosting from the outside, unlike hot-gas defrost)
- Air (only when room temperature is above freezing)
- Electricity ( for small systems where hot-gas defrost will be too complex and water is not available)
- Combinations of above

**System Analysis** Design calculations are made on the basis of the close to the highest refrigeration load; however, the system operates at the design conditions very seldom. The purpose of regulating devices is to adjust the system performance to cooling demands by decreasing the effect or performance of some component. Refrigeration systems have inherent self-regulating control which the engineer can rely on to a certain extent. When the refrigeration load starts to decrease, less refrigerant will evaporate. This causes a drop in evaporation temperature (as long as compressor capacity is unchanged) due to the imbalance in vapor being taken by the compressor and produced by evaporation in the evaporator. With a drop in evaporation pressure, the compressor capacity will decrease due to (1) lower vapor density (lower mass flow for the same volumetric flow rate) and (2) a decrease in volumetric efficiency. However, when the evaporation temperature drops, for the unchanged temperature of the medium being cooled, the evaporator capacity will increase due to an increase in the mean-temperature difference between refrigerant and cooled medium, causing a positive effect (increase) on the cooling load. With a decrease in the evaporation temperature, the heat rejection factor will increase, causing an increase in heat rejected to the condenser, but the refrigerant mass flow rate will decrease because of the compressor characteristics. These will have an opposite effect on the condenser load.

Even a simplified analysis demonstrates the necessity for better understanding of system performance under different operating conditions. Two methods could be used for more accurate analysis. The traditional method of refrigeration-system analysis is through determination of balance points, whereas in recent years, system analysis is performed by system simulation or mathematical modeling, using mathematical (equation-solving) rather than graphical (intersection of two curves) procedures. Systems with a small number of components such as the vapor compression refrigeration system could be analyzed both ways. Graphical presentation, better suited for understanding trends, is not appropriate for more-complex systems, more detailed component description, and frequent change of parameters. There are a variety of different mathematical models tailored to fit specific systems, refrigerants, available resources, demands, and complexity. Although limited in its applications, graphical representation is valuable as the starting tool and for clear understanding of the system performance.

Refrigeration capacity $q_e$ and power $P$ curves for the reciprocating compressor are shown in Fig. 11-91. They are functions of temperatures of evaporation and condensation:

$$q_e = q_e(t_{evap}, t_{cd}) \tag{11-105a}$$

and

$$P = P(t_{evap}, t_{cd}) \tag{11-105b}$$

where $q_e$ (kW) = refrigerating capacity
$P$ (kW) = power required by the compressor
$t_{evap}$ (°C) = evaporating temperature
$t_{cd}$ (°C) = condensing temperature

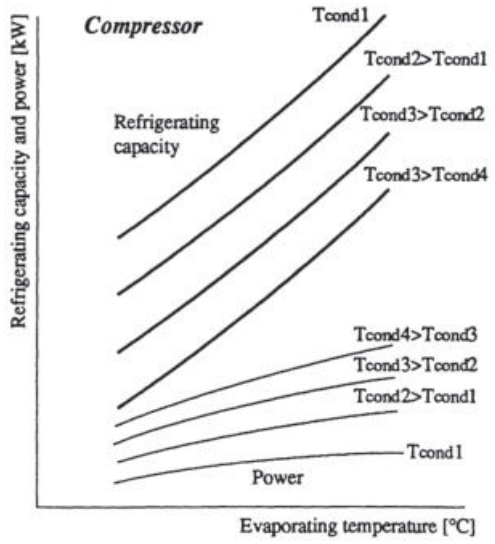

**FIG. 11-91** Refrigerating capacity and power requirement for the reciprocating compressor.

A more detailed description of compressor performance is shown in the subsection on refrigeration compressors.

Condenser performance, shown in Fig. 11-92, could be simplified as

$$q_{cd} = F(t_{cd} - t_{amb}) \tag{11-105c}$$

where $q_{cd}$ (kW) = capacity of condenser
$F$ (kW/°C) = capacity of condenser per unit inlet temperature difference ($F = U \times A$)
$t_{amb}$ (°C) = ambient temperature (or temperature of condenser cooling medium)

In this analysis $F$ will be constant, but it could be described more accurately as a function of parameters influencing heat transfer in the condenser (temperature, pressure, flow rate, fluid thermodynamic, and thermophysical characteristics, etc.).

Condenser performance should be expressed as an *evaporating effect* to enable matching with compressor and evaporator performance. The condenser evaporating effect is the refrigeration capacity of an evaporator served by a particular condenser. It is the function of the cycle, evaporating

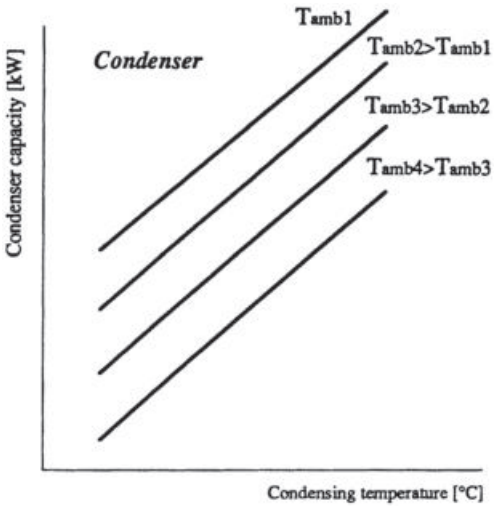

**FIG. 11-92** Condenser performance.

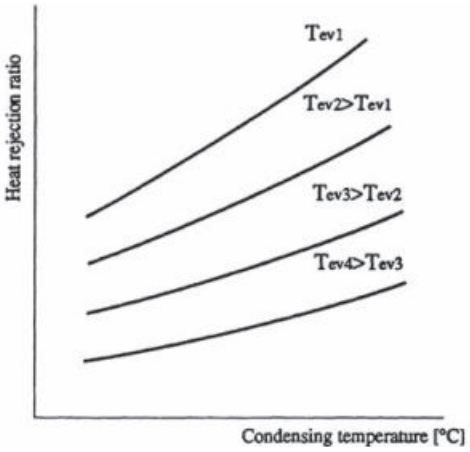

**FIG. 11-93** Heat rejection ratio.

temperature, and the compressor. The evaporating effect could be calculated from the heat-rejection ratio $q_{Cd}/q_e$:

$$q_e = \frac{q_{Cd}}{\text{heat-rejection ratio}} \qquad (11\text{-}105d)$$

The heat rejection rate is presented in Fig. 11-93 (or Fig. 11-88).

Finally, the evaporating effect of the condenser is shown in Fig. 11-94.

The performance of the condensing unit (compressor and condenser) subsystem could be developed as shown in Fig. 11-95 by superimposing two graphs, one for compressor performance and the other for condenser evaporating effect.

Evaporator performance could be simplified as

$$q_e = F_{evap}(t_{amb} - t_{evap}) \qquad (11\text{-}106)$$

where $q_e$ (kW) = evaporator capacity

$F_e$ (kW/°C) = evaporator capacity per unit inlet temperature difference

$t_{amb}$ (°C) = ambient temperature (or temperature of cooled body or fluid).

The diagram of the evaporator performance is shown in Fig. 11-96. The character of the curvature of the lines (variable heat-transfer rate) indicates that the evaporator is cooling air. Influences of the flow rate of cooled fluid are also shown in this diagram; i.e., higher flow rate will increase heat transfer. The same effect could be shown in the condenser performance curve. It is omitted only for the reasons of simplicity.

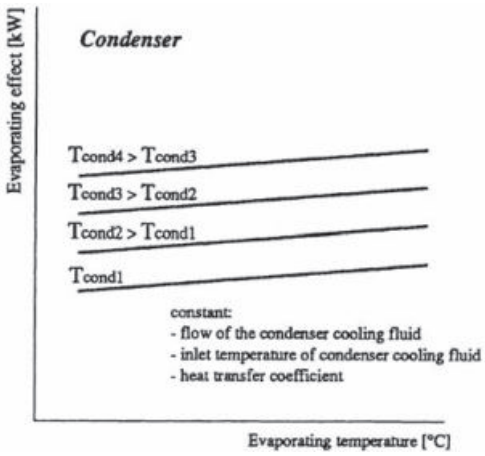

**FIG. 11-94** Condenser evaporating effect.

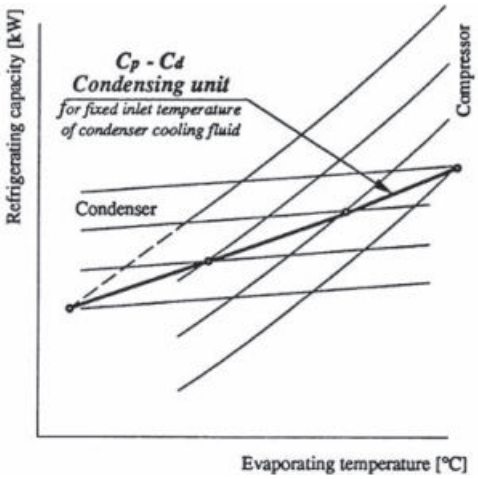

**FIG. 11-95** Balance points of compressor and condenser determine performance of condensing unit for fixed temperature of condenser cooling fluid ( flow rate and heat-transfer coefficient are constant).

The performance of the complete system could be predicted by superimposing the diagrams for the condensing unit and the evaporator, as shown in Fig. 11-97. Point 1 reveals a balance for constant flows and inlet temperatures of chilled fluid and fluid for condenser cooling. When this point is transferred in the diagram for the condensing unit in Fig. 11-94 or 11-95, the condensing temperature could be determined. When the temperature of entering fluid in the evaporator $t_{amb1}$ is lowered to $t_{amb2}$, the new operating conditions will be determined by the state at point 2. Evaporation temperature drops from $t_{evap1}$ to $t_{evap2}$. If the evaporation temperature is unchanged, the same reduction of inlet temperature could be achieved by reducing the capacity of the condensing unit from $Cp$ to $Cp^*$. The new operating point 3 shows reduction in capacity for $\Delta$ due to the reduction in the compressor or the condenser capacity.

Mathematical modeling is essentially the same process, but the description of the component performance is generally much more complex and detailed. This approach enables a user to vary more parameters more easily, look into various possibilities for intervention, and predict the response of the system from different influences. Equation solving does not necessarily have to be done by successive substitution or iteration as this procedure could suggest.

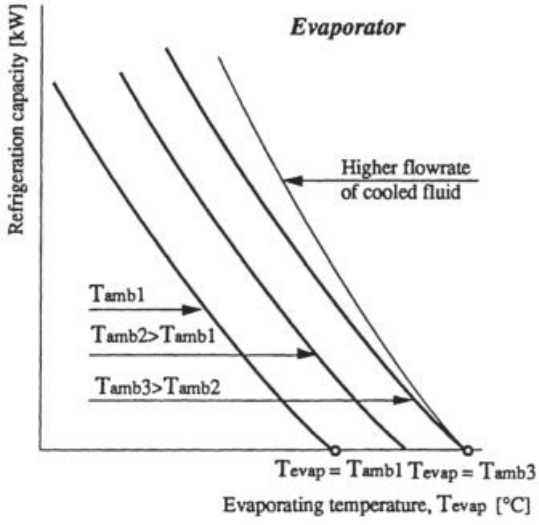

**FIG. 11-96** Refrigerating capacity of evaporator.

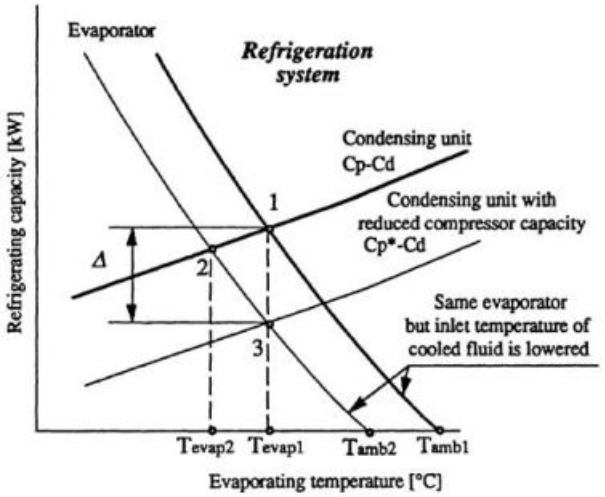

**FIG. 11-97** Performance of complete refrigeration system (1), when there is reduction in heat load (2), and when for the same ambient (or inlet in evaporator) evaporation temperature is maintained constant by reducing capacity of compressor/condenser part (3).

**System, Equipment, and Refrigerant Selection** There is no universal rule that can be used to decide which system, equipment type, or refrigerant is the most appropriate for a given application. A number of variables influence the final-design decision:

- Refrigeration load
- Type of installation
- Temperature level of medium to be cooled
- Condensing media characteristics: type (water, air, etc.), temperature level, available quantities
- Energy source for driving the refrigeration unit (electricity, natural gas, steam, waste heat)
- Location and space available (urban areas, sensitive equipment around, limited space, etc.)
- Funds available (i.e., initial versus run-cost ratio)
- Safety requirements (explosive environment, aggressive fluids, etc.)
- Other demands (compatibility with existing systems, type of load, compactness, level of automatization, operating life, possibility to use process fluid as refrigerant)

Generally, vapor *compression systems* are considered first. They can be used for almost every task. Whenever it is possible, prefabricated elements or complete units are recommended. Reciprocating compressors are widely used for lower rates, more uneven heat loads (when frequent and wider range of capacity reduction is required). They ask for more space and have higher maintenance costs than centrifugal compressors, but are often the most economical in first costs. Centrifugal compressors are considered for huge capacities, when the evaporating temperature is not too low. Screw compressors are considered first when space in the machine room is limited, when the system has operating long hours, and when periods between service should be longer.

Direct expansions are more appropriate for smaller systems which should be compact and where there is just one or few evaporators. Overfeed (recirculation) systems should be considered for all applications where first cost for additional equipment (surge drums, low-pressure receivers, refrigerant pumps, and accessories) is lower than the savings for the evaporator surface.

Choice of refrigerant is complex and not straightforward. For industrial applications, advantages of ammonia (thermodynamic and economic) overcome drawbacks which are mostly related to low-toxicity refrigerants and panics created by accidental leaks when used in urban areas. Halocarbons have many advantages (not toxic, not explosive, odorless, etc.), but environmental issues and slightly inferior thermodynamic and thermophysical properties compared to ammonia or hydrocarbons as well as rising prices are giving the opportunity to use other options. When this text was written, the ozone depletion issue was not resolved, R22 was still used but facing phase-out, and R134a was considered to be the best alternative for CFCs and HCFCs, having similar characteristics to the already banned R12. Very often, fluid to be cooled is used as a refrigerant in the chemical industry. Use of secondary refrigerants in combination with the ammonia central-refrigeration unit is becoming a viable alternative in many applications.

Absorption systems will be considered when there is low-cost, low-pressure steam or waste heat available and the evaporation temperature and refrigeration load are relatively high. Typical application range is for water chilling at 7°C to 10°C, and capacities from 300 kW to 5 MW in a single unit. The main drawback is the difficulty in maintaining a tight system with the highly corrosive lithium bromide and an operating pressure in the evaporator and the absorber below atmospheric.

Ejector (steam-jet) refrigeration systems are used for similar applications, when the chilled-water outlet temperature is relatively high, when relatively cool condensing water and cheap steam at 7 bar are available, and for similar high duties (0.3 to 5 MW). Even though these systems usually have low first and maintenance costs, there are not many steam-jet systems running.

## OTHER REFRIGERATION SYSTEMS APPLIED IN THE INDUSTRY

**Absorption Refrigeration Systems** Two main absorption systems are used in industrial application: lithium bromide–water and ammonia–water. Lithium bromide–water systems are limited to evaporation temperatures above freezing because water is used as the refrigerant, while the refrigerant in an ammonia–water system is ammonia and consequently can be applied for the lower-temperature requirements.

The single-effect indirect-fired lithium bromide cycle is shown in Fig. 11-98. The machine consists of five major components:

The *evaporator* is the heat exchanger where refrigerant (water) evaporates (being sprayed over the tubes) due to low pressure in the vessel. Evaporation chills water flow inside the tubes that bring heat from the external system to be cooled.

The *absorber* is a component where strong absorber solution is used to absorb the water vapor flashed in the evaporator. A solution pump sprays the lithium bromide over the absorber tube section. Cool water is passing through the tubes taking the refrigeration load, heat of dilution, heat to cool condensed water, and sensible heat for solution cooling.

The *heat exchanger* is used to improve the efficiency of the cycle, reducing consumption of steam and condenser water.

The *generator* is a component where heat brought to a system in a tube section is used to restore the solution concentration by boiling off the water vapor absorbed in the absorber.

The *condenser* is an element where water vapor, boiled in the generator, is condensed, preparing pure water (refrigerant) for discharge to an evaporator.

Heat supplied to the generator is boiling weak (dilute) absorbent solution on the outside of the tubes. Evaporated water is condensed on the outside of the condenser tubes. Water utilized to cool the condenser is usually cooled in the cooling tower. Both the condenser and generator are located in the same vessel, being at the absolute pressure of about 6 kPa. The water condensate passes through a liquid trap and enters the evaporator. Refrigerant (water) boils on the evaporator tubes and cools the water flow that brings the refrigeration load. Refrigerant that is not evaporated flows to the recirculation pump to be sprayed over the evaporator tubes. Solution with high water concentration that enters the generator increases in concentration as water evaporates. The resulting strong, absorbent solution (solution with low water concentration) leaves the generator on its way to the heat exchanger. There the stream of high water concentration that flows to the generator cools the stream of solution with low water concentration that flows to the second vessel. The solution with low water concentration is distributed over the absorber tubes. The absorber and evaporator are located in the same vessel, so the refrigerant evaporated on the evaporator tubes is readily absorbed into the absorbent solution. The pressure in the second vessel during the operation is 7 kPa (absolute). Heats of absorption and dilution are removed by cooling water (usually from the cooling tower). The resulting solution with high water concentration is pumped through the heat exchanger to the generator, completing the cycle. The heat exchanger increases the efficiency of the system by preheating, that is, reducing the amount of heat that must be added to the high water solution before it begins to evaporate in the generator.

The absorption machine operation is analyzed with the use of a lithium bromide–water equilibrium diagram, as shown in Fig. 11-99. Vapor pressure is plotted versus the mass concentration of lithium bromide in the solution. The corresponding saturation temperature for a given vapor pressure is shown on the left-hand side of the diagram. The line in the lower right corner of the diagram is the crystallization line. It indicates the point at which the solution will begin to change from liquid to solid, and this is the limit of the cycle. If the solution becomes overconcentrated, the absorption cycle will be interrupted owing to solidification, and capacity will not be restored until the unit is desolidified. This normally requires the addition of heat to the outside of the solution heat exchanger and the solution pump.

The diagram in Fig. 11-100 presents enthalpy data for LiBr–water solutions. It is needed for the thermal calculation of the cycle. Enthalpies for

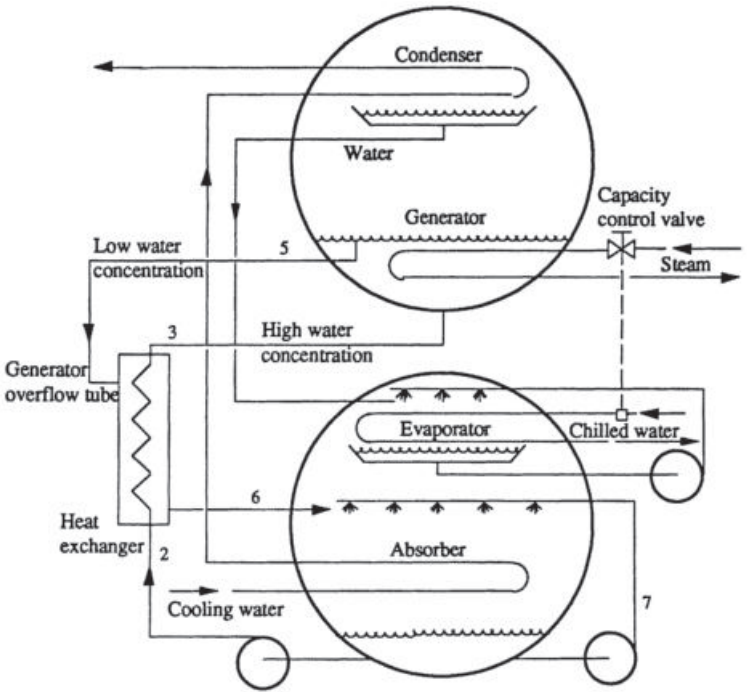

**FIG. 11-98** Two-shell lithium bromide–water cycle chiller.

water and water vapor can be determined from the table of the properties of water. The data in Fig. 11-100 are applicable to saturated or subcooled solutions and are based on a zero enthalpy of liquid water at 0°C and a zero enthalpy of solid LiBr at 25°C. Since the zero enthalpy for the water in the solution is the same as that in conventional tables of properties of water, the water property tables can be used in conjunction with the diagram in Fig. 11-99.

The coefficient of performance of the absorption cycle is defined on the same principle as for the mechanical refrigeration

$$\mathrm{COP}_{\mathrm{abs}} = \frac{\text{useful effect}}{\text{heat input}} = \frac{\text{refrigeration rate}}{\text{heat input at generator}}$$

but note that here the denominator for $\mathrm{COP}_{\mathrm{abs}}$ is heat while for the mechanical refrigeration cycle it is work. Since these two forms of energy are not equal, $\mathrm{COP}_{\mathrm{abs}}$ is not as low (0.6 to 0.8) as it appears compared to COP for mechanical system (2.5 to 3.5).

The double-effect absorption unit is shown in Fig. 11-101. All major components and the operation of the double-effect absorption machine are similar to those for the single-effect machine. The primary generator, located in vessel 1, is using an external heat source to evaporate water from dilute-absorbent (high water concentration) solution. Water vapor readily flows to generator II where it is condensed on the tubes. The absorbent (LiBr) intermediate solution from generator I will pass through the heat exchanger on the way to generator II where it is heated by the condensing water vapor. The throttling valve reduces pressure from vessel 1 (about 103 kPa absolute)

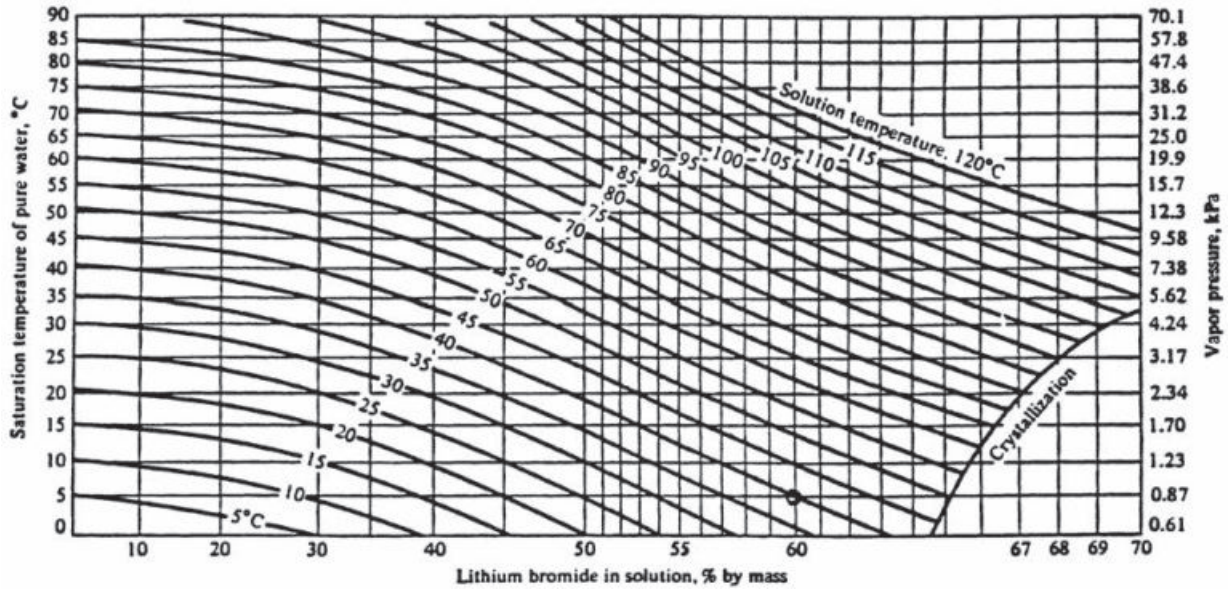

**FIG. 11-99** Temperature–pressure–concentration diagram of saturated LiBr–water solutions (*W. F. Stoecker and J. W. Jones*: *Refrigeration and Air-Conditioning*).

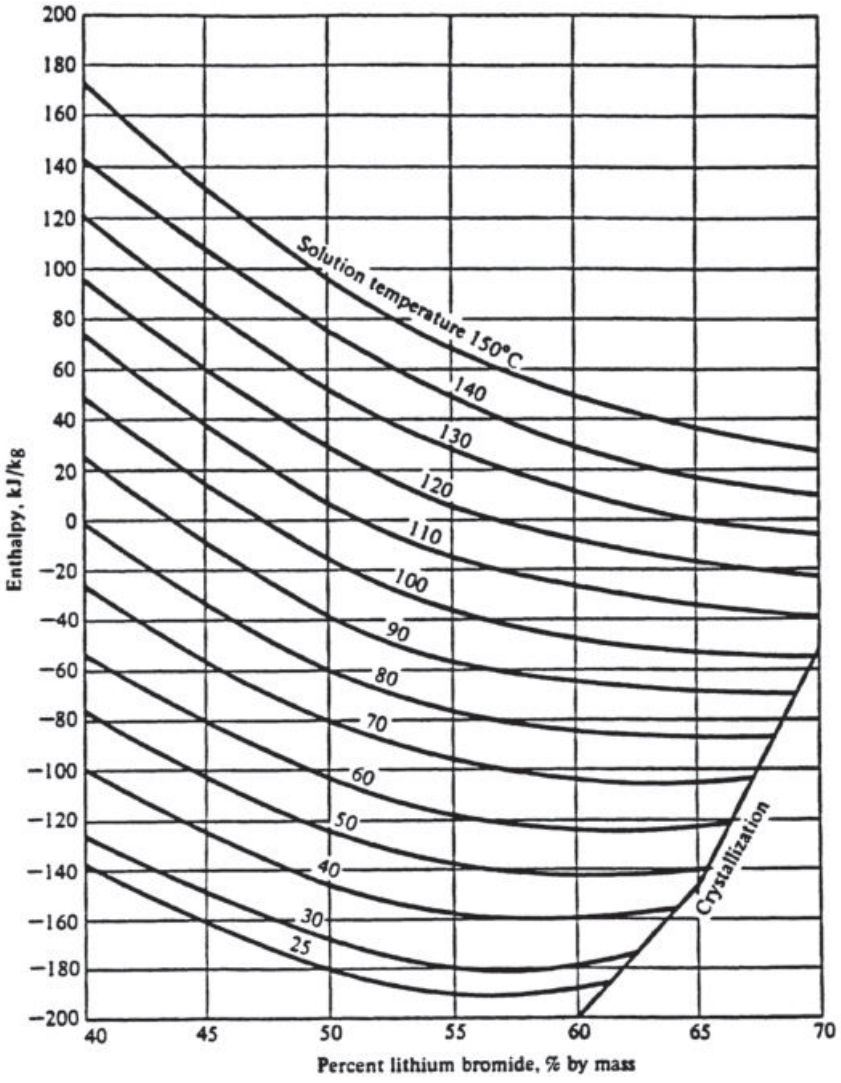

**FIG. 11-100** Enthalpy of LiBr–water solutions (*W. F. Stoecker and J. W. Jones: Refrigeration and Air-Conditioning*).

to that of vessel 2. Following the reduction of pressure, some water in the solution flashes to vapor, which is liquefied at the condenser. In the high-temperature heat exchanger, the intermediate solution heats the weak (high water concentration) solution stream coming from the low-temperature heat exchanger. In the low-temperature heat exchanger, strong solution is being cooled before entering the absorber. The absorber is at the same pressure as the evaporator. The double-effect absorption units achieve higher COPs than the single-stage ones.

The ammonia–water absorption system was extensively used until the 1950s when the LiBr–water combination became popular. Figure 11-102 shows a simplified ammonia–water absorption cycle. The refrigerant is ammonia, and the absorbent is dilute aqueous solution of ammonia. Ammonia–water systems differ from water–lithium bromide equipment to accommodate major differences: Water (here absorbent) is also volatile, so the regeneration of weak water solution to strong water solution is a fractional distillation. Different refrigerant (ammonia) causes different, much higher pressures: about 1100 to 2100 kPa absolute in condenser.

Ammonia vapor from the evaporator and the weak water solution from the generator are producing strong water solution in the absorber. Strong water solution is then separated in the rectifier, producing (1) ammonia with some water vapor content and (2) very strong water solution at the bottom, in the generator. Heat in the generator vaporizes ammonia, and the weak solution returns to absorber. On its way to the absorber, the weak solution stream passes through the heat exchanger, heating the strong solution from the absorber on the way to the rectifier. The other stream, mostly ammonia vapor but with some water vapor content, flows to the condenser. To remove water as much as possible, the vapor from the rectifier passes through the analyzer where it is additionally cooled. The remaining water escaped from the analyzer passes as liquid through the condenser and the evaporator to the absorber.

Ammonia–water units can be arranged for single-stage or cascaded two-stage operation. The advantage of two-stage operation is that it creates the possibility of utilizing only part of the heat on the higher-temperature level and the rest on the lower-temperature level, but the price is increased for first cost and heat required.

Ammonia–water and lithium bromide–water systems operate under comparable COP. The ammonia–water system is capable of achieving evaporating temperatures below 0°C because the refrigerant is ammonia. Water as the refrigerant limits evaporating temperatures to no lower than freezing, better to 3°C. Advantage of the lithium bromide–water system is that it requires less equipment and operates at lower pressures. But this is also a drawback, because pressures are below atmospheric, causing air infiltration in the system which must be purged periodically. Due to corrosion problems, special inhibitors must be used in the lithium bromide–water system. The infiltration of air in the ammonia–water system is also possible, but when evaporating temperature is below –33°C. This can result in formation of corrosive ammonium carbonate.

Houston, Tex., 1981; Stoecker, W. F., and Jones, J. W., *Refrigeration and Air-Conditioning,* McGraw-Hill, New York, 1982.

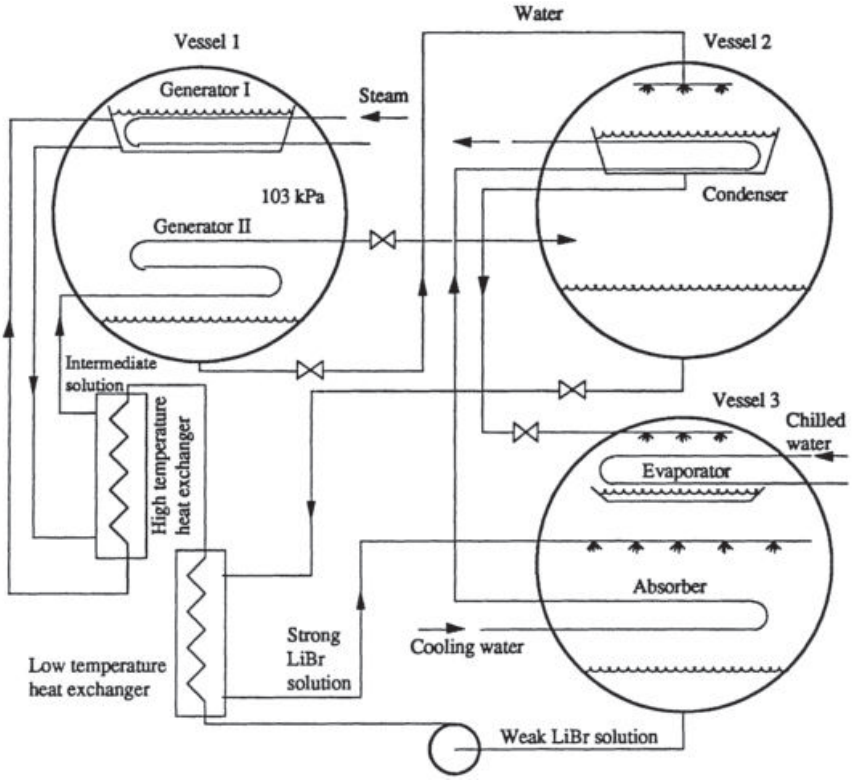

**FIG. 11-101** Double-effect absorption unit.

**Steam-Jet (Ejector) Systems** These systems substitute an ejector for a mechanical compressor in a vapor compression system. Since the refrigerant is water, maintaining temperatures lower than that of the environment requires that the pressure of water in the evaporator be below atmospheric. A typical arrangement for the steam-jet refrigeration cycle is shown in Fig. 11-103.

***Main Components*** These are the main components of steam-jet refrigeration systems:

1. *Primary steam ejector.* This kinetic device utilizes the momentum of a high-velocity jet to entrain and accelerate a slower-moving medium into which it is directed. High-pressure steam is delivered to the ejector nozzle. The steam expands while flowing through the nozzle where the velocity increases rapidly. The velocity of steam leaving the nozzle is around 1200 m/s. Because of this high velocity, flash vapor from the tank is continually aspired into the moving steam. The mixture of steam and flash vapor then enters the diffuser section where the velocity is gradually reduced

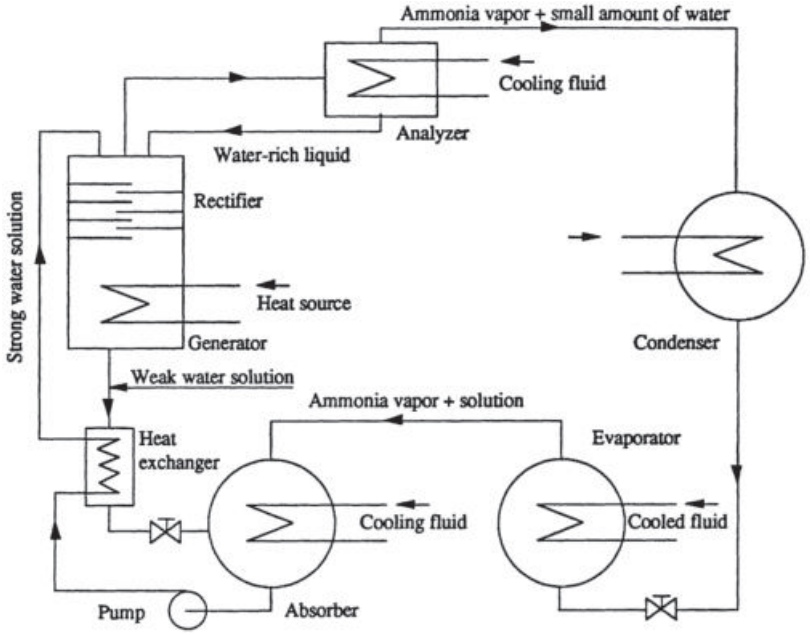

**FIG. 11-102** Simplified ammonia–water absorption cycle.

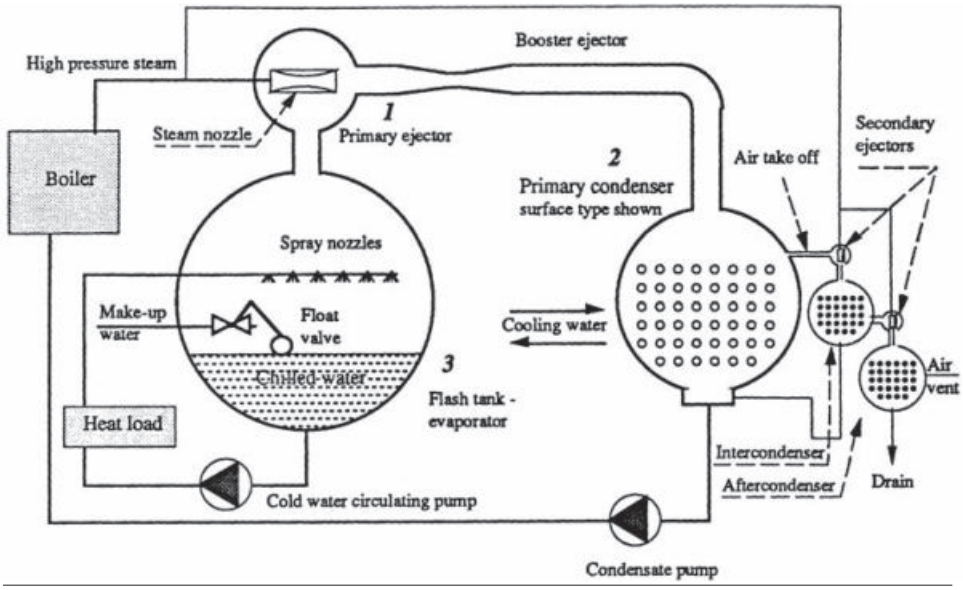

**FIG. 11-103** Ejector (steam-jet) refrigeration cycle (with surface-type condenser).

because of increasing cross-sectional area. The energy of the high-velocity steam compresses the vapor during its passage through the diffuser, raising its temperature above the temperature of the condenser cooling water.

2. *Condenser.* This is the component of the system where the vapor condenses and the heat is rejected. The rate of heat rejected is

$$Q_{cond} = (W_s + W_w)\, hfg \tag{11-107}$$

where $Q_{cond}$ = heat rejection (kW)
$W_s$ = primary booster steam rate (kg/s)
$W_w$ = flash vapor rate (kg/s)
$hfg$ = latent heat (kJ/kg)

The condenser design, surface area, and condenser cooling water quantity should be based on the highest cooling water temperature likely to be encountered. If the inlet cooling water temperature becomes hotter than the design value, the primary booster (ejector) may cease functioning because of the increase in condenser pressure.

Two types of condensers could be used: the surface condenser (shown in Fig. 11-103) and the barometric or jet condenser (Fig. 11-104). The surface condenser is of shell-and-tube design with water flowing through the tubes and steam condensed on the outside surface. In the jet condenser, condensing water and the steam being condensed are mixed directly, and no tubes are provided. The jet condenser can be barometric or a low-level type. The barometric condenser requires a height of ~10 m above the level of the water in the hot well. A tailpipe of this length is needed so that condenser water and condensate can drain by gravity. In the low-level jet type, the tailpipe is eliminated, and it becomes necessary to remove the condenser water and condensate by pumping from the condenser to the hot well. The main advantages of the jet condenser are low maintenance with the absence of tubes and the fact that condenser water of varying degrees of cleanliness may be used.

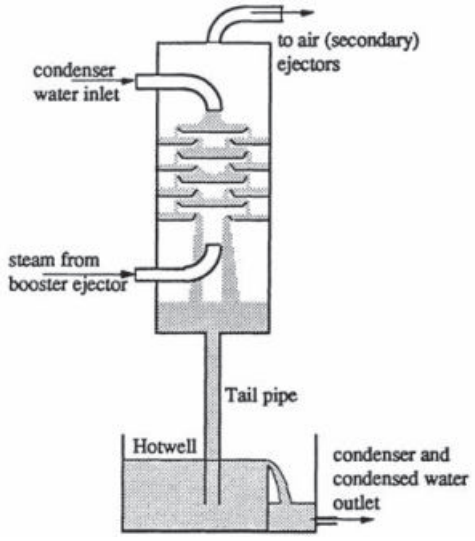

**FIG. 11-104** Barometric condenser for steam-jet system.

3. *Flash tank.* This is the evaporator of the ejector system and is usually a large-volume vessel where large water surface area is needed for efficient evaporative cooling action. Warm water returning from the process is sprayed into the flash chamber through nozzles (sometimes cascades are used for maximizing the contact surface, since they are less susceptible to carryover problems), and the cooled effluent is pumped from the bottom of the flash tank.

When the steam supply to one ejector of a group is closed, some means must be provided for preventing the pressure in the condenser and flash tank from equalizing through that ejector. A compartmental flash tank is frequently used for such purposes. With this arrangement, partitions are provided so that each booster is operating on its own flash tank. When the steam is shut off to any booster, the valve to the inlet spray water to that compartment also is closed.

A float valve is provided to control the supply of makeup water to replace the water vapor that has flashed off. The flash tank should be insulated.

***Applications*** The steam-jet refrigeration is suited for the following:

1. It is suited to processes where direct vaporization is used for concentration or drying of heat-sensitive foods and chemicals and where, besides elimination of the heat exchanger, preservation of the product quality is an important advantage.

2. It enables the use of hard water or even seawater for heat rejection, e.g., for absorption of gases ($CO_2$, $SO_2$, $ClO_2$, etc.) in chilled water (desorption is provided simultaneously with chilling) when a direct-contact barometric condenser is used.

Despite being simple, rugged, reliable, low cost, and vibration-free and requiring low maintenance, steam-jet systems are not widely accepted in water chilling for air conditioning due to characteristics of the cycle.

***Factors Affecting Capacity*** Ejector (steam-jet) units become attractive when cooling relatively high-temperature chilled water with a source of about 7 bar gauge waste steam and relatively cool condensing water. The factors involved with steam-jet capacity include the following:

1. *Steam pressure.* The main boosters can operate on steam pressures from as low as 0.15 bar up to 7 bar gauge. The quantity of steam required increases rapidly as the steam pressure drops (Fig. 11-105). The best steam rates are obtained with about 7 bar. Above this pressure the change

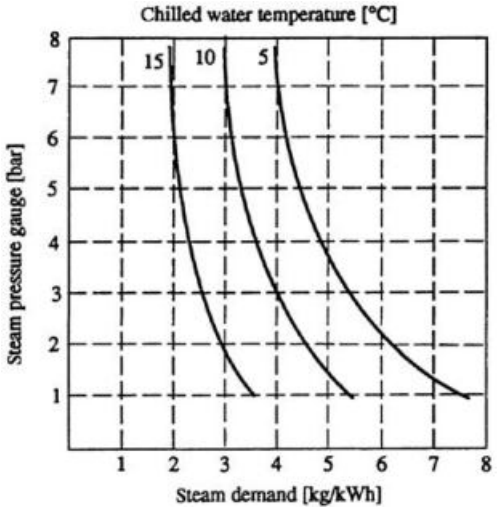

**FIG. 11-105** Effect of steam pressure on steam demand at 38°C condenser temperature. (*ASHRAE 1983 Equipment Handbook*).

in quantity of steam required is practically negligible. Ejectors must be designed for the highest available steam pressure, to take advantage of the lower steam consumption for various steam-inlet pressures.

The secondary ejector systems used for removing air require steam pressures of 2.5 bar or greater. When the available steam pressure is lower than this, an electrically driven vacuum pump is used for either the final secondary ejector or the entire secondary group. The secondary ejectors normally require 0.2 to 0.3 kg/h of steam per kilowatt of refrigeration capacity.

2. *Condenser water temperature.* In comparison with other vapor compression systems, steam-jet machines require relatively large water quantities for condensation. The higher the inlet water temperature, the higher the water requirements (Fig. 11-106). The condensing water temperature has an important effect on steam rate per refrigeration effect, rapidly decreasing with colder condenser cooling water. Figure 11-107 presents data on steam rate versus condenser water inlet for given chilled-water outlet temperatures and steam pressure.

3. *Chilled-water temperature.* As the chilled-water outlet temperature decreases, the ratio of the steam/refrigeration effect decreases, thus increasing condensing temperatures and/or increasing the condensing-water requirements.

Unlike other refrigeration systems, the chilled-water flow rate is of no particular importance in steam-jet system design, because there is, due to direct heat exchange, no influence of evaporator tube velocities and related temperature differences on heat-transfer rates. Widely varying return chilled-water temperatures have little effect on steam-jet equipment.

**Multistage Systems** The majority of steam-jet systems being currently installed are multistage. Up to five-stage systems are in commercial operation.

**Capacity Control** The simplest way to regulate the capacity of most steam vacuum refrigeration systems is to furnish several primary boosters

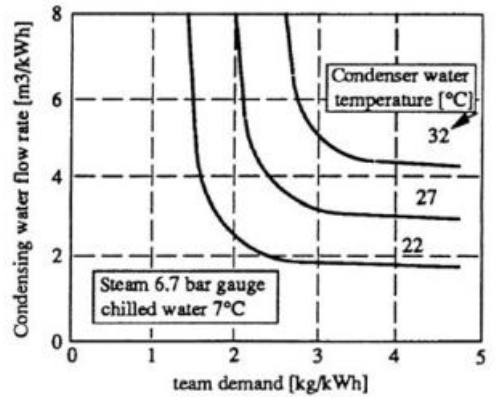

**FIG. 11-106** Steam demand versus condenser water flow rate.

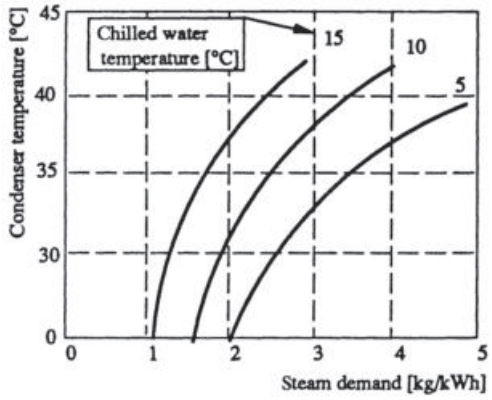

**FIG. 11-107** Steam demand versus chilled-water temperature for typical steam-jet system. (*ASHRAE 1983 Equipment Handbook*).

in parallel and operate only those required to handle the heat load. It is not uncommon to have as many as four main boosters on larger units for capacity variation. A simple automatic on-off type of control may be used for this purpose. By sensing the chilled-water temperature leaving the flash tank, a controller can turn steam on and off to each ejector as required.

Additionally, two other control systems that will regulate steam flow or condenser-water flow to the machine are available. As the condenser-water temperature decreases during various periods of the year, the absolute condenser pressure will decrease. This will permit the ejectors to operate on less steam because of the reduced discharge pressure. Either the steam flow or the condenser water quantities can be reduced to lower operating costs at other than design periods. The arrangement selected depends on cost considerations between the two flow quantities. Some systems have been arranged for a combination of the two, automatically reducing steam flow down to a point, followed by a reduction in condenser-water flow. For maximum operating efficiency, automatic control systems are usually justifiable in keeping operating cost to a minimum without excessive operator attention. In general, steam savings of about 10 percent of rated booster flow are realized for each 2.5°C reduction in condensing-water temperature below the design point.

In some cases, with relatively cold inlet condenser water it has been possible to adjust automatically the steam inlet pressure in response to chilled-water outlet temperatures. In general, however, this type of control is not possible because of the differences in temperature between the flash tank and the condenser. Under usual conditions of warm condenser-water temperatures, the main ejectors must compress water vapor over a relatively high ratio, requiring an ejector with entirely different operating characteristics. In most cases, when the ejector steam pressure is throttled, the capacity of the jet remains almost constant until the steam pressure is reduced to a point at which there is a sharp capacity decrease. At this point, the ejectors are unstable, and the capacity is severely curtailed. With a sufficient increase in steam pressure, the ejectors will once again become stable and operate at their design capacity. In effect, steam jets have a vapor-handling capacity fixed by the pressure at the suction inlet. In order for the ejector to operate along its characteristic pumping curve, it requires a certain minimum steam flow rate which is fixed for any particular pressure in the condenser. (For further information on the design of ejectors, see Sec. 6.)

**Refrigerants** A refrigerant is a body or substance that acts as a cooling agent by absorbing heat from another body or substance which has to be cooled. Primary refrigerants are those that are used in the refrigeration systems, where they alternately vaporize and condense as they absorb and give off heat, respectively. Secondary refrigerants are heat-transfer fluids or heat carriers. Refrigerant pairs in absorption systems are ammonia–water and lithium bromide–water, while steam (water) is used as a refrigerant in ejector systems. Refrigerants used in the mechanical refrigeration systems are far more numerous.

A list of the most significant refrigerants is presented in the *ASHRAE Handbook Fundamentals*. More data are shown in Sec. 2, "Physical and Chemical Data." Because of the rapid changes in the refrigerant issue, readers are advised to consult the most recent data and publications at the time of application.

The first refrigerants were natural: air, ammonia, $CO_2$, $SO_2$, and so on. Fast expansion of refrigeration in the second and third quarters of the 20th

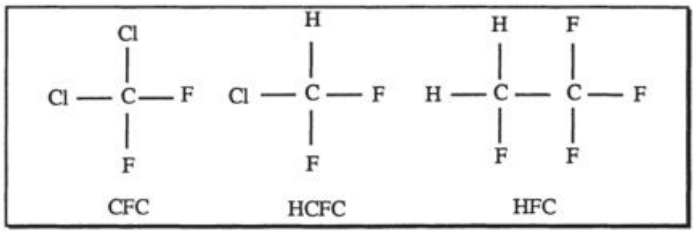

**FIG. 11-108** Halocarbon refrigerants.

century is marked by the new refrigerants, chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs). They are halocarbons that contain one or more of the three halogens chlorine, fluorine, and bromine (Fig. 11-108). These refrigerants introduced many advantageous qualities compared to most of the existing refrigerants: they are odorless, nonflammable, nonexplosive, compatible with the most engineering materials, nontoxic, and have a reasonably high COP.

In the last decade, the refrigerant issue is extensively discussed because of the accepted hypothesis that the chlorine and bromine atoms from halocarbons released to the environment were using up ozone in the stratosphere, depleting it especially above the polar regions. The Montreal Protocol and later agreements ban use of certain CFCs and halon compounds. Presently, all CFCs are out of production and the production, import, and use of HCFCs have been banned in the United States since 2015, except for HCFC-22 and HCFC-142b. A complete ban on all HCFCs in the United States is scheduled for 2030.

Chemical companies are trying to develop safe and efficient refrigerant for the refrigeration industry and application, but uncertainty in CFC and HCFC substitutes is still high. When this text was written, HFCs were a promising solution. That is true especially for R134a which seems to be the best alternative for R12. Substitutes for R22 and R502 are still under debate. Numerous ecologists and chemists are for an extended ban on HFCs as well, mostly due to significant use of CFCs in the production of HFCs. Extensive research is ongoing to find new refrigerants. Many projects are aimed to design and study refrigerant mixtures, both azeotropic (mixture which behaves physically as a single, pure compound) and zeotropic having desirable qualities for the processes with temperature glides in the evaporator and the condenser.

Ammonia (R717) is the single natural refrigerant being used extensively (beside halocarbons). It is significant in industrial applications for its excellent thermodynamic and thermophysical characteristics. Many engineers are considering ammonia as a CFC substitute for various applications. Significant work is being done on reducing the refrigerant inventory and consequently problems related to leaks of this fluid with strong odor. There is growing interest in hydrocarbons in some countries, particularly in Europe. Indirect cooling (secondary refrigeration) is under reconsideration for many applications.

Because of the vibrant refrigerant issue it will be a challenge for every engineer to find the best solution for the particular application, but basic principles are the same. Good refrigerant should have these characteristics:

- Safe: nontoxic, nonflammable, and nonexplosive
- Environmentally friendly
- Compatible with materials normally used in refrigeration: oils, metals, elastomers, etc.
- Desirable thermodynamic and thermophysical characteristics:
  - High latent heat
  - Low specific volume of vapor
  - Low compression ratio
  - Low viscosity
  - Reasonably low pressures for operating temperatures
  - Low specific heat of liquid
  - High specific heat of vapor
  - High conductivity and other heat-transfer related characteristics
  - Reasonably low compressor discharge temperatures
  - Easily detected if leaking
  - High dielectric constant
  - Good stability

**Secondary Refrigerants (Antifreezes or Brines)** These are mostly liquids used for transporting heat energy from the remote heat source (process heat exchanger) to the evaporator of the refrigeration system. Antifreezes or brines do not change state in the process, but there are examples where some secondary refrigerants are either changing state themselves, or just particles which are carried in them.

Indirect refrigeration systems are more prevalent in the chemical industry than in the food industry, commercial refrigeration, or comfort air conditioning. This is even more evident in the cases where a large amount of heat is to be removed or where a low temperature level is involved. The advantage of an indirect system is centralization of refrigeration equipment, which is especially important for relocation of refrigeration equipment in a nonhazardous area, for both people and equipment.

***Salt Brines*** The typical curve of freezing point is shown in Fig. 11-109. Brine of concentration $x$ (water concentration is $1 - x$) will not solidify at 0°C ( freezing temperature for water, point A). When the temperature drops to B, the first crystal of ice is formed. As the temperature decreases to point C, ice crystals continue to form and their mixture with the brine solution forms the slush. At point C there will be part ice in the mixture $l_2/(l_1 + l_2)$ and liquid (brine) $l_1/(l_1 + l_2)$. At point D there is mixture of $m_1$ parts eutectic brine solution $D_1$ [concentration $m_1/(m_1 + m_2)$], and $m_2$ parts of ice [concentration $m_2/(m_1 + m_2)$]. Cooling the mixture below D solidifies the entire solution at the eutectic temperature. The eutectic temperature is the lowest temperature that can be reached with no solidification.

It is obvious that further strengthening of brine has no effect, and can cause a different reaction—salt sometimes freezes out in the installations where the concentration is too high.

Sodium chloride, an ordinary salt (NaCl), is the least expensive per volume of any brine available. It can be used in contact with food and in open systems because of its low toxicity. Heat-transfer coefficients are relatively high. However, its drawbacks are that it has a relatively high freezing point and is highly corrosive (requires inhibitors, thus must be checked on a regular schedule).

Calcium chloride ($CaCl_2$) is similar to NaCl. It is the second-lowest-cost brine, with a somewhat lower freezing point (used for temperatures as low as −37°C). It is highly corrosive and not appropriate for direct contact with food. Heat-transfer coefficients are rapidly reduced at temperatures below −20°C. The presence of magnesium salts in either sodium or calcium chloride is undesirable because they tend to form sludge. Air and carbon dioxide are contaminants, and excessive aeration of the brine should be prevented through the use of closed systems. Oxygen, required for corrosion, normally comes from the atmosphere and dissolves in the brine solution. Dilute brines dissolve oxygen more readily and are generally more corrosive than concentrated brines. It is believed that even a closed brine system will not prevent the infiltration of oxygen.

To adjust an alkaline condition to pH 7.0 to 8.5, use caustic soda (to correct up to pH 7.0) or sodium dichromate (to reduce excessive alkalinity below pH 8.5). Such slightly alkaline brines are generally less corrosive than neutral or acid ones, although with high alkalinity the activity may increase.

If the untreated brine has the proper pH value, the acidifying effect of the dichromate may be neutralized by adding commercial flake caustic soda (76 percent pure) in quantity that corresponds to 27 percent of sodium dichromate used. Caustic soda must be thoroughly dissolved in warm water before it is added to the brine.

Recommended inhibitor (sodium dichromate) concentrations are 2 kg/m$^3$ of $CaCl_2$ and 3.2 kg/m$^3$ of NaCl brine. Sodium dichromate when dissolved in water or brine makes the solution acid. Steel, iron, copper, or red brass can be used with brine circulating systems. Calcium chloride systems are generally equipped with all-iron-and-steel pumps and valves to prevent electrolysis in the event of acidity. Copper and red brass tubing is used for calcium chloride evaporators. Sodium chloride systems are using all-iron or all-bronze pumps.

**Organic Compounds (Inhibited Glycols)** *Ethylene glycol* is colorless, practically odorless, and completely miscible with water. Advantages are low volatility and relatively low corrosivity when properly inhibited. Main drawbacks are relatively low heat-transfer coefficients at lower temperatures due to high viscosities (even higher than for propylene glycol). It is somewhat toxic, but less harmful than methanol–water solutions. It is not appropriate for the food industry and should not stand in open containers.

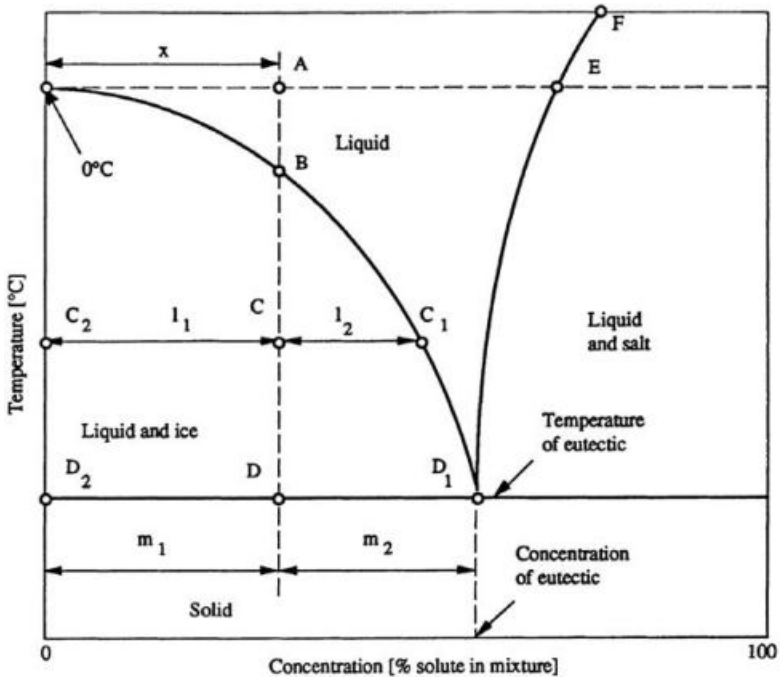

**FIG. 11-109** Phase diagram of the brine.

Preferably waters that are classified as soft and are low in chloride and sulfate ions should be used for preparation of ethylene glycol solution.

Pure ethylene glycol freezes at −12.7°C. Exact composition and temperature for the eutectic point are unknown, since solutions in this region turn to viscous, glassy mass that makes it difficult to determine the true freezing point. For the concentrations lower than eutectic, ice forms on freezing, while on the concentrated, solid glycol separates from the solution.

Ethylene glycol normally has pH of 8.8 to 9.2 and should not be used below pH 7.5. Addition of more inhibitor cannot restore the solution to its original condition. Once inhibitor has been depleted, it is recommended that the old glycol be removed from the system and the new charge be installed.

*Propylene glycol* is very similar to ethylene glycol, but it is not toxic and is used in direct contact with food. It is more expensive and, having higher viscosity, shows lower heat-transfer coefficients.

*Methanol–water* is an alcohol-base compound. It is less expensive than other organic compounds and, due to lower viscosity, has better heat-transfer and pressure drop characteristics. It is used up to −35°C. Disadvantages are that (1) it is considered more toxic than ethylene glycol and thus more suitable for outdoor applications and (2) it is flammable and could be assumed to be a potential fire hazard.

For ethylene glycol systems, copper tubing is often used (up to 3 in), while pumps, cooler tubes, or coils are made of iron, steel, brass, copper, or aluminum. Galvanized tubes should not be used in ethylene glycol systems because of reaction of the inhibitor with the zinc.

Methanolewater solutions are compatible with most materials but in sufficient concentration will badly corrode aluminum.

*Ethanol–water* is a solution of denatured grain alcohol. Its main advantage is that it is nontoxic and thus is widely used in the food and chemical industry. By using corrosion inhibiters it could be made noncorrosive for brine service. It is more expensive than methanol–water and has somewhat lower heat-transfer coefficients. As an alcohol derivate it is flammable.

Secondary refrigerants shown below, listed under their generic names, are sold under different trade names. Some other secondary refrigerants appropriate for various refrigeration applications will be listed under their trade names. More data could be obtained from the manufacturer.

*Syltherm XLT (Dow Corning Corporation).* A silicone polymer (Dimethyl Polysiloxane); recommended temperature range −70°C to 250°C; odorless; low in acute oral toxicity; noncorrosive toward metals and alloys commonly found in heat transfer systems.

*Syltherm 800 (Dow Corning Corporation).* A silicone polymer (Dimethyl Polysiloxane); recommended temperature range −40°C to 400°C; similar to Syltherm XLT, more appropriate for somewhat higher temperatures; flash point is 160°C.

*D-limonene (Florida Chemicals).* A compound of optically active terpene ($C_{10}H_{16}$) derived as an extract from orange and lemon oils; limited data show very low viscosity at low temperatures—only 1 cP at −50°C; natural substance having questionable stability.

*Therminol D-12 (Monsanto).* A synthetic hydrocarbon; clear liquid; recommended range −40°C to 250°C; not appropriate for contact with food; precautions against ignitions and fires should be taken with this product; could be found under trade names Santotherm or Gilotherm.

*Therminol LT (Monsanto).* Akylbenzene, synthetic aromatic ($C_{10}H_{14}$); recommended range −70°C to −180°C; not appropriate for contact with food; precautions against ignitions and fire should be taken when dealing with this product.

*Dowtherm J (Dow Corning Corporation).* A mixture of isomers of an alkylated aromatic; recommended temperature range −70°C to 300°C; noncorrosive toward steel, common metals and alloys; combustible material; flash point 58°C; low toxic; prolonged and repeated exposure to vapors should be limited to 10 ppm for daily exposures of 8 h.

*Dowtherm Q (Dow Corning Corporation).* A mixture of dyphenylehane and alkylated aromatics; recommended temperature range −30°C to 330°C; combustible material; flash point 120°C; considered low toxic, similar to Dowtherm J.

**Safety in Refrigeration Systems** This is of paramount importance and should be considered at every stage of installation.

The design engineer should have safety as the primary concern by choosing a suitable system and refrigerant: selecting components, choosing materials and thicknesses of vessels, pipes, and relief valves of pressure vessels, proper venting of machine rooms, and arranging the equipment for convenient access for service and maintenance (piping arrangements, valve location, machine room layout, etc.). She or he should conform to the stipulation of the safety codes, which is also important for the purposes of professional liability.

During construction and installation, the installer's good decisions and judgments are crucial for safety, because design documentation never specifies all details. This is especially important when there is reconstruction or repair while the facility has been charged.

During operation the plant is in the hands of the operating personnel. They should be properly trained and familiar with the installation. Very often, accidents are caused by an improper practice, such as making an attempt to repair when proper preparation has not been made. Operators should be trained in first-aid procedures and how to respond to emergencies.

Most frequently needed standards and codes are listed below, and the reader can find comments in W. F. Stoecker, *Industrial Refrigeration,* vol. 2, chap. 12, Business News Publishing Co., Troy, Mich., 1995; ASHRAE Handbook,

*Refrigeration System and Applications,* 1994, chap. 51. These are some important standards and codes on safety that a refrigeration engineer should consult: ANSI/ASHRAE Standard 15-92, Safety Code for Mechanical Refrigeration, ASHRAE, Atlanta Ga., 1992; ANSI/ASHRAE Standard 34-92, Number Designation of Refrigerants, ASHRAE, Atlanta, Ga., 1992; ANSI/ASME Boiler and Pressure Vessel Code, ASME, New York, 1989; ANSI/ASME Code for Pressure Piping, B31, B31.5–1987, ASME, New York, 1987; ANSI/IIAR 2—1984, Equipment, Design and Installation of Ammonia Mechanical Refrigeration Systems, IIAR, Chicago, 1984; IIAR Minimum Safety Criteria for a Safe Ammonia Refrigeration Systems, Bulletin 109; IIAR, IIAR Start-up, Inspection, and Maintenance of Ammonia Mechanical Refrigeration Systems, Bulletin 110, Chicago, 1988; IIAR Recommended Procedures in Event of Ammonia Spills, Bulletin 106, IIAR, Chicago, 1977; A Guide to Good Practices for the Operation of an Ammonia Refrigeration System, IIAR Bulletin R1, 1983.

# EVAPORATORS

**General References:** Badger and Banchero, *Introduction to Chemical Engineering,* McGraw-Hill, New York, 1955. Standiford, *Chem. Eng.* **70:** 158–176 (Dec. 9, 1963). *Testing Procedure for Evaporators,* American Institute of Chemical Engineers, 1979. *Upgrading Evaporators to Reduce Energy Consumption,* ERDA Technical Information Center, Oak Ridge, Tenn., 1977.

## PRIMARY DESIGN PROBLEMS

**Heat Transfer** This is the most important single factor in evaporator design, since the heating surface represents the largest part of evaporator cost. Other things being equal, the type of evaporator selected is the one having the highest heat-transfer cost coefficient under desired operating conditions in terms of joules per second per kelvin (British thermal units per hour per degree Fahrenheit) per dollar of installed cost. When power is required to induce circulation past the heating surface, the coefficient must be even higher to offset the cost of power for circulation.

**Vapor-Liquid Separation** This design problem may be important for a number of reasons. The most important is usually prevention of entrainment because of value of product lost, pollution, contamination of the condensed vapor, or fouling or corrosion of the surfaces on which the vapor is condensed. Vapor-liquid separation in the vapor head may also be important when spray forms deposits on the walls, when vortices increase the head requirements of circulating pumps, and when short-circuiting allows vapor or unflashed liquid to be carried back to the circulating pump and heating element. Evaporator performance is rated on the basis of *steam economy*—kilograms of solvent evaporated per kilogram of steam used. Heat is required (1) to raise the feed from its initial temperature to the boiling temperature, (2) to provide the minimum thermodynamic energy to separate liquid solvent from the feed, and (3) to vaporize the solvent. The first can be changed appreciably by reducing the boiling temperature or by heat interchange between the feed and the residual product and/or condensate. The greatest increase in steam economy is achieved by reusing the vaporized solvent. This is done in a *multiple-effect evaporator* by using the vapor from one effect as the heating medium for another effect in which boiling takes place at a lower temperature and pressure. Another method of increasing the utilization of energy is to employ a *thermocompression* evaporator, in which the vapor is compressed so that it will condense at a temperature high enough to permit its use as the heating medium in the same evaporator.

**Selection Problems** Aside from heat-transfer considerations, the selection of type of evaporator best suited for a particular service is governed by the characteristics of the feed and product. Points that must be considered include crystallization, salting and scaling, product quality, corrosion, and foaming. In the case of a *crystallizing evaporator,* the desirability of producing crystals of a definite uniform size usually limits the choice to evaporators having a positive means of circulation. *Salting,* which is the growth on body and heating-surface walls of a material having a solubility that increases with an increase in temperature, is frequently encountered in crystallizing evaporators. It can be reduced or eliminated by keeping the evaporating liquid in close or frequent contact with a large surface area of crystallized solid. *Scaling* is the deposition and growth on body walls, and especially on heating surfaces, of a material undergoing an irreversible chemical reaction in the evaporator or having a solubility that decreases with an increase in temperature. Scaling can be reduced or eliminated in the same general manner as salting. Both salting and scaling liquids are usually best handled in evaporators that do not depend on boiling to induce circulation. *Fouling* is the formation of deposits other than salt or scale and may be due to corrosion, solid matter entering with the feed, or deposits formed by the condensing vapor.

**Product Quality** Considerations of product quality may require low holdup time and low-temperature operation to avoid thermal degradation. The low holdup time eliminates some types of evaporators, and other types are also eliminated because of poor heat-transfer characteristics at low temperature. Product quality may dictate special materials of construction to avoid metallic contamination or a catalytic effect on decomposition of the product. *Corrosion* may also influence evaporator selection, since the advantages of evaporators having high heat-transfer coefficients are more apparent when expensive materials of construction are indicated. Corrosion and erosion are frequently more severe in evaporators than in other types of equipment because of the high liquid and vapor velocities used, the frequent presence of solids in suspension, and the necessary concentration differences.

## EVAPORATOR TYPES AND APPLICATIONS

Evaporators may be classified as follows:

1. Heating medium is separated from evaporating liquid by tubular heating surfaces.
2. Heating medium is confined by coils, jackets, double walls, flat plates, etc.
3. Heating medium is brought into direct contact with the evaporating liquid.
4. Heating is done by solar radiation.

By far the largest number of industrial evaporators employ tubular heating surfaces. Circulation of liquid past the heating surface may be induced by boiling or by mechanical means. In the latter case, boiling may or may not occur at the heating surface.

**Forced-Circulation Evaporators (Fig. 11-110*a, b, c*)** Although it may not be the most economical for many uses, the forced-circulation (FC) evaporator is suitable for the widest variety of evaporator applications. The use of a pump to ensure circulation past the heating surface makes it possible to separate the functions of heat transfer, vapor-liquid separation, and crystallization. The pump withdraws liquor from the flash chamber and forces it through the heating element back to the flash chamber. Circulation is maintained regardless of the evaporation rate; so this type of evaporator is well suited to *crystallizing operation,* in which solids must be maintained in suspension at all times. The liquid velocity past the heating surface is limited only by the pumping power needed or available and by accelerated corrosion and erosion at the higher velocities. *Tube velocities* normally range from a minimum of about 1.2 m/s (4 ft/s) in salt evaporators with copper or brass tubes and liquid containing 5 percent or more solids up to about 3 m/s (10 ft/s) in caustic evaporators having nickel tubes and liquid containing only a small amount of solids. Even higher velocities can be used when corrosion is not accelerated by erosion.

Highest heat-transfer coefficients are obtained in FC evaporators when the liquid is allowed to boil in the tubes, as in the type shown in Fig. 11-110*a.* The heating element projects into the vapor head, and the liquid level is maintained near and usually slightly below the top tube sheet. This type of FC evaporator is not well suited to salting solutions because boiling in the tubes increases the chances of salt deposit on the walls and the sudden flashing at the tube exits promotes excessive nucleation and production of fine crystals. Consequently, this type of evaporator is seldom used except when there are headroom limitations or when the liquid forms neither salt nor scale.

**Swirl Flow Evaporators** One of the most significant problems in the thermal design of once-through, tube-side evaporators is the poor predictability of the loss of $\Delta T$ upon reaching the critical heat flux condition. This situation may occur through flashing due to a high wall temperature or due to process needs to evaporate most of, if not all, the liquid entering the evaporator. It is the result of sensible heating of the vapor phase which accumulates at the heat-transfer surface, dries out the tube wall, and blocks the transfer of heat to the remaining liquid.

In some cases, even with correctly predicted heat-transfer coefficients, the unexpected $\Delta T$ loss can reduce the actual performance of the evaporator by as much as 200 percent below the predicted performance. The best approach is to maintain a high level of mixing of the phases through the heat exchanger near the heat-transfer surface.

The use of swirl flow—whereby a rotational vortex is imparted to the boiling fluid to centrifuge the liquid droplets out to the tube wall—has proved to be the most reliable means to correct for and eliminate this loss of $\Delta T$. The

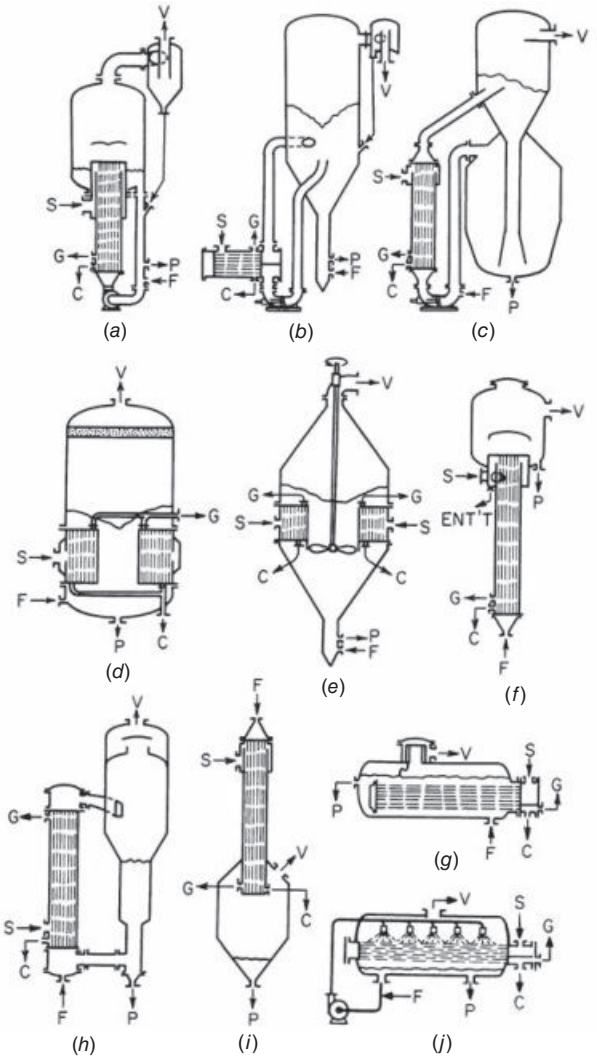

**FIG. 11-110** Evaporator types. (*a*) Forced circulation. (*b*) Submerged-tube forced circulation. (*c*) Oslo-type crystallizer. (*d*) Short-tube vertical. (*e*) Propeller calandria. (*f*) Long-tube vertical. (*g*) Recirculating long-tube vertical. (*h*) Falling film. (*i, j*) Horizontal-tube evaporators. C = condensate; F = feed; G = vent; P = product; S = steam; V = vapor; ENT'T = separated entrainment outlet.

use of this technique almost always corrects the design to operate as well as or better than predicted. Also, the use of swirl flow eliminates the need to choose between horizontal and vertical orientation for most two-phase velocities. Both orientations work about the same in swirl flow.

Many commercially viable methods of inducing swirl flow inside tubes are available in the form of either swirl flow tube inserts (twisted tapes, helical cores, spiral wire inserts) or special tube configurations (twisted tube, internal spiral fins). All are designed to impart a natural swirl component to the flow inside the tubes. Each has been proved to solve the problem of tube-side vaporization at high vapor qualities up to and including complete tube-side vaporization.

By far the largest number of forced-circulation evaporators is of the submerged-tube type, as shown in Fig. 11-110*b*. The heating element is placed far enough below the liquid level or return line to the flash chamber to prevent boiling in the tubes. Preferably, the hydrostatic head should be sufficient to prevent boiling even in a tube that is plugged (and hence at steam temperature), since this prevents salting of the entire tube. Evaporators of this type sometimes have horizontal heating elements (usually two-pass), but the vertical single-pass heating element is used whenever sufficient headroom is available. The vertical element usually has a lower friction loss and is easier to clean or retube than a horizontal heater. The submerged-tube forced-circulation evaporator is relatively immune to salting in the tubes, since no supersaturation is generated by evaporation in the tubes. The tendency toward scale formation is also reduced, since supersaturation in the heating element is generated only by a controlled amount of heating and not by both heating and evaporation.

The type of *vapor* head used with the FC evaporator is chosen to suit the product characteristics and may range from a simple centrifugal separator to the crystallizing chambers shown in Fig. 11-110*b* and *c*. Figure 11-110*b* shows a type frequently used for common salt. It is designed to circulate a slurry of crystals throughout the system. Figure 11-110*c* shows a submerged-tube FC evaporator in which heating, flashing, and crystallization are completely separated. The crystallizing solids are maintained as a fluidized bed in the chamber below the vapor head, and little or no solids circulate through the heater and flash chamber. This type is well adapted to growing coarse crystals, but the crystals usually approach a spherical shape, and careful design is required to avoid production of tines in the flash chamber.

In a submerged-tube FC evaporator, all heat is imparted as sensible heat, resulting in a temperature rise of the circulating liquor that reduces the overall temperature difference available for heat transfer. Temperature rise, tube proportions, tube velocity, and head requirements on the circulating pump all influence the selection of circulation rate. Head requirements are frequently difficult to estimate since they consist not only of the usual friction, entrance and contraction, and elevation losses when the return to the flash chamber is above the liquid level, but also of increased friction losses due to flashing in the return line and vortex losses in the flash chamber. Circulation is sometimes limited by vapor in the pump suction line. This may be drawn in as a result of inadequate vapor-liquid separation or may come from vortices near the pump suction connection to the body or may be formed in the line itself by short-circuiting from heater outlet to pump inlet of liquor that has not flashed completely to equilibrium at the pressure in the vapor head.

Advantages of forced-circulation evaporators:
1. High heat-transfer coefficients
2. Positive circulation
3. Relative freedom from salting, scaling, and fouling

Disadvantages of forced-circulation evaporators:
1. High cost
2. Power required for circulating pump
3. Relatively high holdup or residence time

Best applications of forced-circulation evaporators:
1. Crystalline product
2. Corrosive solutions
3. Viscous solutions

Frequent difficulties with forced-circulation evaporators:
1. Plugging of tube inlets by salt deposits detached from walls of equipment
2. Poor circulation due to higher than expected head losses
3. Salting due to boiling in tubes
4. Corrosion-erosion

**Short-Tube Vertical Evaporators (Fig. 11-110*d*)** This is one of the earliest types still in widespread commercial use. Its principal use at present is in the evaporation of cane-sugar juice. Circulation past the heating surface is induced by boiling in the tubes, which are usually 50.8 to 76.2 mm (2 to 3 in) in diameter by 1.2 to 1.8 m (4 to 6 ft) long. The body is a vertical cylinder, usually of cast iron, and the tubes are expanded into horizontal tube sheets that span the body diameter. The circulation rate through the tubes is many times the feed rate; so there must be a return passage from above the top tube sheet to below the bottom tube sheet. Most commonly used is a central well or *downtake,* as shown in Fig. 11-110*d*. So that friction losses through the downtake do not appreciably impede circulation up through the tubes, the area of the downtake should be of the same order of magnitude as the combined cross-sectional area of the tubes. This results in a downtake almost half of the diameter of the tube sheet.

Circulation and heat transfer in this type of evaporator are strongly affected by the "liquid level." Highest heat-transfer coefficients are achieved when the level, as indicated by an external gauge glass, is only about halfway up the tubes. Slight reductions in level below the optimum result in incomplete wetting of the tube walls with a consequent increased tendency to foul and a rapid reduction in capacity. When this type of evaporator is used with a liquid that can deposit salt or scale, it is customary to operate with the liquid level appreciably higher than the optimum and usually appreciably above the top tube sheet.

Circulation in the standard short-tube vertical evaporator is dependent entirely on boiling, and when boiling stops, any solids present settle out of suspension. Consequently, this type is seldom used as a crystallizing

evaporator. By installing a propeller in the downtake, this objection can be overcome. Such an evaporator, usually called a *propeller calandria*, is illustrated in Fig. 11-110*e.* The propeller is usually placed as low as possible to reduce cavitation and is shrouded by an extension of the downtake well. The use of the propeller can sometimes double the capacity of a short-tube vertical evaporator. The evaporator shown in Fig. 11-110*e* includes an elutriation leg for salt manufacture similar to that used on the FC evaporator of Fig. 11-110*b.* The shape of the bottom will, of course, depend on the particular application and on whether the propeller is driven from above or below. To avoid salting when the evaporator is used for crystallizing solutions, the liquid level must be kept appreciably above the top tube sheet.

Advantages of short-tube vertical evaporators:

1. High heat-transfer coefficients at high temperature differences
2. Low headroom
3. Easy mechanical descaling
4. Relatively inexpensive

Disadvantages of short-tube vertical evaporators:

1. Poor heat transfer at low temperature differences and low temperature
2. High floor space and weight
3. Relatively high holdup
4. Poor heat transfer with viscous liquids

Best applications of short-tube vertical evaporators:

1. Clear liquids
2. Crystalline product if propeller is used
3. Relatively noncorrosive liquids, since body is large and expensive if built of materials other than mild steel or cast iron
4. Mild scaling solutions requiring mechanical cleaning, since tubes are short and large in diameter

**Long-Tube Vertical Evaporators (Fig. 11-110*f, h, i*)** More total evaporation is accomplished in this type than in all the others combined because it is normally the *cheapest per unit of capacity.* The *long-tube vertical* (LTV) evaporator consists of a simple one-pass vertical shell-and-tube heat exchanger discharging into a relatively small vapor head. Normally, no liquid level is maintained in the vapor head, and the residence time of liquor is only a few seconds. The tubes are usually about 50.8 mm (2 in) in diameter but may be smaller than 25.4 mm (1 in). Tube length may vary from less than 6 to 10.7 m (20 to 35 ft) in the rising-film version and to as great as 20 m (65 ft) in the falling-film version. The evaporator is usually operated single-pass, concentrating from the feed to discharge density in just the time that it takes the liquid and evolved vapor to pass through a tube. An extreme case is the caustic high concentrator, producing a substantially anhydrous product at 370°C (700°F) from an inlet feed of 50 percent NaOH at 149°C (300°F) in one pass up 22-mm- (8/8-in-) OD nickel tubes 6 m (20 ft) long. The largest use of LTV evaporators is for concentrating black liquor in the pulp and paper industry. Because of the long tubes and relatively high heat-transfer coefficients, it is possible to achieve higher single-unit capacities in this type of evaporator than in any other.

The LTV evaporator shown in Fig. 11-110*f* is typical of those commonly used, especially for black liquor. Feed enters at the bottom of the tube and starts to boil partway up the tube, and the mixture of liquid and vapor leaving at the top at high velocity impinges against a deflector placed above the tube sheet. This deflector is effective both as a primary separator and as a foam breaker.

In many cases, as when the ratio of feed to evaporation or the ratio of feed to heating surface is low, it is desirable to provide for *recirculation of product* through the evaporator. This can be done in the type shown in Fig. 11-110*f* by adding a pipe connection between the product line and the feed line. Higher recirculation rates can be achieved in the type shown in Fig. 11-110*h,* which is used widely for condensed milk. By extending the enlarged portion of the vapor head still lower to provide storage space for liquor, this type can be used as a batch evaporator.

Liquid temperatures in the tubes of an LTV evaporator are far from uniform and are difficult to predict. At the lower end, the liquid is usually not boiling, and the liquor picks up heat as sensible heat. Since entering liquid velocities are usually very low, true heat-transfer coefficients are low in this nonboiling zone. At some point up the tube, the liquid starts to boil, and from that point on the liquid temperature decreases because of the reduction in static, friction, and acceleration heads until the vapor-liquid mixture reaches the top of the tubes at substantially the vapor-head temperature. Thus the true temperature difference in the boiling zone is always less than the total temperature difference as measured from steam and vapor-head temperatures.

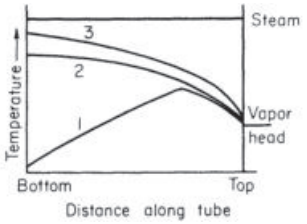

**FIG. 11-111** Temperature variations in a long-tube vertical evaporator.

Although the true heat-transfer coefficients in the boiling zone are quite high, they are partially offset by the reduced temperature difference. The point in the tubes at which boiling starts and at which the maximum temperature is reached is sensitive to operating conditions, such as feed properties, feed temperature, feed rate, and heat flux. Figure 11-111 shows typical variations in liquid temperature in tubes of an LTV evaporator operating at a constant terminal temperature difference. Curve 1 shows the normal case in which the feed is not boiling at the tube inlet. Curve 2 gives an indication of the temperature difference lost when the feed enters at the boiling point. Curve 3 is for exactly the same conditions as curve 2 except that the feed contained 0.01 percent Teepol to reduce surface tension [Coulson and Mehta, *Trans. Inst. Chem. Eng.* **31:** 208 (1953)]. The surface-active agent yields a more intimate mixture of vapor and liquid, with the result that liquid is accelerated to a velocity more nearly approaching the vapor velocity, thereby increasing the pressure drop in the tube. Although the surface-active agent caused an increase of more than 100 percent in the true heat-transfer coefficient, this was more than offset by the reduced temperature difference so that the net result was a reduction in evaporator capacity. This sensitivity of the LTV evaporator to changes in operating conditions is less pronounced at high than at low temperature differences and temperature levels.

The *falling-film* version of the LTV evaporator (Fig. 11-110*i*) eliminates these problems of hydrostatic head. Liquid is fed to the tops of the tubes and flows down the walls as a film. Vapor-liquid separation usually takes place at the bottom, although some evaporators of this type are arranged for vapor to rise through the tube countercurrently to the liquid. The pressure drop through the tubes is usually very small, and the boiling-liquid temperature is substantially the same as the vapor-head temperature. The falling-film evaporator is widely used for concentrating *heat-sensitive materials,* such as fruit juices, because the holdup time is very small, the liquid is not overheated during passage through the evaporator, and heat-transfer coefficients are high even at low boiling temperatures.

The principal problem with the falling-film LTV evaporator is *feed distribution* to the tubes. It is essential that all tube surfaces be wetted continually. This usually requires recirculation of the liquid unless the ratio of feed to evaporation is quite high. An alternative to the simple recirculation system of Fig. 11-110*i* is sometimes used when the feed undergoes an appreciable concentration change and the product is viscous and/or has a high boiling point rise. The feed chamber and vapor head are divided into a number of liquor compartments, and separate pumps are used to pass the liquor through the various banks of tubes in series, all in parallel as to steam and vapor pressures. The actual distribution of feed to the individual tubes of a falling-film evaporator may be accomplished by orifices at the inlet to each tube, by a perforated plate above the tube sheet, or by one or more spray nozzles.

Both rising- and falling-film LTV evaporators are generally unsuited to salting or severely scaling liquids. However, both are widely used for black liquor, which presents a mild scaling problem, and also are used to carry solutions beyond saturation with respect to a crystallizing salt. In the latter case, deposits can usually be removed quickly by increasing the feed rate or reducing the steam rate in order to make the product unsaturated for a short time. The falling-film evaporator is not generally suited to liquids containing solids because of difficulty in plugging the feed distributors. However, it has been applied to the evaporation of saline waters saturated with $CaSO_4$ and containing 5 to 10 percent $CaSO_4$ seeds in suspension for scale prevention (Anderson, ASME Pap. 76-WA/Pwr-5, 1976).

Because of their simplicity of construction, compactness, and generally high heat-transfer coefficients, LTV evaporators are well suited to service with corrosive liquids. An example is the reconcentration of rayon spin-bath liquor, which is highly acid. These evaporators employ impervious graphite tubes, lead, rubber-covered or impervious graphite tube sheets, and rubber-lined vapor heads. Polished stainless-steel LTV evaporators are widely used for food products. The latter evaporators are usually similar to that shown in Fig. 11-110*h,* in which the heating element is at one side of the vapor head to permit easy access to the tubes for cleaning.

Advantages of long-tube vertical evaporators:
1. Low cost
2. Large heating surface in one body
3. Low holdup
4. Small floor space
5. Good heat-transfer coefficients at reasonable temperature differences (rising film)
6. Good heat-transfer coefficients at all temperature differences ( falling film)

Disadvantages of long-tube vertical evaporators:
1. High headroom
2. Generally unsuitable for salting and severely scaling liquids
3. Poor heat-transfer coefficients of rising-film version at low temperature differences
4. Recirculation usually required for falling-film version

Best applications of long-tube vertical evaporators:
1. Clear liquids
2. Foaming liquids
3. Corrosive solutions
4. Large evaporation loads
5. High temperature differences—rising film, low temperature differences—falling film
6. Low-temperature operation—falling film
7. Vapor compression operation—falling film

Frequent difficulties with long-tube vertical evaporators:
1. Sensitivity of rising-film units to changes in operating conditions
2. Poor feed distribution to falling-film units

**Horizontal-Tube Evaporators (Fig. 11-110*j*)** In these types the steam is inside and the liquor outside the tubes. The submerged-tube version of Fig. 11-110*j* is seldom used except for the preparation of boiler feedwater. Low entrainment loss is the primary aim: the horizontal cylindrical shell yields a large disengagement area per unit of vessel volume. Special versions use deformed tubes between restrained tube sheets that crack off much of a scale deposit when sprayed with cold water. By showering liquor over the tubes in the version of Fig. 11-110*f,* hydrostatic head losses are eliminated and heat-transfer performance is improved to that of the falling-film tubular type of Fig. 11-110*i*. Originally called the *Lillie*, this evaporator is now also called the *spray-film* or simply the *horizontal-tube evaporator.* Liquid distribution over the tubes is accomplished by sprays or perforated plates above the topmost tubes. Maintaining this distribution through the bundle to avoid overconcentrating the liquor is a problem unique to this type of evaporator. It is now used primarily for seawater evaporation.

Advantages of horizontal-tube evaporators:
1. Very low headroom
2. Large vapor-liquid disengaging area—submerged-tube type
3. Relatively low cost in small-capacity straight-tube type
4. Good heat-transfer coefficients
5. Easy semiautomatic descaling—bent-tube type

Disadvantages of horizontal-tube evaporators:
1. Unsuitable for salting liquids
2. Unsuitable for scaling liquids—straight-tube type
3. High cost—bent-tube type
4. Maintaining liquid distribution—film type

Best applications of horizontal-tube evaporators:
1. Limited headroom
2. Small capacity
3. Nonscaling nonsalting liquids—straight-tube type
4. Severely scaling liquids—bent-tube type

**Miscellaneous Forms of Heating Surface** Special evaporator designs are sometimes indicated when heat loads are small, special product characteristics are desired, or the product is especially difficult to handle. *Jacketed kettles,* frequently with agitators, are used when the product is very viscous, batches are small, intimate mixing is required, and/or ease of cleaning is an important factor. Evaporators with steam in coiled *tubes* may be used for small capacities with scaling liquids in designs that permit "cold shocking," or complete withdrawal of the coil from the shell for manual scale removal. Other designs for scaling liquids employ flat-plate heat exchangers, since in general a scale deposit can be removed more easily from a flat plate than from a curved surface. One such design, the *channel-switching evaporator,* alternates the duty of either side of the heating surface periodically from boiling liquid to condensing vapor so that scale formed when the surface is in contact with boiling liquid is dissolved when the surface is next in contact with condensing vapor.

*Agitated thin-film evaporators* employ a heating surface consisting of one large-diameter tube that may be either straight or tapered, horizontal or vertical. Liquid is spread on the tube wall by a rotating assembly of blades that either maintain a close clearance from the wall or actually ride on the film of liquid on the wall. The expensive construction limits application to the most difficult materials. High agitation [on the order of 12 m/s (40 ft/s) rotor-tip speed] and power intensities of 2 to 20 kW/m$^2$ (0.25 to 2.5 hp/ft$^2$) permit handling extremely viscous materials. Residence times of only a few seconds permit concentration of heat-sensitive materials at temperatures and temperature differences higher than in other types [Mutzenberg, Parker, and Fischer, *Chem. Eng.* **72:** 175–190 (Sept. 13, 1965)]. High feed-to-product ratios can be handled without recirculation.

Economic and process considerations usually dictate that agitated thin-film evaporators be operated in single-effect mode. Very high temperature differences can then be used: many are heated with Dowtherm or other high-temperature media. This enables one to achieve reasonable capacities in spite of the relatively low heat-transfer coefficients and the small surface that can be provided in a single tube [to about 20 m$^2$ (200 ft$^2$)]. The structural need for wall thicknesses of 6 to 13 mm (¼ to ½ in) is a major reason for the relatively low heat-transfer coefficients when evaporating waterlike materials.

**Evaporators without Heating Surfaces** The *submerged-combustion* evaporator makes use of combustion gases bubbling through the liquid as the means of heat transfer. It consists simply of a tank to hold the liquid, a burner and gas distributor that can be lowered into the liquid, and a combustion control system. Since there are no heating surfaces on which scale can deposit, this evaporator is well suited to use with severely scaling liquids. The ease of constructing the tank and burner of special alloys or nonmetallic materials makes practical the handling of highly corrosive solutions. However, since the vapor is mixed with large quantities of noncondensible gases, it is impossible to reuse the heat in this vapor, and installations are usually limited to areas of low fuel cost. One difficulty frequently encountered in the use of submerged-combustion evaporators is a high entrainment loss. Also, these evaporators cannot be used when control of crystal size is important.

*Disk* or *cascade evaporators* are used in the pulp and paper industry to recover heat and entrained chemicals from boiler stack gases and to effect a final concentration of the black liquor before it is burned in the boiler. These evaporators consist of a horizontal shaft on which are mounted disks perpendicular to the shaft or bars parallel to the shaft. The assembly is partially immersed in the thick black liquor so that films of liquor are carried into the hot-gas stream as the shaft rotates.

Some forms of *flash evaporators* require no heating surface. An example is a recrystallizing process for separating salts having normal solubility curves from salts having inverse solubility curves, as in separating sodium chloride from calcium sulfate [Richards, *Chem. Eng.* **59**(3): 140 (1952)]. A suspension of raw solid feed in a recirculating brine stream is heated by direct steam injection. The increased temperature and dilution by the steam dissolve the salt having the normal solubility curve. The other salt remains undissolved and is separated from the hot solution before it is flashed to a lower temperature. The cooling and loss of water on flashing cause recrystallization of the salt having the normal solubility curve, which is separated from the brine before the brine is mixed with more solid feed for recycling to the heater. This system can be operated as a multiple effect by flashing down to the lower temperature in stages and using flash vapor from all but the last stage to heat the recycle brine by direct injection. In this process no net evaporation occurs from the total system, and the process cannot be used to concentrate solutions unless heating surfaces are added.

## UTILIZATION OF TEMPERATURE DIFFERENCE

Temperature difference is the driving force for evaporator operation and usually is limited, as by compression ratio in vapor compression evaporators and by available steam pressure and heat-sink temperature in single- and multiple-effect evaporators. A fundamental objective of evaporator design is to make as much of this total temperature difference available for heat transfer as is economically justifiable. Some losses in temperature difference, such as those due to *boiling point rise* (BPR), are unavoidable. However, even these can be minimized, such as by passing the liquor through effects or through different sections of a single effect in series so that only a portion of the heating surface is in contact with the strongest liquor.

Figure 11-112 shows approximate BPR losses for a number of process liquids. A correlation for concentrated solutions of many inorganic salts

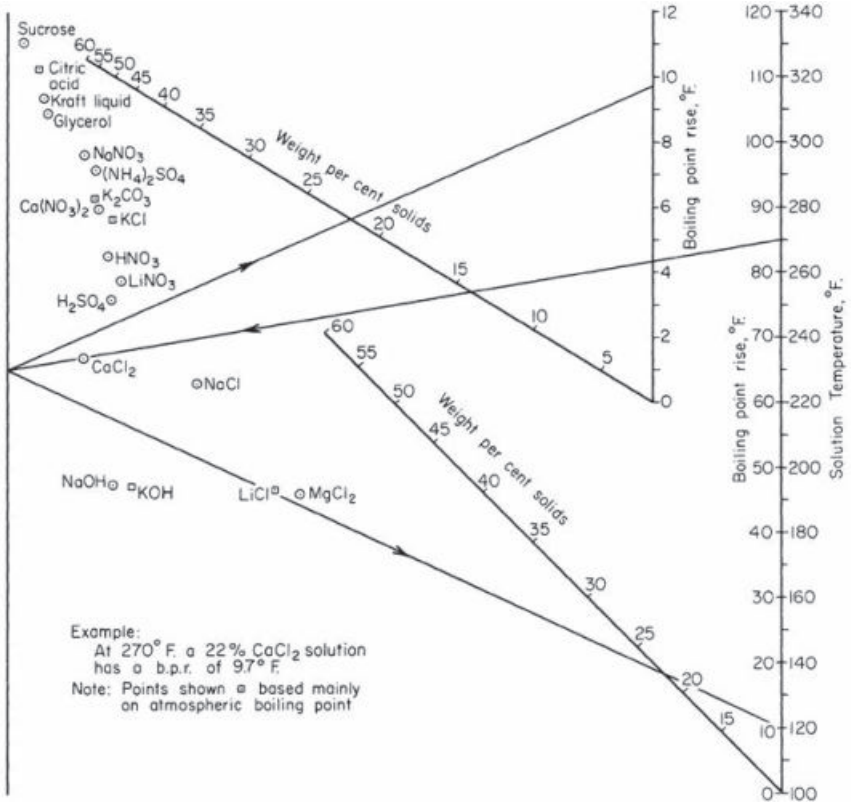

**FIG. 11-112** Boiling-point rise of aqueous solutions. °C = 5/9 (°F − 32).

at the atmospheric pressure boiling point [Meranda and Furter, *J. Ch. and E. Data* **22:** 315–7 (1977)] is

$$\text{BPR} = 104.9N_2^{1.14} \tag{11-108}$$

where $N_2$ is the mole fraction of salts in solution. Correction to other pressures, when heats of solution are small, can be based on a constant ratio of vapor pressure of the solution to that of water at the same temperature.

The principal reducible loss in $\Delta T$ is that due to friction and to entrance and exit losses in vapor piping and entrainment separators. Pressure-drop losses here correspond to a reduction in condensing temperature of the vapor and hence a loss in available $\Delta T$. These losses become most critical at the low-temperature end of the evaporator, both because of both the increasing specific volume of the vapor and the reduced slope of the vapor-pressure curve. Sizing of vapor lines is part of the economic optimization of the evaporator, extra costs of larger vapor lines being balanced against savings in $\Delta T$, which correspond to savings in heating-surface requirements. Note that entrance and exit losses in vapor lines usually exceed by several-fold the straight-pipe friction losses, so they cannot be ignored.

## VAPOR-LIQUID SEPARATION

Product losses in evaporator vapor may result from foaming, splashing, or entrainment. Primary separation of liquid from vapor is accomplished in the vapor head by making the horizontal plan area large enough that most of the entrained droplets can settle out against the rising flow of vapor. Allowable velocities are governed by the Souders-Brown equation $V = k\sqrt{(\rho_l - \rho_v)/\rho_v}$, in which $k$ depends on the size distribution of droplets and the decontamination factor $F$ desired. For most evaporators and for $F$ between 100 and 10,000, $k \cong 0.245/(F - 50)^{0.4}$ (Standiford, *Chemical Engineers' Handbook*, 4th ed., McGraw-Hill, New York, 1963, pp. 11–35). Higher values of $k$ (to about 0.15) can be tolerated in the falling-film evaporator, where most of the entrainment separation occurs in the tubes, the vapor is scrubbed by liquor leaving the tubes, and the vapor must reverse direction to reach the outlet.

*Foaming losses* usually result from the presence in the evaporating liquid of colloids or of surface-tension depressants and finely divided solids. Antifoam agents are often effective. Other means of combatting foam include the use of steam jets impinging on the foam surface, the removal of product at the surface layer, where the foaming agents seem to concentrate, and operation at a very low liquid level so that hot surfaces can break the foam. Impingement at high velocity against a baffle tends to break the foam mechanically, and this is the reason that the long-tube vertical, forced-circulation, and agitated-film evaporators are particularly effective with foaming liquids. Operating at lower temperatures and/or higher dissolved solids concentrations may also reduce foaming tendencies.

*Splashing losses* are usually insignificant if a reasonable height has been provided between the liquid level and the top of the vapor head. The height required depends on the violence of boiling. Heights of 2.4 to 3.6 m (8 to 12 ft) or more are provided in short-tube vertical evaporators, in which the liquid and vapor leaving the tubes are projected upward. Less height is required in forced-circulation evaporators, in which the liquid is given a centrifugal motion or is projected downward as by a baffle. The same is true of long-tube vertical evaporators, in which the rising vapor-liquid mixture is projected against a baffle.

*Entrainment losses by flashing* are frequently encountered in an evaporator. If the feed is above the boiling point and is introduced above or only a short distance below the liquid level, then entrainment losses may be excessive. This can occur in a short-tube-type evaporator if the feed is introduced at only one point below the lower tube sheet (Kerr, *Louisiana Agric. Expt. Stn. Bull.* 149, 1915). The same difficulty may be encountered in forced-circulation evaporators having too high a temperature rise through the heating element and thus too wide a flashing range as the circulating liquid enters the body. Poor vacuum control, especially during start-up, can cause the generation of far more vapor than the evaporator was designed to handle, with a consequent increase in entrainment.

*Entrainment separators* are frequently used to reduce product losses. There are a number of specialized designs available, practically all of which rely on a change in direction of the vapor flow when the vapor is traveling at high velocity. Typical separators are shown in Fig. 11-110, although not necessarily with the type of evaporator with which they may be used. The most common separator is the cyclone, which may have either a top or a bottom outlet, as shown in Fig. 11-110*a* and *b,* or may even be wrapped around the heating element of the next effect, as shown in Fig. 11-110*f.* The separation efficiency of a cyclone increases with an increase in inlet velocity, although at the cost of some pressure drop, which means a loss in available

temperature difference. Pressure drop in a cyclone is from 10 to 16 velocity heads [Lawrence, *Chem. Eng. Prog.* **48:** 241 (1952)], based on the velocity in the inlet pipe. Such cyclones can be sized in the same manner as a cyclone dust collector [using velocities of about 30 m/s (100 ft/s) at atmospheric pressure] although sizes may be increased somewhat in order to reduce losses in available temperature difference.

*Knitted wire mesh* serves as an effective entrainment separator when it cannot be easily fouled by solids in the liquor. The mesh is available in woven metal wire of most alloys and is installed as a blanket across the top of the evaporator (Fig. 11-110*d*) or in a monitor of reduced diameter atop the vapor head. These separators have low-pressure drops, usually on the order of 13 mm (½ in) of water, and collection efficiency is above 99.8 percent in the range of vapor velocities from 2.5 to 6 m/s (8 to 20 ft/s) [Carpenter and Othmer, *Am. Inst. Chem. Eng. J.* **1:** 549 (1955)]. Chevron (hook-and-vane) type of separators is also used because of the higher-allowable velocities or because of the reduced tendency to foul with solids suspended in the entrained liquid.

## EVAPORATOR ARRANGEMENT

**Single-Effect Evaporators** Single-effect evaporators are used when the required capacity is small, steam is cheap, the material is so corrosive that very expensive materials of construction are required, or the vapor is so contaminated that it cannot be reused. Single-effect evaporators may be operated in batch, semibatch, or continuous-batch modes or continuously. Strictly speaking, *batch evaporators* are ones in which filling, evaporating, and emptying are consecutive steps. This method of operation is rarely used since it requires that the body be large enough to hold the entire charge of feed and the heating element be placed low enough so as not to be uncovered when the volume is reduced to that of the product. The more usual method of operation is *semibatch,* in which feed is continually added to maintain a constant level until the entire charge reaches final density. *Continuous-batch* evaporators usually have a continuous feed and, over at least part of the cycle, a continuous discharge. One method of operation is to circulate from a storage tank to the evaporator and back until the entire tank is up to desired concentration and then to finish in batches. *Continuous evaporators* have essentially continuous feed and discharge, and concentrations of both feed and product remain substantially constant.

**Thermocompression** The simplest means of reducing the energy requirements of evaporation is to compress the vapor from a single-effect evaporator so that the vapor can be used as the heating medium in the same evaporator. The compression may be accomplished by mechanical means or by a steam jet. To keep the compressor cost and power requirements within reason, the evaporator must work with a fairly narrow temperature difference, usually from about 5.5°C to 11°C (10°F to 20°F). This means that a large evaporator heating surface is needed, which usually makes the vapor compression evaporator more expensive in first cost than a multiple-effect evaporator. However, total installation costs may be reduced when purchased power is the energy source, since the need for boiler and heat sink is eliminated. Substantial savings in operating cost are realized when electric or mechanical power is available at a low cost relative to low-pressure steam, when only high-pressure steam is available to operate the evaporator, or when the cost of providing cooling water or other heat sink for a multiple-effect evaporator is high.

*Mechanical thermocompression* may employ reciprocating, rotary positive-displacement, centrifugal, or axial-flow compressors. Positive-displacement compressors are impractical for all but the smallest capacities, such as portable seawater evaporators. Axial-flow compressors can be built for capacities of more than 472 $m^3/s$ ($1 \times 10^6$ $ft^3/min$). Centrifugal compressors are usually cheapest for the intermediate-capacity ranges that are normally encountered. In all cases, great care must be taken to keep entrainment at a minimum, since the vapor becomes superheated on compression and any liquid present will evaporate, leaving the dissolved solids behind. In some cases, a vapor-scrubbing tower may be installed to protect the compressor. A mechanical recompression evaporator usually requires more heat than is available from the compressed vapor. Some of this extra heat can be obtained by preheating the feed with the condensate and, if possible, with the product. Rather extensive heat-exchange systems with close approach temperatures are usually justified, especially if the evaporator is operated at high temperature to reduce the volume of vapor to be compressed. When the product is a solid, an elutriation leg such as that shown in Fig. 11-110*b* is advantageous, since it cools the product almost to the feed temperature. The remaining heat needed to maintain the evaporator in operation must be obtained from outside sources.

While theoretical compressor power requirements are reduced slightly by going to lower evaporating temperatures, the volume of vapor to be compressed and hence compressor size and cost increase so rapidly that low-temperature operation is more expensive than high-temperature operation. The requirement of low temperature for fruit juice concentration has led to the development of an evaporator employing a *secondary fluid,* usually Freon or ammonia. In this evaporator, the vapor is condensed in an exchanger cooled by boiling Freon. The Freon, at a much higher vapor density than the water vapor, is then compressed to serve as the heating medium for the evaporator. This system requires that the latent heat be transferred through two surfaces instead of one, but the savings in compressor size and cost are enough to justify the extra cost of heating surface or the cost of compressing through a wider temperature range.

*Steam-jet thermocompression* is advantageous when steam is available at a pressure appreciably higher than can be used in the evaporator. The steam jet then serves as a reducing valve while doing some useful work. The efficiency of a steam jet is quite low and falls off rapidly when the jet is not used at the vapor flow rate and terminal pressure conditions for which it was designed. Consequently, multiple jets are used when wide variations in evaporation rate are expected. Because of the low first cost and the ability to handle large volumes of vapor, steam-jet thermocompressors are used to increase the economy of evaporators that must operate at low temperatures and hence cannot be operated in multiple effect. The steam-jet thermocompression evaporator has a heat input larger than that needed to balance the system, and some heat must be rejected. This is usually done by venting some of the vapor at the suction of the compressor.

**Multiple-Effect Evaporation** Multiple-effect evaporation is the principal means in use for economizing on energy consumption. Most such evaporators operate on a continuous basis, although for a few difficult materials a continuous-batch cycle may be employed. In a multiple-effect evaporator, steam from an outside source is condensed in the heating element of the first effect. If the feed to the effect is at a temperature near the boiling point in the first effect, 1 kg of steam will evaporate almost 1 kg of water. The first effect operates at (but is not controlled at) a boiling temperature high enough that the evaporated water can serve as the heating medium of the second effect. Here almost another kilogram of water is evaporated, and this may go to a condenser if the evaporator is a double-effect or may be used as the heating medium of the third effect. This method may be repeated for any number of effects. Large evaporators having 6 and 7 effects are common in the pulp and paper industry, and evaporators having as many as 17 effects have been built. As a first approximation, the *steam economy* of a multiple-effect evaporator will increase in proportion to the number of effects and usually will be somewhat less numerically than the number of effects.

The increased steam economy of a multiple-effect evaporator is gained at the expense of evaporator first cost. The total heat-transfer surface will increase substantially in proportion to the number of effects in the evaporator. This is only an approximation since going from one to two effects means that about one-half of the heat transfer is at a higher temperature level, where heat-transfer coefficients are generally higher. On the other hand, operating at lower temperature differences reduces the heat-transfer coefficient for many types of evaporator. If the material has an appreciable boiling-point elevation, this will also lower the available temperature difference. The only accurate means of predicting the changes in steam economy and surface requirements with changes in the number of effects is by detailed heat and material balances together with an analysis of the effect of changes in operating conditions on heat-transfer performance.

The approximate temperature distribution in a multiple-effect evaporator is under the control of the designer, but once built, the evaporator establishes its own equilibrium. Basically, the effects are a number of series resistances to heat transfer, each resistance being approximately proportional to $1/U_nA_n$. The total available temperature drop is divided between the effects in proportion to their resistances. If one effect starts to scale, its temperature drop will increase at the expense of the temperature drops across the other effects. This provides a convenient means of detecting a drop in the heat-transfer coefficient in an effect of an operating evaporator. If the steam pressure and final vacuum do not change, the temperature in the effect that is scaling will decrease and the temperature in the preceding effect will increase.

The feed to a multiple-effect evaporator is usually transferred from one effect to another in series so that the ultimate product concentration is reached in only one effect of the evaporator. In backward-feed operation, the raw feed enters the last (coldest) effect, the discharge from this effect becomes the feed to the next-to-the-last effect, and so on until product is discharged from the first effect. This method of operation is advantageous when the feed is cold, since much less liquid must be heated to the higher temperature existing in the early effects. It is also used when the product is so viscous that high temperatures are needed to keep the viscosity low enough to give reasonable heat-transfer coefficients. When product viscosity is high but a hot product is not needed, the liquid from the first effect is sometimes flashed to a lower temperature in one or more stages and the flash vapor added to the vapor from one or more later effects of the evaporator.

In *forward-feed* operation, raw feed is introduced in the first effect and passed from effect to effect parallel to the steam flow. Product is withdrawn from the last effect. This method of operation is advantageous when the feed is hot or when the concentrated product would be damaged or would deposit scale at high temperature. Forward feed simplifies operation when liquor can be transferred by pressure difference alone, thus eliminating all intermediate liquor pumps. When the feed is cold, forward feed gives a low steam economy since an appreciable part of the prime steam is needed to heat the feed to the boiling point and thus accomplishes no evaporation. If forward feed is necessary and feed is cold, steam economy can be improved markedly by preheating the feed in stages with vapor bled from intermediate effects of the evaporator. This usually represents little increase in total heating surface or cost since the feed must be heated in any event and shell-and-tube heat exchangers are generally less expensive per unit of surface area than evaporator heating surface.

*Mixed-feed* operation is used only for special applications, as when liquor at an intermediate concentration and a certain temperature is desired for additional processing.

*Parallel feed* involves the introduction of raw feed and the withdrawal of product at each effect of the evaporator. It is used primarily when the feed is substantially saturated and the product is a solid. An example is the evaporation of brine to make common salt. Evaporators of the types shown in Fig. 11-110*b* or *e* are used, and the product is withdrawn as a slurry. In this case, parallel feed is desirable because the feed washes impurities from the salt leaving the body.

*Heat recovery systems* are frequently incorporated in an evaporator to increase the steam economy. Ideally, product and evaporator condensate should leave the system at a temperature as low as possible. Also, heat should be recovered from these streams by exchange with feed or evaporating liquid at the highest possible temperature. This would normally require separate liquid-liquid heat exchangers, which add greatly to the complexity of the evaporator and are justifiable only in large plants. Normally, the loss in thermodynamic availability due to flashing is tolerated since the flash vapor can then be used directly in the evaporator effects. The most commonly used is a *condensate flash* system in which the condensate from each effect but the first (which normally must be returned to the boiler) is flashed in successive stages to the pressure in the heating element of each succeeding effect of the evaporator. Product flash tanks may also be used in a backward- or mixed-feed evaporator. In a forward-feed evaporator, the principal means of heat recovery may be by use of *feed preheaters* heated by vapor bled from each effect of the evaporator. In this case, condensate may be either flashed as before or used in a separate set of exchangers to accomplish some of the feed preheating. A feed preheated by last-effect vapor may also materially reduce condenser water requirements.

**Seawater Evaporators** The production of potable water from saline water represents a large and growing field of application for evaporators. Extensive work done in this field to 1972 was summarized in the annual *Saline Water Conversion Reports* of the Office of Saline Water, U.S. Department of the Interior. *Steam economies* on the order of 10 kg evaporation/kg steam are usually justified because (1) unit production capacities are high, (2) fixed charges are low on capital used for public works (i.e., they use long amortization periods and have low interest rates, with no other return on investment considered), (3) heat-transfer performance is comparable with that of pure water, and (4) properly treated seawater causes little deterioration due to scaling or fouling.

Figure 11-113*a* shows a *multiple-effect* ( falling-film) flow sheet as used for seawater. Twelve effects are needed for a steam economy of 10. Seawater is used to condense last-effect vapor, and a portion is then treated to prevent scaling and corrosion. Treatment usually consists of acidification to break down bicarbonates, followed by deaeration, which also removes the carbon dioxide generated. The treated seawater is then heated to successively higher temperatures by a portion of the vapor from each effect and finally is fed to the evaporating surface of the first effect. The vapor generated therein and the partially concentrated liquid are passed to the second effect, and so on until the last effect. The feed rate is adjusted relative to the steam rate so that the residual liquid from the last effect can carry away all the salts in solution, in a volume about one-third of that of the feed. Condensate formed in each effect but the first is flashed down to the following effects in sequence and constitutes the product of the evaporator.

As the feed-to-steam ratio is increased in the flow sheet of Fig. 11-113*a*, a point is reached where all the vapor is needed to preheat the feed and none is available for the evaporator tubes. This limiting case is the *multistage flash evaporator,* shown in its simplest form in Fig. 11-113*b.* Seawater is treated as before and then pumped through a number of feed heaters in series. It is

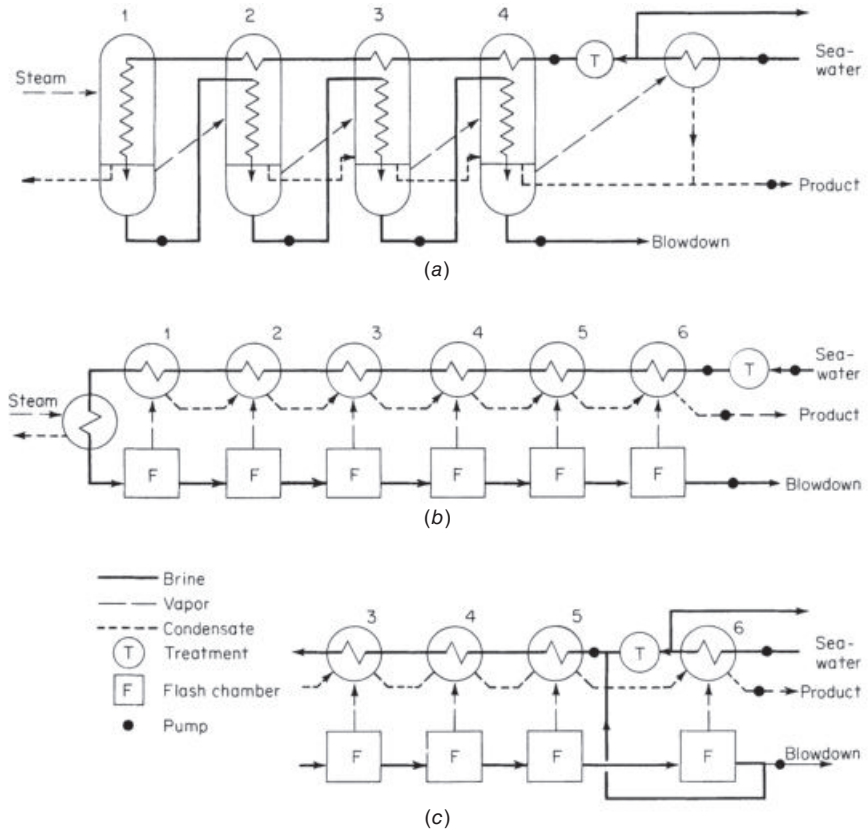

**FIG. 11-113** Flow sheets for seawater evaporators. (*a*) Multiple effect ( falling film). (*b*) Multistage flash (once-through). (*c*) Multistage flash (recirculating).

given a final boost in temperature with prime steam in a *brine heater* before it is flashed down in series to provide the vapor needed by the feed heaters. The amount of steam required depends on the approach-temperature difference in the feed heaters and the flash range per stage. Condensate from the feed heaters is flashed down in the same manner as the brine.

Since the flow being heated is identical to the total flow being flashed, the temperature rise in each heater is equal to the flash range in each flasher. This temperature difference represents a loss from the temperature difference available for heat transfer. There are thus two ways of increasing the steam economy of such plants: increasing the heating surface and increasing the number of stages. Whereas the number of effects in a multiple-effect plant will be about 20 percent greater than the steam economy, the number of stages in a flash plant will be 3 to 4 times the steam economy. However, a large number of stages can be provided in a single vessel by means of internal bulkheads. The heat-exchanger tubing is placed in the same vessel, and the tubes usually are continuous through a number of stages. This requires ferrules or special close tube-hole clearances where the tubes pass through the internal bulkheads. In a plant for a steam economy of 10, the ratio of flow rate to heating surface is usually such that the seawater must pass through about 152 m of 19-mm (500 ft of ¾-in) tubing before it reaches the brine heater. This places a limitation on the physical arrangement of the vessels.

Inasmuch as it requires a flash range of about 61°C (110°F) to produce 1 kg of flash vapor for every 10 kg of seawater, the multistage flash evaporator requires handling a large volume of seawater relative to the product. In the flow sheet of Fig. 11-113*b* all this seawater must be deaerated and treated for scale prevention. In addition, the last-stage vacuum varies with the ambient seawater temperature, and ejector equipment must be sized for the worst condition. These difficulties can be eliminated by using the *recirculating multistage flash* flow sheet of Fig. 11-113*c.* The last few stages, called the *reject stages,* are cooled by a flow of seawater that can be varied to maintain a reasonable last-stage vacuum. A small portion of the last-stage brine is blown down to carry away the dissolved salts, and the balance is recirculated to the *heat recovery stages.* This arrangement requires a much smaller makeup of fresh seawater and hence a lower treatment cost.

The multistage flash evaporator is similar to a multiple-effect forced-circulation evaporator, but with all the forced-circulation heaters in series. This has the advantage of requiring only one large-volume forced-circulation pump, but the sensible heating and short-circuiting losses in available temperature differences remain. A disadvantage of the flash evaporator is that the liquid throughout the system is at almost the discharge concentration. This has limited its industrial use to solutions in which no great concentration differences are required between feed and product and where the liquid can be heated through wide temperature ranges without scaling. A partial remedy is to arrange several multistage flash evaporators in series, the heat rejection section of one being the brine heater of the next. This permits independent control of concentration but eliminates the principal advantage of the flash evaporator, which is the small number of pumps and vessels required. An unusual feature of the flash evaporator is that fouling of the heating surfaces reduces primarily the steam economy rather than the capacity of the evaporator. Capacity is not affected until the heat rejection stages can no longer handle the increased flashing resulting from the increased heat input.

## EVAPORATOR CALCULATIONS

**Single-Effect Evaporators** The heat requirements of a single-effect continuous evaporator can be calculated by the usual methods of stoichiometry. If enthalpy data or specific heat and heat-of-solution data are not available, the heat requirement can be estimated as the sum of the heat needed to raise the feed from feed to product temperature and the heat required to evaporate the water. The latent heat of water is taken at the vapor-head pressure instead of at the product temperature in order to compensate partially for any heat of solution. If sufficient vapor pressure data are available for the solution, methods are available to calculate the true latent heat from the slope of the Dühring line [Othmer, *Ind. Eng. Chem.* **32:** 841 (1940)].

The heat requirements in batch evaporation are the same as those in continuous evaporation except that the temperature (and sometimes pressure) of the vapor changes during the course of the cycle. Since the enthalpy of water vapor changes but little relative to temperature, the difference between continuous and batch heat requirements is almost always negligible. More important usually is the effect of variation of fluid properties, such as viscosity and boiling point rise, on heat transfer. These can only be estimated by a step-by-step calculation.

In selecting the *boiling temperature,* consideration must be given to the effect of temperature on heat-transfer characteristics of the type of evaporator to be used. Some evaporators show a marked drop in coefficient at low temperature—more than enough to offset any gain in available temperature difference. The condenser cooling-water temperature and cost must also be considered.

**Thermocompression Evaporators** Thermocompression evaporator calculations [Pridgeon, *Chem. Metall. Eng.* **28:** 1109 (1923); Peter, *Chimia* (*Switzerland*) **3:** 114 (1949); Petzold, *Chem. Ing. Tech.* **22:** 147 (1950); and Weimer, Dolf, and Austin, *Chem. Eng. Prog.* **76**(11): 78 (1980)] are much the same as single-effect calculations with the added complication that the heat supplied to the evaporator from compressed vapor and other sources must exactly balance the heat requirements. Some knowledge of compressor efficiency is also required. Large axial-flow machines on the order of 236 $m^3/s$ (500,000 $ft^3/min$) capacity may have efficiencies of 80 to 85 percent. Efficiency drops to about 75 percent for a 14 $m^3/s$ (30,000 $ft^3/min$) centrifugal compressor. Steam-jet compressors have thermodynamic efficiencies on the order of only 25 to 30 percent.

**Flash Evaporators** The calculation of a heat and material balance on a flash evaporator is relatively easy once it is understood that the temperature rise in each heater and the temperature drop in each flasher must all be substantially equal. The steam economy *E,* kg evaporation/kg of 1055-kJ steam (lb/lb of 1000-Btu steam) may be approximated from

$$E = \left(1 - \frac{\Delta T}{1250}\right)\frac{\Delta T}{Y + R + \Delta T/N} \tag{11-109}$$

where $\Delta T$ is the total temperature drop between feed to the first flasher and discharge from the last flasher, °C; $N$ is the number of flash stages; $Y$ is the approach between vapor temperature from the first flasher and liquid leaving the heater in which this vapor is condensed, °C (the approach is usually substantially constant for all stages); and $R$°C is the sum of the boiling-point rise and the short-circuiting loss in the first flash stage. The expression for the mean effective temperature difference $\Delta t$ available for heat transfer then becomes

$$\Delta t = \frac{\Delta T}{N \ln \dfrac{1 - \Delta T/1250 - RE/\Delta T}{1 - \Delta T/1250 - RE/\Delta T - E/N}} \tag{11-110}$$

**Multiple-Effect Evaporators** A number of approximate methods have been published for estimating performance and heating-surface requirements of a multiple-effect evaporator [Coates and Pressburg, *Chem. Eng.* **67**(6): 157 (1960); Coates, *Chem. Eng. Prog.* **45:** 25 (1949); and Ray and Carnahan, *Trans. Am. Inst. Chem. Eng.* **41:** 253 (1945)]. However, because of the wide variety of methods of feeding and the added complication of feed heaters and condensate flash systems, the only certain way to determine performance is by detailed heat and material balances. Algebraic solutions may be used, but if more than a few effects are involved, trial-and-error methods are usually quicker. These frequently involve trial-and-error within trial-and-error solutions. Usually, if condensate flash systems or feed heaters are involved, it is best to start at the first effect. The basic steps in the calculation are then as follows:

1. Estimate temperature distribution in the evaporator, taking into account boiling-point elevations. If all heating surfaces are to be equal, the temperature drop across each effect will be approximately inversely proportional to the heat-transfer coefficient in that effect.
2. Determine total evaporation required, and estimate steam consumption for the number of effects chosen.
3. From assumed feed temperature (forward feed) or feed flow (backward feed) to the first effect and assumed steam flow, calculate evaporation in the first effect. Repeat for each succeeding effect, checking intermediate assumptions as the calculation proceeds. Heat input from condensate flash can be incorporated easily since the condensate flow from the preceding effects will have already been determined.
4. The result of the calculation will be a feed to or a product discharge from the last effect that may not agree with actual requirements. The calculation must then be repeated with a new assumption of steam flow to the first effect.
5. These calculations should yield liquor concentrations in each effect that enable a revised estimate of boiling-point rises. They also give the quantity of heat that must be transferred in each effect. From the heat loads, assumed temperature differences, and heat-transfer coefficients, the heating-surface requirements can be determined. If the distribution of heating surface is not as desired, the entire calculation may need to be repeated with revised estimates of the temperature in each effect.
6. If sufficient data are available, heat-transfer coefficients under the proposed operating conditions can be calculated in greater detail and surface requirements readjusted.

Such calculations require considerable judgment to avoid repetitive trials but are usually well worth the effort. Sample calculations are given in

the American Institute of Chemical Engineers' *Testing Procedure for Evaporators* and by Badger and Banchero, *Introduction to Chemical Engineering,* McGraw-Hill, New York, 1955. These balances may be done by computer, but programming time frequently exceeds the time needed to do them manually, especially when variations in flow sheet are to be investigated. The MASSBAL program of SACDA, London, Ont., provides a considerable degree of flexibility in this regard. Another program, not specific to evaporators, is ASPEN PLUS by Aspen Tech., Cambridge, Mass. Many such programs include simplifying assumptions and approximations that are not explicitly stated and can lead to erroneous results.

**Optimization** The primary purpose of evaporator design is to enable production of the necessary amount of satisfactory product at the lowest total cost. This requires economic-balance calculations that may include a great number of variables. Among the possible variables are the following:

1. Initial steam pressure versus cost or availability.
2. Final vacuum versus water temperature, water cost, heat-transfer performance, and product quality.
3. Number of effects versus steam, water, and pump power cost.
4. Distribution of heating surface between effects versus evaporator cost.
5. Type of evaporator versus cost and continuity of operation.
6. Materials of construction versus product quality, tube life, evaporator life, and evaporator cost.
7. Corrosion, erosion, and power consumption versus tube velocity.
8. Downtime for retubing and repairs.
9. Operating-labor and maintenance requirements.
10. Method of feeding and use of heat recovery systems.
11. Size of recovery heat exchangers.
12. Possible withdrawal of steam from an intermediate effect for use elsewhere.
13. Entrainment separation requirements.

The type of evaporator to be used and the materials of construction are generally selected on the basis of past experience with the material to be concentrated. The method of feeding can usually be decided on the basis of known feed temperature and the properties of feed and product. However, few of the listed variables are completely independent. For instance, if a large number of effects are to be used, with a consequent low temperature drop per effect, it is impractical to use a natural-circulation evaporator. If expensive materials of construction are desirable, it may be found that the forced-circulation evaporator is the cheapest and that only a few effects are justifiable.

The variable having the greatest influence on total cost is the number of effects in the evaporator. An economic balance can establish the optimum number where the number is not limited by such factors as viscosity, corrosiveness, freezing point, boiling-point rise, or thermal sensitivity. Under present U.S. conditions, savings in steam and water costs justify the extra capital, maintenance, and power costs of about seven effects in large commercial installations when the properties of the fluid are favorable, as in black-liquor evaporation. Under government financing conditions, as for plants to supply freshwater from seawater, evaporators containing from 12 to 30 or more effects can be justified.

As a general rule, the optimum number of effects increases with an increase in steam cost or plant size. Larger plants favor more effects, partly because they make it easier to install heat recovery systems that increase the steam economy attainable with a given number of effects. Such recovery systems usually do not increase the total surface needed, but do require that the heating surface be distributed between a greater number of pieces of equipment.

The most common evaporator design is based on the use of the same heating surface in each effect. This is by no means essential since few evaporators are "standard" or involve the use of the same patterns. In fact, there is no reason why all effects in an evaporator must be of the same type. For instance, the cheapest salt evaporator might use propeller calandrias for the early effects and forced-circulation effects at the low-temperature end, where their higher cost per unit area is more than offset by higher heat-transfer coefficients.

Bonilla [*Trans. Am. Inst. Chem. Eng.* **41:** 529 (1945)] developed a simplified method for distributing the heating surface in a multiple-effect evaporator to achieve minimum cost. If the cost of the evaporator per unit area of heating surface is constant throughout, then minimum cost and area will be achieved if the ratio of area to temperature difference $A/\Delta T$ is the same for all effects. If the cost per unit area $z$ varies, as when different tube materials or evaporator types are used, then $zA/\Delta T$ should be the same for all effects.

## EVAPORATOR ACCESSORIES

**Condensers** The vapor from the last effect of an evaporator is usually removed by a condenser. *Surface condensers* are employed when mixing of condensate with condenser cooling water is not desired. For the most part, they are shell-and-tube condensers with vapor on the shell side and a multipass flow of cooling water on the tube side. Heat loads, temperature differences, sizes, and costs are usually of the same order of magnitude as for another effect of the evaporator. Surface condensers use more cooling water and are so much more expensive that they are never used when a direct-contact condenser is suitable.

The most common type of direct-contact condenser is the countercurrent *barometric condenser,* in which vapor is condensed by rising against a rain of cooling water. The condenser is set high enough that water can discharge by gravity from the vacuum in the condenser. Such condensers are inexpensive and are economical on water consumption. They can usually be relied on to maintain a vacuum corresponding to a saturated-vapor temperature within 2.8°C (5°F) of the water temperature leaving the condenser [How, *Chem. Eng.* **63**(2): 174 (1956)]. The ratio of water consumption to vapor condensed can be determined from the following equation:

$$\frac{\text{Water flow}}{\text{Vapor flow}} = \frac{H_v - h_2}{h_2 - h_1} \tag{11-111}$$

where $H_v$ = vapor enthalpy and $h_1$ and $h_2$ = water enthalpies entering and leaving the condenser. Another type of direct-contact condenser is the *jet* or *wet condenser,* which makes use of high-velocity jets of water both to condense the vapor and to force noncondensible gases out the tailpipe. This type of condenser is frequently placed below barometric height and requires a pump to remove the mixture of water and gases. Jet condensers usually require more water than the more common barometric-type condensers and cannot be throttled easily to conserve water when operating at low evaporation rates.

**Vent Systems** Noncondensible gases may be present in the evaporator vapor as a result of leakage, air dissolved in the feed, or decomposition reactions in the feed. When the vapor is condensed in the succeeding effect, the noncondensibles increase in concentration and impede heat transfer. This occurs partially because of the reduced partial pressure of vapor in the mixture but mainly because the vapor flow toward the heating surface creates a film of poorly conducting gas at the interface. (See Thermal Design of Condensers, Multicomponent Condensers earlier in this section for means of estimating the effect of noncondensible gases on the steam-film coefficient.) The most important means of reducing the influence of noncondensibles on heat transfer is by properly channeling them past the heating surface. A positive vapor flow path from inlet to vent outlet should be provided, and the path should preferably be tapered to avoid pockets of low velocity where noncondensibles can be trapped. Excessive clearances and low-resistance channels that could bypass vapor directly from the inlet to the vent should be avoided [Standiford, *Chem. Eng. Prog.* **75:** 59–62 (July 1979)].

In any event, noncondensible gases should be vented well before their concentration reaches 10 percent. Since gas concentrations are difficult to measure, the usual practice is to overvent. This means that an appreciable amount of vapor can be lost.

To help conserve steam economy, venting is usually done from the steam chest of one effect to the steam chest of the next. In this way, excess vapor in one vent does useful evaporation at a steam economy only about 1 less than the overall steam economy. Only when there are large amounts of noncondensible gases present, as in beet sugar evaporation, is it desirable to pass the vents directly to the condenser to avoid serious losses in heat-transfer rates. In such cases, it can be worthwhile to recover heat from the vents in separate heat exchangers, which preheat the entering feed.

The noncondensible gases eventually reach the condenser (unless vented from an effect above atmospheric pressure to the atmosphere or to auxiliary vent condensers). These gases will be supplemented by air dissolved in the condenser water and by carbon dioxide given off on decomposition of bicarbonates in the water if a barometric condenser is used. These gases may be removed by the use of a water-jet-type condenser but are usually removed by a separate vacuum pump.

The vacuum pump is usually of the steam-jet type if high-pressure steam is available. If high-pressure steam is not available, more expensive mechanical pumps may be used. These may be either a water-ring (Hytor) type or a reciprocating pump.

The primary source of noncondensible gases usually is air dissolved in the condenser water. Figure 11-114 shows the dissolved-gas content of freshwater and seawater, calculated as equivalent air. The lower curve for seawater includes only dissolved oxygen and nitrogen. The upper curve includes carbon dioxide that can be evolved by complete breakdown of bicarbonate in seawater. Breakdown of bicarbonates is usually not appreciable in a condenser but may go almost to completion in a seawater evaporator. The large increase in gas volume as a result of possible bicarbonate breakdown is illustrative of the uncertainties involved in sizing vacuum systems.

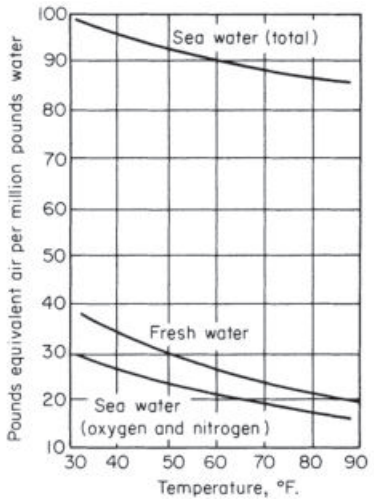

**FIG. 11-114** Gas content of water saturated at atmospheric pressure. °C = 5/9 (°F − 32).

By far the largest load on the vacuum pump is water vapor carried with the noncondensible gases. Standard power-plant practice assumes that the mixture leaving a surface condenser will have been cooled 4.2°C (7.5°F) below the saturation temperature of the vapor. This usually corresponds to about 2.5 kg water vapor/kg air. One advantage of the countercurrent barometric condenser is that it can cool the gases almost to the temperature of the incoming water and thus reduce the amount of water vapor carried with the air.

In some cases, as with pulp mill liquors, the evaporator vapors contain constituents more volatile than water, such as methanol and sulfur compounds. Special precautions may be necessary to minimize the effects of these compounds on heat transfer, corrosion, and condensate quality. They can include removing most of the condensate countercurrent to the vapor entering an evaporator heating element, channeling vapor and condensate flow to concentrate most of the "foul" constituents into the last fraction of vapor condensed (and keeping this condensate separate from the rest of the condensate), and flashing the warm evaporator feed to a lower pressure to remove much of the foul constituents in only a small amount of flash vapor. In all such cases, special care is needed to properly channel vapor flow past the heating surfaces so there is a positive flow from steam inlet to vent outlet with no pockets, where foul constituents or noncondensibles can accumulate.

**Salt Removal** When an evaporator is used to make a crystalline product, a number of means are available for concentrating and removing the salt from the system. The simplest is to provide settling space in the evaporator itself. This is done in the types shown in Fig. 11-110*b, c,* and *e* by providing a relatively quiescent zone in which the salt can settle. Sufficiently high slurry densities can usually be achieved in this manner to reach the limit of pumpability. The evaporators are usually placed above barometric height so that the slurry can be discharged intermittently on a short time cycle. This permits the use of high velocities in large lines that have little tendency to plug.

If the amount of salts crystallized is on the order of 1 ton/h or less, a salt trap may be used. This is simply a receiver that is connected to the bottom of the evaporator and is closed off from the evaporator periodically for emptying. Such traps are useful when insufficient headroom is available for gravity removal of the solids. However, traps require a great deal of labor, give frequent trouble with the shutoff valves, and also can upset evaporator operation completely if a trap is reconnected to the evaporator without first displacing all air with feed liquor.

## EVAPORATOR OPERATION

The two principal elements of evaporator control are *evaporation rate* and *product concentration.* Evaporation rate in single- and multiple-effect evaporators is usually achieved by steam flow control. Conventional-control instrumentation is used (see Sec. 22), with the added precaution that the pressure drop across the meter and control valve, which reduces temperature difference available for heat transfer, not be excessive when maximum capacity is desired. Capacity control of thermocompression evaporators depends on the type of compressor; positive-displacement compressors can utilize speed control or variations in operating pressure level. Centrifugal machines normally utilize adjustable inlet-guide vanes. Steam jets may have an adjustable spindle in the high-pressure orifice or be arranged as multiple jets that can individually be cut out of the system.

Product concentration can be controlled by any property of the solution that can be measured with the requisite accuracy and reliability. The preferred method is to impose control on the rate of product withdrawal. Feed rates to the evaporator effects are then controlled by their levels. When level control is impossible, as with the rising-film LTV, product concentration is used to control the feed rate—frequently by ratioing of feed to steam with the ratio reset by product concentration, sometimes also by feed concentration. Other controls that may be needed include vacuum control of the last effect (usually by air bleed to the condenser) and temperature-level control of thermocompression evaporators (usually by adding makeup heat or by venting excess vapor, or both, as feed or weather conditions vary). For more control details, see N. Lior, ed., *Measurement and Control in Water Desalination,* Elsevier Science Publ. Co., New York, 1986, pp. 241–305.

Control of an evaporator requires more than proper instrumentation. Operator logs should reflect changes in basic characteristics, as by use of *pseudo heat-transfer* coefficients, which can detect obstructions to heat flow, hence to capacity. These are merely the ratio of any convenient measure of heat flow to the temperature drop across each effect. *Dilution* by wash and seal water should be monitored since it absorbs evaporative capacity. Detailed tests, routine measurements, and operating problems are covered more fully in AICE, *Testing Procedure for Evaporators* and by Standiford [*Chem. Eng. Prog.* **58**(11): 80 (1962)].

By far the best application of computers to evaporators is for working up operators' data into the basic performance parameters such as heat-transfer coefficients, steam economy, and dilution.

### Nomenclature and Units

| Symbol | Definition | SI units | U.S. Customary System units |
|---|---|---|---|
| $A$ | Area | $m^2$ | $ft^2$ |
| $a_w$ | Water activity | — | — |
| $a_w^{vapor}$ | Activity of water in vapor phase | — | — |
| $a_w^{solid}$ | Activity of water in solid phase | — | — |
| $C$ | Concentration | $kg/m^3$ | $lb/ft^3$ |
| $C_p$ | Specific heat capacity at constant pressure | $J/(kg \cdot K)$ | $Btu/(lb \cdot °F)$ |
| $C_w$ | Concentration of water in solid | $kg/m^3$ | $lb/ft^3$ |
| $D(u)$ | Diffusion coefficient of water in a solid or liquid as a function of moisture content | $m^2/s$ | $ft^2/s$ |
| $D_{water/air}$ | Diffusion coefficient of water in air | $m^2/s$ | $ft^2/s$ |
| $D$ | Diameter (particle) | m | in |
| $E$ | Power | W | Btu/h |
| $F$ | Solids or liquid mass flow rate | kg/s | lb/h |
| $F$ | Mass flux of water at surface | $kg/(m^2 \cdot s)$ | $lb/(ft^2 \cdot s)$ |
| $F$ | Relative drying rate | — | — |
| $G$ | Gas mass flow rate | kg/s | lb/h |
| $g$ | Acceleration due to gravity, 9.81 $m/s^2$ (32.2 $ft/s^2$) | $m/s^2$ | $ft/s^2$ |
| $H$ | Enthalpy of a pure substance | J/kg | Btu/lb |

| Symbol | Definition | SI units | U.S. Customary System units |
|---|---|---|---|
| $\Delta H_{vap}$ | Heat of vaporization | J/kg | Btu/lb |
| $h$ | Heat-transfer coefficient | $W/(m^2 \cdot K)$ | $Btu/(ft^2 \cdot h \cdot °F)$ |
| $I$ | Humid enthalpy (dry substance and associated moisture or vapor) | J/kg | Btu/lb |
| $J$ | Mass flux (of evaporating liquid) | $kg/(m^2 \cdot s)$ | $lb/(ft^2 \cdot h)$ |
| $K$ | Mass-transfer coefficient | m/s | $lb/(ft^2 \cdot h \cdot atm)$ |
| $k_{air}$ | Thermal conductivity of air | $W/(m \cdot K)$ | $Btu/(ft \cdot h \cdot °F)$ |
| $k_c$ | Mass-transfer coefficient for a concentration driving force | m/s | $ft^2/s$ |
| $k_p$ | Mass-transfer coefficient for a partial pressure driving force | $kg/(m^2 \cdot s)$ | $lbm/(ft^3 \cdot s)$ |
| $L$ | Length; length of drying layer | m | ft |
| $M$ | Molecular weight | kg/mol | lb/mol |
| $m$ | Mass | kg | lb |
| $m_{solids}$ | Mass of dry solids | kg | lb |
| $N$ | Specific drying rate ($-dX/dt$) | 1/s | 1/s |
| $N$ | Rotational speed (drum, impeller, etc.) | 1/s | rpm |
| $P$ | Total pressure | $kg/(m \cdot s^2)$ | $lb/in^2$ |
| $P_w^{bulk}$ | Partial pressure of water vapor in air far from the drying material | $kg/(m \cdot s^2)$ | $lb/in^2$ |
| $P_w^{surface}$ | Partial pressure of water vapor in air at the solid interface | $kg/(m \cdot s^2)$ | $lb/in^2$ |

| Symbol | Definition | SI units | U.S. Customary System units |
|---|---|---|---|
| $P$ | Partial pressure/vapor pressure of component | $kg/(m \cdot s^2)$ | $lb/in^2$ |
| $p^{sat}_{pure}$ | Pure component vapor pressure | $kg/(m \cdot s^2)$ | $lb/in^2$ |
| $p_w$, air | Partial pressure of water vapor in air | $kg/(m \cdot s^2)$ | $lb/in^2$ |
| $Q$ | Heat-transfer rate | W | Btu/h |
| $Q$ | Heat flux | $W/m^2$ | $Btu/(ft^2 \cdot h)$ |
| $R$ | Universal gas constant, 8314 J/(kmol · K) | J/(mol · K) | Btu/(mol · °F) |
| $r$ | Droplet radius | m | ft |
| $r$ | Radius; radial coordinate | m | ft |
| RH | Relative humidity | — | — |
| $S$ | Percentage saturation | — | — |
| $S$ | Solid-fixed coordinate | Depends on geometry | |
| $T$ | Absolute temperature | K | °R |
| $T, t$ | Temperature | °C | °F |
| $T$ | Time | s | h |
| $U$ | Velocity | m/s | ft/s |
| $U$ | Mass of water/mass of dry solid | — | — |
| $V$ | Volume | $m^3$ | $ft^3$ |
| $V$ | Air velocity | m/s | ft/s |
| $\upsilon$ | Specific volume | $m^3/kg$ | $ft^3/lb$ |
| $\upsilon_{droplet}$ | Droplet volume | $m^3$ | $ft^3$ |
| $W$ | Wet-basis moisture content | — | — |
| $w_{avg\ dry\text{-}basis}$ | Average wet-basis moisture content | — | — |
| $X$ | Solids moisture content (dry basis) | — | — |
| $Y$ | Mass ratio | — | — |
| $Z$ | Distance coordinate | m | ft |
| | Dimensionless groups | | |
| Ar | Archimedes number, $(gd_p^3\rho g/\mu^2)(\rho_p - \rho_G)$ | — | — |
| Bi | Biot number, $hL/\kappa$ | — | — |

Psychrometry is concerned with the determination of the properties of gas-vapor mixtures. These are important in calculations for humidification and dehumidification, particularly in cooling towers, air-conditioning systems, and dryers. The first two cases involve the air–water vapor system at near-ambient conditions, but dryers normally operate at elevated temperatures and may also use elevated or subatmospheric pressures and other gas-solvent systems.

## TERMINOLOGY

Terminology and nomenclature pertinent to psychrometry are given below. There is often considerable confusion between the dry and wet basis, and between mass, molar, and volumetric quantities, in both definitions and calculations. Dry- and wet-basis humidities are similar at ambient conditions but can differ significantly at elevated humidities, e.g., in dryer exhaust streams. Complete interconversion formulas between four key humidity parameters are given in Table 12-1 for the air-water system and in Table 12-2 for a general gas-vapor system.

Definitions related to humidity, vapor pressure, saturation, and volume are as follows; the most useful are absolute humidity, vapor pressure, and relative humidity.

***Absolute Humidity Y*** Mass of water (or solvent) vapor carried by unit mass of dry air (or other carrier gas). It is also known as the *humidity ratio, mixing ratio, mass ratio,* or *dry-basis humidity.* Preferred units are lb/lb or kg/kg, but g/kg and gr/lb are often used, as are $ppm_w$ and $ppb_w$ (parts per million/billion by weight); $ppm_w = 10^6 Y$, $ppb_w = 10^9 Y$.

***Specific Humidity $Y_W$*** Mass of vapor per unit mass of gas-vapor mixture. Also known as *mass fraction* or *wet-basis humidity*, and is used much more rarely than dry-basis absolute humidity. $Y_W = Y/(1 + Y)$; $Y = Y_W/(1 - Y_W)$.

***Mole Ratio z*** Number of moles of vapor per mole of gas (dry basis), mol/mol; $z = (M_g/M_\upsilon)Y$, where $M_\upsilon$ = molecular weight of vapor and $M_g$ = molecular weight of gas. It may also be expressed as $ppm_v$ and $ppb_v$ (parts per million/billion by volume); $ppm_v = 10^6\, z$, $ppb_v = 10^9\, z$.

**TABLE 12-1 Interconversion Formulas for Air-Water System, to Three Significant Figures**

$T$ = temperature in **kelvins** (K); $P$ = total pressure in **pascals** (Pa or N/m$^2$)

| Convert from: | $Y$ (or ppm$_w$)* | $y$ | $p$ | $Y_\upsilon$ |
|---|---|---|---|---|
| Convert to: Absolute humidity (mixing ratio) $Y$ (kg · kg$^{-1}$) | 1 | $Y=\dfrac{0.622Y}{1-Y}$ | $Y=\dfrac{0.622\,p}{P-p}$ | $Y=\dfrac{0.622}{0.002167\,P/(Y_\upsilon T)-1}$ |
| Mole fraction $y$ (mol · mol$^{-1}$) | $y=\dfrac{Y}{0.622+Y}$ | 1 | $y=\dfrac{p}{P}$ | $y=\dfrac{461.5Y_\upsilon T}{P}$ |
| Vapor pressure $p$ (Pa) | $p=\dfrac{PY}{0.622+Y}$ | $p=yP$ | 1 | $p=461.5Y_\upsilon T$ |
| Volumetric humidity $Y_\upsilon$ (kg · m$^{-3}$) | $Y_\upsilon=\dfrac{0.002167\,PY}{(0.622+Y)T}$ | $Y_\upsilon=\dfrac{0.002167\,yP}{T}$ | $Y_\upsilon=\dfrac{0.002167\,p}{T}$ | 1 |

***Mole Fraction y*** Number of moles of vapor per mole of gas-vapor mixture (wet basis); $y=z/(1+z)$; $z=y/(1-y)$. If a mixture contains $m_\upsilon$ kg and $n_\upsilon$ mol of vapor (e.g., water) and $m_g$ kg and $n_g$ mol of noncondensible gas (e.g., air), with $m_\upsilon=n_\upsilon M_\upsilon$ and $m_g=n_g M_g$, then the four quantities above are defined by

$$Y=\frac{m_\upsilon}{m_g}\qquad Y_w=\frac{m_\upsilon}{m_g+m_\upsilon}\qquad z=\frac{n_\upsilon}{n_g}\qquad y=\frac{n_\upsilon}{n_g+n_\upsilon}$$

***Volumetric Humidity $Y_\upsilon$*** Mass of vapor per unit volume of gas-vapor mixture. It is sometimes, confusingly, called the absolute humidity, but it is really a vapor concentration; preferred units are kg/m$^3$ or lb/ft$^3$, but g/m$^3$ and gr/ft$^3$ are also used. It is inconvenient for calculations because it depends on temperature and pressure and on the units system; absolute humidity $Y$ is always preferable for heat and mass balances. It is proportional to the specific humidity (wet basis); $Y_\upsilon = Y_W\rho_g$, where $\rho_g$ is the *humid gas density* (mass of gas-vapor mixture per unit volume, wet basis). Also

$$Y_\upsilon=\frac{M_\upsilon P n_\upsilon}{RT(n_g+n_\upsilon)}$$

***Vapor Pressure p*** Partial pressure of vapor in gas-vapor mixture, which is proportional to the mole fraction of vapor; $p=yP$, where $P$ = total pressure, in the same units as $p$ (Pa, N/m$^2$, bar, atm, or psi). Hence

$$p=\frac{n_\upsilon}{n_g+n_\upsilon}P$$

***Saturation Vapor Pressure $p_s$*** Pressure exerted by pure vapor at a given temperature. When the vapor partial pressure $p$ in the gas-vapor mixture at a given temperature equals the saturation vapor pressure $p_s$ at the same temperature, the air is *saturated* and the absolute humidity is designated the *saturation humidity* $Y_s$.

***Relative Humidity RH or Ψ*** The partial pressure of vapor divided by the saturation vapor pressure at the given temperature, usually expressed as a percentage. Thus RH = $100p/p_s$.

***Percentage Absolute Humidity (Percentage Saturation) S*** Ratio of absolute humidity to saturation humidity, given by $S=100Y/Y_s=100p\,(P-p_s)/[p_s(P-p)]$. It is used much less commonly than relative humidity.

***Dew Point $T_{dew}$, or Saturation Temperature*** The temperature at which a given mixture of water vapor and air becomes saturated on cooling; i.e., the temperature at which water exerts a vapor pressure equal to the partial pressure of water vapor in the given mixture.

***Humid Volume υ*** Volume in cubic meters (cubic feet) of 1 kg (1 lb) of dry air and the water vapor it contains.

***Saturated Volume $v_s$*** Humid volume when the air is saturated.

Terms related to heat balances are as follows:

***Humid Heat $C_s$*** Heat capacity of unit mass of dry air and the moisture it contains. $C_s = C_{Pg} + C_{Pv}Y$, where $C_{Pg}$ and $C_{Pv}$ are the heat capacities of dry air and water vapor, respectively, and both are assumed constant. For approximate engineering calculations at near-ambient temperatures, in SI units, $C_s = 1 + 1.9Y$ kJ/(kg · K) and in USCS units, $C_s = 0.24 + 0.45Y$ (Btu/(lb · °F).

***Humid Enthalpy H*** Heat content at a given temperature $T$ of unit mass of dry air and the moisture it contains, relative to a datum temperature $T_0$, usually 0°C. As water is liquid at 0°C, the humid enthalpy also contains a term for the latent heat of water. If heat capacity is invariant with temperature, $H=(C_{Pg}+C_{Pv}Y)(T-T_0)+\lambda_0 Y$, where $\lambda_0$ is the latent heat of water at 0°C, 2501 kJ/kg (1075 Btu/lb). In practice, for accurate calculations, it is often easier to obtain the vapor enthalpy $H_\upsilon$ from steam tables, when $H = H_g + H_v = C_{Pg}T + H_\upsilon$.

***Adiabatic Saturation Temperature $T_{as}$*** Final temperature reached by a small quantity of vapor-gas mixture into which water is evaporating. It is sometimes called the *thermodynamic wet-bulb temperature.*

***Wet-Bulb Temperature $T_{wb}$*** Dynamic equilibrium temperature attained by a liquid surface from which water is evaporating into a flowing airstream when the rate of heat transfer to the surface by convection equals the rate of mass transfer away from the surface. It is very close to the adiabatic saturation temperature for the air-water system, but not for most other vapor-gas systems; see later.

## CALCULATION FORMULAS

Table 12-1 gives formulas for conversion between absolute humidity, mole fraction, vapor pressure, and volumetric humidity for the air-water system, and Table 12-2 does likewise for a general gas-vapor system. Where relationships are not included in the definitions, they are given below.

In USCS units, the formulas are the same except for the volumetric humidity $Y_\upsilon$. Because of the danger of confusion with pressure units, it is recommended that in both Tables 12-1 and 12-2, $Y_\upsilon$ be calculated in SI units and then converted.

Volumetric humidity is also related to absolute humidity and humid gas density by

$$Y_\upsilon = Y_W\rho_g = \frac{Y}{1+Y}\rho_g \tag{12-1}$$

**TABLE 12-2 Interconversion Formulas for a General Gas-Vapor System**

$M_g, M_\upsilon$ = molal mass of gas and vapor, respectively; $R$ = 8314 J/(kmol · K); $T$ = temperature in **kelvins** (K); $P$ = total pressure in **pascals** (Pa or N/m$^2$)

| Convert from: | $Y$ (or ppm$_w$)* | $y$ | $p$ | $Y_\upsilon$ |
|---|---|---|---|---|
| Convert to: Absolute humidity (mixing ratio) $Y$ (kg · kg$^{-1}$) | 1 | $Y=\dfrac{M_\upsilon y}{M_g(1-Y)}$ | $Y=\dfrac{pM_\upsilon}{(P-p)M_g}$ | $Y=\dfrac{M_\upsilon}{M_g(PM_\upsilon/(Y_\upsilon RT)-1}$ |
| Mole fraction $y$ (mol · mol$^{-1}$) | $y=\dfrac{Y}{M_\upsilon/M_g+Y}$ | 1 | $y=\dfrac{p}{P}$ | $y=\dfrac{Y_\upsilon RT}{PM_\upsilon}$ |
| Vapor pressure $p$ (Pa) | $p=\dfrac{PY}{M_\upsilon/M_g+Y}$ | $p=yP$ | 1 | $p=\dfrac{Y_\upsilon RT}{M_\upsilon}$ |
| Volumetric humidity $Y_\upsilon$ (kg · m$^{-3}$) | $Y_\upsilon=\dfrac{M_\upsilon}{RT}\dfrac{PY}{M_\upsilon/M_g+Y}$ | $Y_\upsilon=\dfrac{M_\upsilon yP}{RT}$ | $Y_\upsilon=\dfrac{M_\upsilon p}{RT}$ | 1 |

Two further useful formulas are as follows:

| Parameter | General vapor-gas system | Air-water system, SI units, to 3 significant figures | Eq. no. |
|---|---|---|---|
| Density of humid gas (moist air) $\rho_g$, kg/m$^3$ | $\rho_g = \frac{M_g}{RT}\left(P - p + \frac{M_v}{M_g}p\right)$ | $\rho_g = \frac{P - 0.378p}{287.1T}$ | (12-2) |
| Humid volume $\upsilon$ per unit mass of dry air, m$^3$/kg | $\upsilon = \frac{RT}{M_g(P-p)} = \frac{RT}{P} \times \left(\frac{1}{M_g} + \frac{Y}{M_v}\right)$ | $\upsilon = \frac{461.5T}{P}(0.622 + Y)$ | (12-3) |

From Eq. (12-2), the density of dry air at 0°C (273.15 K) and 1 atm (101,325 Pa) is 1.292 kg/m$^3$ (0.08065 lb/ft$^3$). Note that the density of moist air is always lower than that of dry air.

Equation (12-3) gives the humid volume of dry air at 0°C (273.15 K) and 1 atm as 0.774 m$^3$/kg (12.4 ft$^3$/lb). For moist air, the humid volume is not the reciprocal of humid gas density; $\upsilon = (1 + Y)/\rho_g$.

The *saturation vapor pressure* of water is given by Sonntag (1990) in Pa (N/m$^2$) at absolute temperature $T$ (K).

Over water:

$$\ln p_s = -6096.9385T^{-1} + 21.2409642 - 2.711193 \times 10^{-2}T + 1.673952 \times 10^{-5}T^2 + 2.433502 \ln T \qquad (12\text{-}4a)$$

Over ice:

$$\ln p_s = -6024.5282T^{-1} + 29.32707 + 1.0613868 \times 10^{-2}T - 1.3198825 \times 10^{-5}T^2 - 0.49382577 \ln T \qquad (12\text{-}4b)$$

Simpler equations for saturation vapor pressure are the Antoine equation and Magnus formula. These are slightly less accurate, but easier to calculate and also easily reversible to give $T$ in terms of $p$. For the Antoine equation, given below, coefficients for numerous other solvent-gas systems are given in Poling, Prausnitz, and O'Connell, *The Properties of Gases and Liquids*, 5th ed., McGraw-Hill, New York, 2000.

$$\ln p_s = C_0 - \frac{C_1}{T - C_2} \qquad T = \frac{C_1}{C_0 - \ln ps} + C_2 \qquad (12\text{-}5)$$

Values for Antoine coefficients for the air-water system are given in Table 12-3. The standard values give vapor pressure within 0.1 percent of steam tables over the range 50 to 100°C, but an error of nearly 3 percent at 0°C. The alternative coefficients give a close fit at 0 and 100°C and an error of less than 1.2 percent over the intervening range.

The Sonntag equation strictly only applies to water vapor with no other gases present (i.e., in a partial vacuum). The vapor pressure of a gas mixture, e.g., water vapor in air, is given by multiplying the pure liquid vapor pressure by an enhancement factor $f$, for which various equations are available (see British Standard BS 1339 Part 1, 2002). However, the correction is typically less than 0.5 percent, except at elevated pressures, and it is therefore usually neglected for engineering calculations.

## RELATIONSHIP BETWEEN WET-BULB AND ADIABATIC SATURATION TEMPERATURES

If a stream of air is intimately mixed with a quantity of water in an adiabatic system, the temperature of the air will drop and its humidity will increase. If the equilibration time or the number of transfer units approaches infinity, the air-water mixture will reach saturation. The *adiabatic saturation temperature* $T_{as}$ is given by a heat balance between the initial unsaturated vapor-gas mixture and the final saturated mixture at thermal equilibrium:

$$C_s(T - T_{as}) = \lambda_{as}(Y_{as} - Y) \qquad (12\text{-}6)$$

This equation has to be reversed and solved iteratively to obtain $Y_{as}$ (absolute humidity at adiabatic saturation) and hence $T_{as}$ (the calculation is divergent in the opposite direction). Approximate direct formulas are available from various sources, e.g., British Standard BS 1339 (2002) and Liley [*IJMEE* **21**(2), 1993]. The latent heat of evaporation evaluated at the adiabatic saturation temperature is $\lambda_{as}$, which may be obtained from steam tables; humid heat $C_s$ is evaluated at initial humidity $Y$. On a psychrometric chart, the adiabatic saturation process almost exactly follows a *constant-enthalpy line*, as the sensible heat given up by the gas-vapor mixture exactly balances the latent heat of the liquid that evaporates back into the mixture. The only difference is due to the sensible heat added to the water to take it from the datum temperature to $T_{as}$. The adiabatic saturation line differs from the constant-enthalpy line as follows, where $C_{PL}$ is the specific heat capacity of the liquid:

$$H_{as} - H = C_{PL}T_{as}(Y_{as} - Y) \qquad (12\text{-}7)$$

Equation (12-7) is useful for calculating the adiabatic saturation line for a given $T_{as}$ and gives an alternative iterative method for finding $T_{as}$, given $T$ and $Y$; compared with Eq. (12-6), it is slightly more accurate and converges faster, but the calculation is more cumbersome.

The *wet-bulb temperature* is the temperature attained by a fully wetted surface, such as the wick of a wet-bulb thermometer or a droplet or wet particle undergoing drying, in contact with a flowing unsaturated gas stream. It is regulated by the rates of vapor-phase heat and mass transfer to and from the wet bulb. Assuming mass transfer is controlled by diffusion effects and heat transfer is purely convective,

$$h(T - T_{wb}) = k_y \lambda_{wb}(Y_{wb} - Y) \qquad (12\text{-}8)$$

where $k_y$ is the corrected mass-transfer coefficient [kg/(m$^2 \cdot$ s)], $h$ is the heat-transfer coefficient [kW/(m$^2 \cdot$ K)], $Y_{wb}$ is the saturation mixing ratio at $t_{wb}$, and $\lambda_{wb}$ is the latent heat (kJ/kg) evaluated at $T_{wb}$. Again, this equation must be solved iteratively to obtain $T_{wb}$ and $Y_{wb}$.

In practice, for any practical psychrometer or wetted droplet or particle, there is significant extra heat transfer from radiation. For an Assmann psychrometer at near-ambient conditions, this is approximately 10 percent. This means that any measured real value of $T_{wb}$ is slightly higher than the "pure convective" value in the definition. It is often more convenient to obtain wet-bulb conditions from adiabatic saturation conditions (which are much easier to calculate) by the following formula:

$$\frac{T - T_{wb}}{Y_{wb} - Y} = \frac{T - T_{as}}{Y_{as} - Y}\beta \qquad (12\text{-}9)$$

where the psychrometric ratio $\beta = \overline{C_s}k_y/h$ and $\overline{C_s}$ is the mean value of the humid heat over the range from $T_{as}$ to $T$.

The advantage of using $\beta$ is that it is approximately constant over normal ranges of temperature and pressure for any given pair of vapor and gas values. This avoids having to estimate values of heat- and mass-transfer coefficients $h$ and $k_y$ from uncertain correlations. For the air-water system, considering convective heat transfer alone, $\beta \sim 1.1$. In practice, there is an additional contribution from radiation, and $\beta$ is very close to 1. As a result, the wet-bulb and adiabatic saturation temperatures differ by less than 1°C for the air-water system at near-ambient conditions (0 to 100°C, $Y < 0.1$ kg/kg) and can be taken as equal for normal calculation purposes. Indeed, typically the $T_{wb}$ measured by a practical psychrometer or at a wetted solid surface is closer to $T_{as}$ than to the "pure convective" value of $T_{wb}$.

However, for nearly all other vapor-gas systems, particularly for organic solvents, $\beta < 1$, and hence $T_{wb} > T_{as}$. This is illustrated in Fig. 12-5. The surface (wet-bulb) temperature can change as drying progresses, whereas in the air-water system it stays constant. For these systems the psychrometric ratio may be obtained by determining $h/k_y$ from heat- and mass-transfer analogies such as the Chilton-Colburn analogy. The basic form of the equation is

$$\beta = \left(\frac{\text{Sc}}{\text{Pr}}\right)^n = \text{Le}^{-n} \qquad (12\text{-}10)$$

**TABLE 12-3 Alternative Set of Values for Antoine Coefficients for Air-Water Systems**

| | | $C_0$ | $C_1$ | $C_2$ | | $C_0$ | $C_1$ | $C_2$ |
|---|---|---|---|---|---|---|---|---|
| Standard values | $p$ in Pa | 23.1963 | 3816.44 | 46.13 K | $p$ in mmHg | 18.3036 | 3816.44 | 46.13 K |
| Alternative values | $p$ in Pa | 23.19 | 3830 | 44.83 K | $p$ in mmHg | 18.3 | 3830 | 44.87 K |

where Sc is the Schmidt number for mass-transfer properties, Pr is the Prandtl number for heat-transfer properties, and Le is the Lewis number $\kappa/(C_s\rho_g D)$, where $\kappa$ is the gas thermal conductivity and $D$ is the diffusion coefficient for the vapor through the gas. Experimental and theoretical values of the exponent $n$ range from 0.56 [Bedingfield and Drew, *Ind. Eng. Chem.* **42:** 1164 (1950)] to $\frac{2}{3}$ [Chilton and Colburn, *Ind. Eng. Chem.* **26:** 1183 (1934)]. A detailed discussion is given by Keey (1992). Values of $\beta$ for any system can be estimated from the specific heats, diffusion coefficients, and other data given in Sec. 2. See the example below.

For calculation of wet-bulb (and adiabatic saturation) conditions, the most commonly used formula in industry is the *psychrometer equation*. This is a simple linear formula that gives vapor pressure directly if the wet-bulb temperature is known, and it is therefore ideal for calculating humidity from a wet-bulb measurement using a psychrometer, although the calculation of wet-bulb temperature from humidity still requires an iteration

$$p = p_{wb} - AP(T - T_{wb}) \tag{12-11}$$

where $A$ is the psychrometer coefficient. For the air-water system, the following formulas based on equations given by Sonntag [*Zeitschrift für Meteorologie* **40**(5): 340–344 (1990)] may be used to give $A$ for $T_{wb}$ up to 30°C; they are based on extensive experimental data for Assmann psychrometers.

Over water (wet-bulb temperature):

$$A = 6.5 \times 10^{-4}(1 + 0.000944T_{wb}) \tag{12-12a}$$

Over ice (ice-bulb temperature):

$$A_i = 5.72 \times 10^{-4} \tag{12-12b}$$

For other vapor-gas systems, $A$ is given by

$$A = \frac{M_g C_s}{M_v \beta \lambda_{wb}} \tag{12-13}$$

Here $\beta$ is the psychrometric coefficient for the system. As a cross-check, for the air-water system at 20°C wet-bulb temperature, 50°C dry-bulb temperature, and absolute humidity 0.002 kg/kg, $C_s = 1.006 + 1.9 \times 0.002 = 1.01$ kJ/(kg·K) and $\lambda_{wb} = 2454$ kJ/kg. Since $M_g = 28.97$ kg/kmol and $M_v = 18.02$ kg/kmol, Eq. (12-12) gives $A$ as $6.617 \times 10^{-4}/\beta$, compared with Sonntag's value of $6.653 \times 10^{-4}$ at this temperature, giving a value for the psychrometric coefficient $\beta$ of 0.995; that is, $\beta \approx 1$, as expected for the air-water system.

## PSYCHROMETRIC CHARTS

Psychrometric charts are plots of humidity, temperature, enthalpy, and other useful parameters of a gas-vapor mixture. They are helpful for rapid estimates of conditions and for visualization of process operations such as humidification and drying. They apply to a given system at a given pressure, the most common, of course, being air-water at atmospheric pressure. There are four types, of which the Grosvenor and Mollier types are most widely used.

The *Grosvenor chart* plots temperature (abscissa) versus humidity (ordinate). Standard charts produced by ASHRAE and other groups, or by computer programs, are usually of this type. The saturation line is a curve from bottom left to top right, and curves for constant relative humidity are approximately parallel to this. Lines from top left to bottom right may be of either constant wet-bulb temperature or constant enthalpy, depending on the chart. The two are not quite identical, so if only one is shown, correction factors are required for the other parameter. Examples are shown in Figs. 12-1 (SI units) and 12-2 (USCS units). An additional chart for a wider temperature range in USCS units is given in Perry's 8th Edition (Fig. 12-2*b*).

The *Bowen chart* is a plot of enthalpy (abscissa) versus humidity (ordinate). It is convenient to be able to read enthalpy directly, especially for near-adiabatic convective drying where the operating line approximately follows a line of constant enthalpy. However, it is very difficult to read accurately because the key information is compressed in a narrow band near the saturation line. See Cook and DuMont, *Process Drying Practice,* McGraw-Hill, New York, 1991, chap. 6.

The *Mollier chart* plots humidity (abscissa) versus enthalpy (lines sloping diagonally from top left to bottom right). Lines of constant temperature are shallow curves at a small slope to the horizontal. The chart is nonorthogonal (no horizontal lines) and hence a little difficult to plot and interpret initially. However, the area of greatest interest is expanded, and they are therefore easy to read accurately. They tend to cover a wider temperature range than Grosvenor charts, so are useful for dryer calculations. The slope of the enthalpy lines is normally $-1/\lambda$, where $\lambda$ is the latent heat of evaporation. Adiabatic saturation lines are not quite parallel to constant-enthalpy lines and are slightly curved; the deviation increases as humidity increases. Figure 12-3 shows an example.

The *Salen-Soininen* perspective transformed *chart* is a triangular plot. It is tricky to plot and read, but covers a much wider range of humidity than do the other types of chart (up to 2 kg/kg) and is thus very effective for high-humidity mixtures and calculations near the boiling point, e.g., in pulp and paper drying. See Soininen, *Drying Technol.* **4**(2): 295–305 (1986).

Figure 12-4 shows a psychrometric chart for combustion products in air. The thermodynamic properties of moist air are given in Table 12-1. Figure 12-4 shows a number of useful additional relationships, e.g., specific volume and latent heat variation with temperature. Accurate figures should always be obtained from physical properties tables or by calculation using the formulas given earlier, and these charts should only be used as a quick check for verification. Figure 12-5 shows a psychrometric chart for an organic solvent system.

In the past, psychrometric charts have been used to perform quite precise calculations. To do this, additive corrections are often required for enthalpy of added water or ice, and for variations in barometric pressure from the standard level (101,325 Pa, 14.696 lbf/in$^2$, 760 mmHg, 29.921 inHg). It is preferable to use formulas, which give an accurate figure at any set of conditions. Psychrometric charts and tables can be used as a rough cross-check that the result has been calculated correctly. Table 12-4 gives values of saturation humidity, specific volume, enthalpy, and entropy of saturated moist air at selected conditions. Below the freezing point, these become virtually identical to the values for dry air, as saturation humidity is very low. For pressure corrections, an altitude increase of approximately 275 m (900 ft) gives a pressure decrease of 0.034 bar (1 inHg). For a recorded wet-bulb temperature of 10°C (50°F), this gives an increase in humidity of 0.00027 kg/kg (1.9 gr/lb) and the enthalpy increases by 0.68 kJ/kg (0.29 Btu/lb). This correction increases roughly proportionately for further changes in pressure, but climbs sharply as wet-bulb temperature is increased; when $T_{wb}$ reaches 38°C (100°F), $\Delta Y = 0.0016$ kg/kg (11.2 gr/lb) and $\Delta H = 4.12$ kJ/kg (1.77 Btu/lb). Equivalent, more detailed tables in SI units can be found in the ASHRAE Handbook.

**Examples Illustrating Use of Psychrometric Charts** In these examples the following nomenclature is used:

$t$ = dry-bulb temperature, °F
$t_w$ = wet-bulb temperature, °F
$t_d$ = dew point temperature, °F
$H$ = moisture content, lb water/lb dry air
$\Delta H$ = moisture added to or rejected from airstream, lb water/lb dry air
$h'$ = enthalpy at saturation, Btu/lb dry air
$D$ = enthalpy deviation, Btu/lb dry air
$h = h' + D$ = true enthalpy, Btu/lb dry air
$h_w$ = enthalpy of water added to or rejected from system, Btu/lb dry air
$q_a$ = heat added to system, Btu/lb dry air
$q_r$ = heat removed from system, Btu/lb dry air

Subscripts 1, 2, 3, etc., indicate entering and subsequent states.

***Example 12-1 Determination of Moist Air Properties*** Find the properties of moist air when the dry-bulb temperature is 80°F and the wet-bulb temperature is 67°F.

*Solution* Read directly from Fig. 12-2 (Fig. 12-6*a* shows the solution diagrammatically).

Moisture content $H$ = 78 gr/lb dry air
= 0.011 lb water/lb dry air
Enthalpy at saturation $h'$ = 31.6 Btu/lb dry air
Enthalpy deviation $D$ = −0.1 Btu/lb dry air
True enthalpy $h$ = 31.5 Btu/lb dry air
Specific volume $\upsilon$ = 13.8 ft$^3$/lb dry air
Relative humidity = 51 percent
Dew point $t_d$ = 60.3°F

***Example 12-2 Air Heating*** Air is heated by a steam coil from 30°F dry-bulb temperature and 80 percent relative humidity to 75°F dry-bulb temperature. Find the relative humidity, wet-bulb temperature, and dew point of the heated air. Determine the quantity of heat added per pound of dry air.

*Solution* Reading directly from the psychrometric chart (Fig. 12-2),

Relative humidity = 15 percent
Wet-bulb temperature = 51.5°F
Dew point = 25.2°F

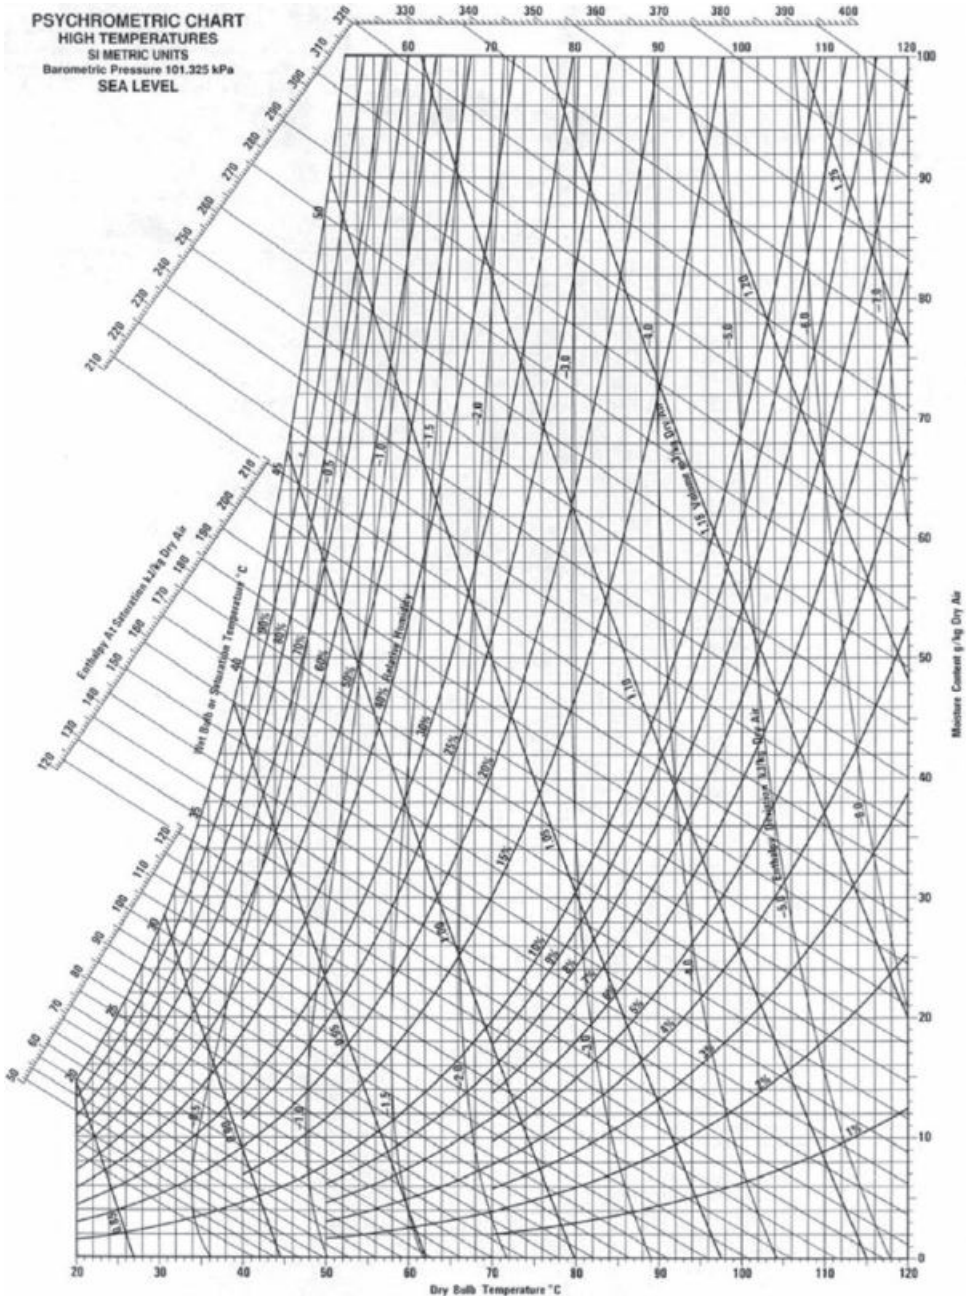

**FIG. 12-1** Grosvenor psychrometric chart for the air-water system at standard atmospheric pressure, 101,325 Pa, SI units. (*Courtesy Carrier Corporation.*)

The enthalpy of the inlet air is obtained from Fig. 12-2 as $h_1 = h'_1 + D_1 = 10.1 + 0.06 = 10.16$ Btu/lb dry air; at the exit, $h_2 = h'_2 + D_2 = 21.1 - 0.1 = 21$ Btu/lb dry air. The heat added equals the enthalpy difference, or

$$q_a = \Delta h = h_2 - h_1 = 21 - 10.16 = 10.84 \text{ Btu/lb dry air}$$

If the enthalpy deviation is ignored, the heat added $q_a$ is $\Delta h = 21.1 - 10.1 = 11$ Btu/lb dry air, or the result is 1.5 percent high. Figure 12-6*b* shows the heating path on the psychrometric chart.

***Example 12-3 Evaporative Cooling*** Air at 95°F dry-bulb temperature and 70°F wet-bulb temperature contacts a water spray, where its relative humidity is increased to 90 percent. The spray water is recirculated; makeup water enters at 70°F. Determine the exit dry-bulb temperature, wet-bulb temperature, change in enthalpy of the air, and quantity of moisture added per pound of dry air.

*Solution* Figure 12-6*c* shows the path on a psychrometric chart. The leaving dry-bulb temperature is obtained directly from Fig. 12-2 as 72.2°F. Since the spray water enters at the wet-bulb temperature of 70°F and there is no heat added to or removed from it, this is by definition an adiabatic process and there will be no change in wet-bulb temperature. The only change in enthalpy is that from the heat content of the makeup water. This can be demonstrated as follows:

$$\text{Inlet moisture } H_1 = 70 \text{ gr/lb dry air}$$
$$\text{Exit moisture } H_2 = 107 \text{ gr/lb dry air}$$
$$\Delta H = 37 \text{ gr/lb dry air}$$
$$\text{Inlet enthalpy } h_1 = h'_1 + D_1 = 34.1 - 0.22$$
$$= 33.88 \text{ Btu/lb dry air}$$
$$\text{Exit enthalpy } h_2 = h'_2 + D_2 = 34.1 - 0.02$$
$$= 34.08 \text{ Btu/lb dry air}$$
$$\text{Enthalpy of added water } h_w = 0.2 \text{ Btu/lb dry air (from small diagram, 37 gr at 70°F)}$$

Then
$$q_a = h_2 - h_1 + h_w$$
$$= 34.08 - 33.88 + 0.2 = 0$$

NOTE: Compiled by John A. Goff and S. Gratch. See also Keenan and Kaye. *Thermodynamic Properties of Air*, Wiley, New York, 1945. Enthalpy of dry air taken as zero at 0°F. Enthalpy of liquid water taken as zero at 32°F.

To convert British thermal units per pound to joules per kilogram, multiply by 2326; to convert British thermal units per pound dry air-degree Fahrenheit to joules per kilogram-kelvin, multiply by 4186.8; and to convert cubic feet per pound to cubic meters per kilogram, multiply by 0.0624.

*Entrapolated to represent metastable equilibrium with undercooled liquid.

***Example 12-4 Cooling and Dehumidification*** Find the cooling load per pound of dry air resulting from infiltration of room air at 80°F dry-bulb temperature and 67°F wet-bulb temperature into a cooler maintained at 30°F dry-bulb and 28°F wet-bulb temperatures, where moisture freezes on the coil, which is maintained at 20°F.

*Solution* The path followed on a psychrometric chart is shown in Fig. 12-6*d*.

$$\text{Inlet enthalpy } h_1 = h_1' + D_1 = 31.62 - 0.1$$
$$= 31.52 \text{ Btu/lb dry air}$$
$$\text{Exit enthalpy } h_2 = h_2' + D_2 = 10.1 + 0.06$$
$$= 10.16 \text{ Btu/lb dry air}$$
$$\text{Inlet moisture } H_1 = 78 \text{ gr/lb dry air}$$
$$\text{Exit moisture } H_2 = 19 \text{ gr/lb dry air}$$
$$\text{Moisture rejected } \Delta H = 59 \text{ gr/lb dry air}$$
$$\text{Enthalpy of rejected moisture} = -1.26 \text{ Btu/lb dry air (from small diagram of Fig. 12-2)}$$
$$\text{Cooling load } q_r = 31.52 - 10.16 + 1.26$$
$$= 22.62 \text{ Btu/lb dry air}$$

Note that if the enthalpy deviations were ignored, the calculated cooling load would be about 5 percent low.

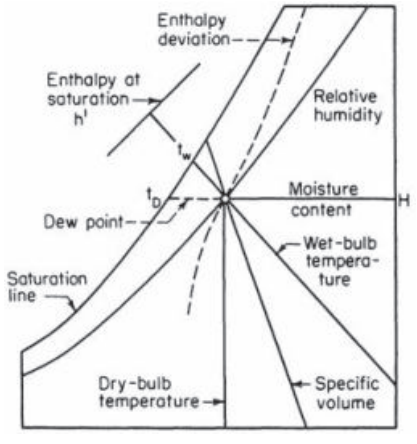

**FIG. 12-6*a*** Diagram of psychrometric chart showing the properties of moist air.

***Example 12-5 Cooling Tower*** Determine water consumption and the amount of heat dissipated per 1000 ft³/min of entering air at 90°F dry-bulb temperature and 70°F wet-bulb temperature when the air leaves saturated at 110°F and the makeup water is at 75°F.

*Solution* The path followed is shown in Fig. 12-6*e*.

$$\text{Exit moisture } H_2 = 416 \text{ gr/lb dry air}$$
$$\text{Inlet moisture } H_1 = 78 \text{ gr/lb dry air}$$
$$\text{Moisture added } \Delta H = 338 \text{ gr/lb dry air}$$
$$\text{Enthalpy of added moisture } h_w = 2.1 \text{ Btu/lb dry air (from small diagram of Fig. 12-2)}$$

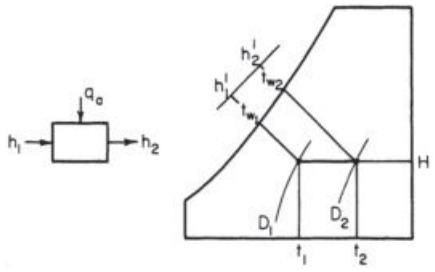

**FIG. 12-6*b*** Heating process.

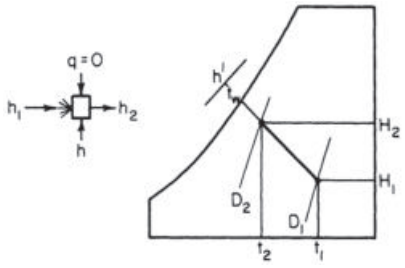

**FIG. 12-6*c*** Spray or evaporative cooling.

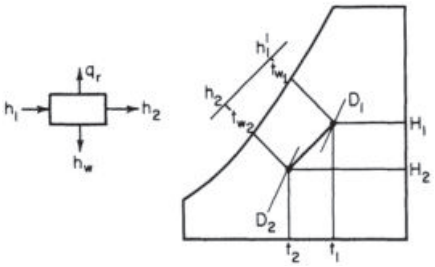

**FIG. 12-6*d*** Cooling and dehumidifying process.

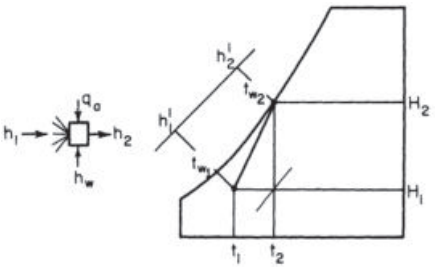

**FIG. 12-6*e*** Cooling tower.

If greater precision is desired, $h_w$ can be calculated as

$$h_w = (338/7000)(1)(75 - 32)$$
$$= 2.08 \text{ Btu/lb dry air}$$
$$\text{Enthalpy of inlet air } h_1 = h'_1 + D_1 = 34.1 - 0.18$$
$$= 33.92 \text{ Btu/lb dry air}$$
$$\text{Enthalpy of exit air } h_2 = h'_2 + D_2 = 92.34 + 0$$
$$= 92.34 \text{ Btu/lb dry air}$$
$$\text{Heat dissipated} = h_2 - h_1 - h_w$$
$$= 92.34 - 33.92 - 2.08$$
$$= 56.34 \text{ Btu/lb dry air}$$
$$\text{Specific volume of inlet air} = 14.1 \text{ ft}^3\text{/lb dry air}$$
$$\text{Total heat dissipated} = \frac{(1000)(56.34)}{14.1} = 3990 \text{ Btu/min}$$

***Example 12-6 Recirculating Dryer*** A dryer is removing 100 lb water/h from the material being dried. The air entering the dryer has a dry-bulb temperature of 180°F and a wet-bulb temperature of 110°F. The air leaves the dryer at 140°F. A portion of the air is recirculated after mixing with room air having a dry-bulb temperature of 75°F and a relative humidity of 60 percent. Determine the quantity of air required, recirculation rate, and load on the preheater if it is assumed that the system is adiabatic. Neglect the heat up of the feed and of the conveying equipment.

*Solution* The path followed is shown in Fig. 12-6*f*.

$$\text{Humidity of room air } H_1 = 0.0113 \text{ lb/lb dry air}$$
$$\text{Humidity of air entering dryer } H_3 = 0.0418 \text{ lb/lb dry air}$$
$$\text{Humidity of air leaving dryer } H_4 = 0.0518 \text{ lb/lb dry air}$$

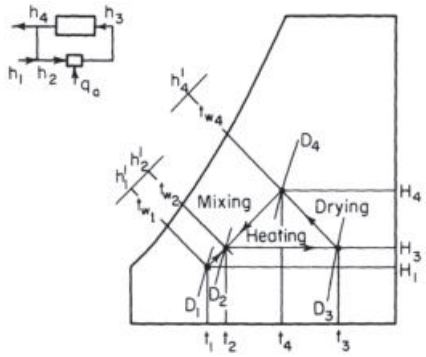

**FIG. 12-6*f*** Drying process with recirculation.

$$\text{Enthalpy of room air } h_1 = 30.2 - 0.3 = 29.9 \text{ Btu/lb dry air}$$
$$\text{Enthalpy of entering air } h_3 = 92.5 - 1.3 = 91.2 \text{ Btu/lb dry air}$$
$$\text{Enthalpy of leaving air } h_4 = 92.5 - 0.55 = 91.95 \text{ Btu/lb dry air}$$

Quantity of air required is $100/(0.0518 - 0.0418) = 10{,}000$ lb dry air/h. At the dryer inlet the specific volume is 17.1 ft$^3$/lb dry air. Air volume is $(10{,}000)(17.1)/60 = 2850$ ft$^3$/min. Fraction exhausted is

$$\frac{X}{W_a} = \frac{0.0518 - 0.0418}{0.0518 - 0.0113} = 0.247$$

where $X$ = quantity of fresh air and $W_a$ = total airflow. Thus 75.3 percent of the air is recirculated. Load on the preheater is obtained from an enthalpy balance

$$q_a = 10{,}000(91.2) - 2470(29.9) - 7530(91.95) = 146{,}000 \text{ Btu/h}$$

## PSYCHROMETRIC CALCULATIONS

Table 12-5 gives the steps required to perform the most common humidity calculations, using the formulas given earlier.

Methods (i) to (iii) are used to find the humidity and dew point from temperature readings from a wet- and dry-bulb psychrometer.

Method (iv) is used to find the absolute humidity and dew point from a relative humidity measurement at a given temperature.

Methods (v) and (vi) give the adiabatic saturation and wet-bulb temperatures from absolute humidity (or relative humidity) at a given temperature.

Method (vii) gives the absolute and relative humidity from a dew point measurement.

Method (viii) allows the calculation of all the main parameters if the absolute humidity is known, e.g., from a mass balance on a process plant.

Method (ix) converts the volumetric form of absolute humidity to the mass form (mixing ratio).

Method (x) allows the dew point to be corrected for pressure. The basis is that the mole fraction $y = p/P$ is the same for a given mixture composition at all values of total pressure $P$. In particular, the dew point measured in a compressed air duct can be converted to the dew point at atmospheric pressure, from which the humidity can be calculated. It is necessary to check that the temperature change associated with compression or expansion does not bring the dry-bulb temperature to a point where condensation can occur. Also, at these elevated pressures, it is strongly advisable to apply the enhancement factor (see British Standard BS1339 Part 1).

**Psychrometric Software and Tables** As an alternative to using charts or individual calculations, lookup tables have been published for many years for common psychrometric conversions, e.g., to find relative humidity given the dry-bulb and wet-bulb temperatures. These were often very extensive. To give precise coverage of $T_{wb}$ in 1°C or 0.1°C steps, a complete table would be needed for each individual dry-bulb temperature.

Software is available that will perform calculations of humidity parameters for any point value, and for plotting psychrometric charts. Moreover, British Standard BS 1339 Part 2 (2006) provides functions as macros that can be embedded into any Excel-compatible spreadsheet. Users can therefore generate their own tables for any desired combination of parameters as well as perform point calculations. Hence, the need for published lookup tables has been eliminated. However, this software, like the previous lookup tables, is only valid for the air-water system. For other vapor-gas systems, the equations given in previous sections must be used.

**TABLE 12-5 Calculation Methods for Various Humidity Parameters**

| | Known | Required | Method |
|---|---|---|---|
| i. | $T$, $T_{wb}$ | $Y$ | Find saturation vapor pressure $p_{wb}$ at wet-bulb temperature $T_{wb}$ from Eq. (12-4). Find actual vapor pressure $p$ at dry-bulb temperature $T$ from psychrometer equation (12-11). Find mixing ratio $Y$ by conversion from $p$ (Table 12-1). |
| ii. | $T$, $T_{wb}$ | $T_{dp}$, $d_v$ | Find $p$ if necessary by method (i) above. Find dew point $T_{dp}$ from Eq. (12-4) by calculating the $T$ corresponding to $p$ [iteration required; Antoine equation (12-5) gives a first estimate]. Calculate volumetric humidity $Y_v$, using Eq. (12-1). |
| iii. | $T$, $T_{wb}$ | %RH ($\psi$) | Use method (i) to find $p$. Find saturation vapor pressure $p_s$ at $T$ from Eq. (12-4). Now relative humidity %RH = $100p/p_s$. |
| iv. | $T$, %RH | $Y$, $d_v$ | Find saturation vapor pressure $p_s$ at $T$ from Eq. (12-4). Actual vapor pressure $p = p_s$(%RH/100). Convert to $Y$ (Table 12-1). Find $Y_v$ from Eq. (12-1). |
| v. | $T$, %RH (or $T$, $Y$) | $T_{as}$ | Use method (iv) to find $p$ and $Y$. Make an initial estimate of $T_{as}$, say, using a psychrometric chart. Calculate $Y_{as}$ from Eq. (12-6). Find $p$ from Table 12-1 and $T_{as}$ from Antoine equation (12-5). Repeat until iteration converges (e.g., using spreadsheet). Alternative method: Evaluate enthalpy $H_{est}$ at these conditions and $H$ at initial conditions. Find $H_{as}$ from Eq. (12-7) and compare with $H_{est}$. Make new estimate of $Y_{as}$ which would give $H_{est}$ equal to $H_{as}$. Find $p$ from Table 12-1 and $T_{as}$ from Antoine equation (12-5). Reevaluate $H_{as}$ from Eq. (12-7) and iterate to refine value of $Y_{as}$. |
| vi. | $T$, %RH (or $T$, $Y$) | $T_{wb}$ | Use method (iv) to find $p$ and $Y$. Make an initial estimate of $T_{wb}$, e.g., using a psychrometric chart, or ( for air-water system) by estimating adiabatic saturation temperature $T_{as}$. Find $p_{wb}$ from psychrometer equation (12-11). Calculate new value of $T_{wb}$ corresponding to $p_{wb}$ by reversing Eq. (12-4) or using the Antoine equation (12-5). Repeat last two steps to solve iteratively for $T_{wb}$ (computer program is preferable method). |
| vii. | $T$, $T_{dp}$ | $Y$, %RH | Find saturation vapor pressure at dew point $T_{dp}$ from Eq. (12-4); this is the actual vapor pressure $p$. Find $Y$ from Table 12-1. Find saturation vapor pressure $p_s$ at dry-bulb temperature $T$ from Eq. (12-4). Now %RH = $100p/p_s$. |
| viii. | $T$, $Y$ | $T_{dp}$, $d_v$, %RH, $T_{wb}$ | Find $p$ by conversion from $Y$ (Table 12-1). Then use method (ii), (iii), or (v) as appropriate. |
| ix. | $T$, $Y_v$ | $Y$ | Find specific humidity $Y_W$ from Eqs. (12-2) and (12-1). Convert to absolute humidity $Y$ using $Y = Y_W/(1 - Y_W)$. |
| x. | $T_{dp}$ at $P_1$ (elevated) | $T_{dp}$ at $P_2$ (ambient) | Find vapor pressure $p_1$ at $T_{dp}$ and $P_1$ from Eq. (12-4). Convert to vapor pressure $p_2$ at new pressure $P_2$ by the formula $p_2 = p_1P_2/P_1$. Find new dew point $T_{dp}$ from Eq. (12-4) by calculating the $T$ corresponding to $p_2$ [iteration required as in (ii)]. |

Software may be effectively used to draw psychrometric charts or perform calculations. A wide variety of other psychrometric software may be found on the Internet, but quality varies considerably; the source and basis of the calculation methods should be carefully checked before using the results. In particular, most methods only apply for the air-water system at moderate temperatures (below 100°C). For high-temperature dryer calculations, only software stated as suitable for this range should be used.

Reliable sources include the following:

1. The American Society of Agricultural Engineers (ASAE): http://www.asae.org. Psychrometric data in chart and equation form in both SI and USCS units. Charts for temperature ranges of −35 to 600°F in USCS units and −10 to 120°C in SI units. Equations and calculation procedures. Air-water system and Grosvenor (temperature-humidity) charts only.

2. The American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE): http://www.ashrae.org. Psychrometric Analysis CD with energy calculations and creation of custom charts at virtually any altitude or pressure. Detailed scientific basis given in ASHRAE Handbook. Air-water system and Grosvenor charts only.

3. Carrier Corporation, a United Technologies Company: http://www.training.carrier.com. PSYCH+, computerized psychrometric chart and instructional guide, including design of air-conditioning processes and/or cycles. Printed psychrometric charts also supplied. Air-water system and Grosvenor charts only.

4. Linric Company: http://www.linric.com. PsycPro generates custom psychrometric charts in English (USCS) or metric (SI) units, based on ASHRAE formulas. Air-water system and Grosvenor charts only.

5. Aspen Technology: http://www.aspentech.com. PSYCHIC, one of the Process Tools in the Aspen Engineering Suite, generates customized psychrometric charts. Mollier and Bowen enthalpy-humidity charts are produced in addition to Grosvenor. Any gas-vapor system can be handled as well as air-water; data supplied for common organic solvents. It can draw operating lines and spot points, as shown in Fig. 12-7.

6. British Standards Institution: http://www.bsigroup.com. British Standard BS 1339 Part 2 is a spreadsheet-based software program providing functions based on the latest internationally agreed standards. It calculates all key psychrometric parameters and can produce a wide range of psychrometric tables. Users can embed the functions in their own spreadsheets to do psychrometric calculations. Air-water system only (although BS 1339 Part 1 text gives full calculation methods for other gas-vapor systems). SI (metric) units. It does not plot psychrometric charts.

7. Akton Associates: http://www.aktonassoc.com. Akton provides digital versions of psychrometry charts.

## PSYCHROMETRIC CALCULATIONS—WORKED EXAMPLES

***Example 12-7 Determination of Moist Air Properties*** An air-water mixture is found from the heat and mass balance to be at 60°C (333 K) and 0.025 kg/kg (25 g/kg) absolute humidity. Calculate the other main parameters for the mixture. Take atmospheric pressure as 101,325 Pa.

*Method:* Consult item (vi) in Table 12-5 for the calculation methodology.

From the initial terminology section, specific humidity $Y_W = 0.02439$ kg/kg, mole ratio $z = 0.0402$ kmol/kmol, mole fraction $y = 0.03864$ kmol/kmol.

From Table 12-1, vapor pressure $p = 3915$ Pa (0.03915 bar) and volumetric humidity $Y_v = 0.02547$ kg/m$^3$. Dew point is given by the temperature corresponding to $p$ at saturation. From the reversed Antoine equation (12-5), $T_{dp} = 3830/(23.19 - \ln 3915) + 44.83 = 301.58$ K = 28.43°C.

Relative humidity is the ratio of actual vapor pressure to saturation vapor pressure at dry-bulb temperature. From the Antoine equation (12-5), $p_s = \exp[23.19 - 3830/(333.15 - 44.83)] = 20{,}053$ Pa (new coefficients), or $p_s = \exp[23.1963 - 3816.44/(333.15 - 46.13)] = 19{,}921$ Pa (old coefficients).

From Sonntag equation (12-4), $p_s = 19{,}948$ Pa; the difference from the Antoine is less than 0.5 percent. Relative humidity = $100 \times 3915/19{,}948 = 19.6$ percent. From a psychrometric chart, e.g., Fig. 12-1, a humidity of 0.025 kg/kg at $T = 60$°C lies very close to the adiabatic saturation line for 35°C. Hence a good first estimate for $T_{as}$ and $T_{wb}$ will be 35°C. Refining the estimate of $T_{wb}$ by using the psychrometer equation and iterating gives

$$p_{wb} = 3915 + 6.46 \times 10^{-4}\,(1.033)(101{,}325)\,(60 - 35) = 5605 \text{ Pa}$$

From the Antoine equation,

$$T_{wb} = 3830/(23.19 - \ln 5605) + 44.83 = 307.9 \text{ K} = 34.75°\text{C}$$

Second iteration:

$$p_{wb} = 3915 + 6.46 \times 10^{-4}(1.033)(101{,}325)(60 - 34.75) = 5622 \text{ Pa}$$
$$T_{wb} = 307.96 \text{ K} = 34.81°\text{C}$$

To a sensible level of precision, $T_{wb} = 34.8$°C.

From Table 12-1, $Y_{wb} = 5622 \times 0.622/(101{,}325 - 5622) = 0.0365(4)$ kg/kg.

Enthalpy of original hot air is approximately given by $H = (C_{Pg} + C_{Pv}Y)(T - T_0) + \lambda_0 Y\ (1 + 1.9 \times 0.025) \times 60 + 2501 \times 0.025 = 62.85 + 62.5 = 125.35$ kJ/kg. A more accurate calculation can be obtained from steam tables; $C_{Pg} = 1.005$ kJ/(kg·K) over this range, $H_v$ at 60°C = 2608.8 kJ/kg, $H = 60.3 + 65.22 = 125.52$ kJ/kg.

Calculation (v), method 1: If $T_{as} = 34.8$, from Eq. (12-6), with $C_s = 1 + 1.9 \times 0.025 = 1.048$ kJ/(kg·K), then $\lambda_{as} = 2419$ kJ/kg (steam tables), $Y_{as} = 0.025 + 1.048/2419\ (60 - 34.8) = 0.0359(2)$ kg/kg. From Table 12-1, $p = 5530$ Pa. From the Antoine equation (12-5), $T_{as} = 3830/(23.19 - \ln 5530) + 44.83 = 307.65$ K = 34.52°C. Repeat until iteration converges (e.g., using spreadsheet). Final value $T_{as} = 34.57$°C, $Y_{as} = 0.0360$ kg/kg.

Enthalpy check: From Eq. (12-7), $H_{as} - H = 4.1868 \times 34.57 \times (0.036 - 0.025) = 1.59$ kJ/kg. So $H_{as} = 127.11$ kJ/kg. Compare $H_{as}$ calculated from enthalpies; $H_g$ at 34.57°C = 2564 kJ/kg, $H_{est} = 34.90 + 92.29 = 127.19$ kJ/kg. The iteration has converged successfully.

Note that $T_{as}$ is 0.2°C lower than $T_{wb}$ and $Y_{as}$ is 0.0005 kg/kg lower than $Y_{wb}$, both negligible differences.

***Example 12-8 Calculation of Humidity and Wet-Bulb Condition*** A dryer exhaust which can be taken as an air-water mixture at 70°C (343.15 K) is measured to have a relative humidity of 25 percent. Calculate the humidity parameters and wet-bulb conditions for the mixture. Pressure is 1 bar (100,000 Pa).

*Method:* Consult item (v) in Table 12-5 for the calculation methodology.

From the Antoine equation (12-5), using standard coefficients (which give a better fit in this temperature range), $p_s = \exp[23.1963 - 3816.44/(343.15 - 46.13)] = 31{,}170$ Pa. Actual vapor pressure $p = 25$ percent of 31,170 = 7792 Pa (0.078 bar).

From Table 12-1, absolute humidity $Y = 0.05256$ kg/kg and volumetric humidity $Y_v = 0.0492$ kg/m$^3$. From the terminology section, mole fraction $y = 0.0779$ kmol/kmol, mole ratio $z = 0.0845$ kmol/kmol, specific humidity $Y_W = 0.04994$ kg/kg.

$$\text{Dew point } T_{dp} = 3816.44/(23.1963 - \ln 7792) + 46.13 = 314.22 \text{ K} = 41.07°\text{C}$$

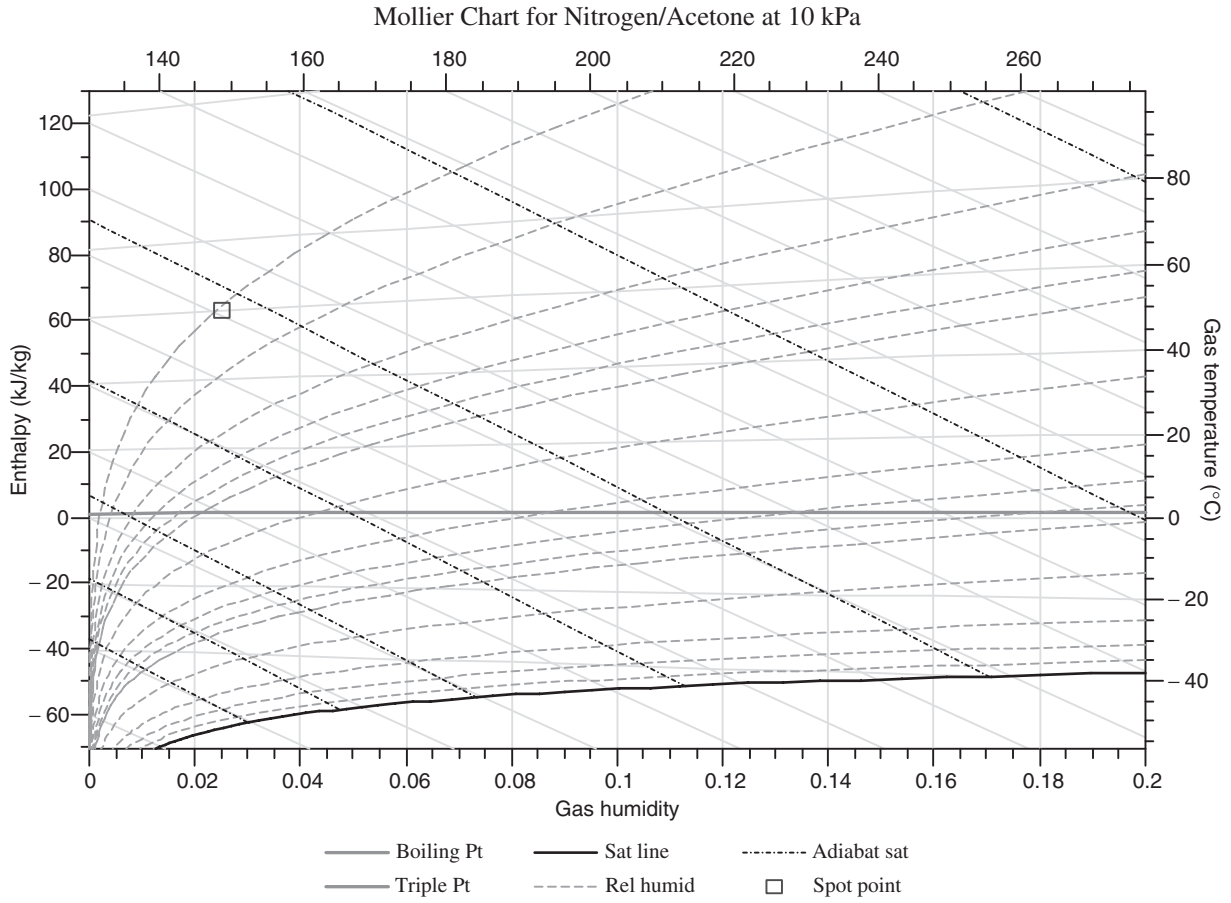

**FIG. 12-7** Mollier psychrometric chart (from PSYCHIC software program) showing determination of adiabatic saturation temperature plots of humidity (abscissa) against enthalpy (lines sloping diagonally from top left to bottom right). (*Courtesy AspenTech.*)

From the psychrometric chart, a humidity of 0.0526 kg/kg at $T = 70°C$ falls just below the adiabatic saturation line for 45°C. Estimate $T_{as}$ and $T_{wb}$ as 45°C. Refining the estimate of $T_{wb}$ by using the psychrometer equation and iterating gives

$$p_{wb} = 7792 + 6.46 \times 10^{-4}\,(1.0425)(10^5)(70 - 45) = 9476$$

From the Antoine equation,

$$T_{wb} = 3816.44/(23.1963 - \ln 9476) + 46.13 = 317.96\ \text{K} = 44.81°C$$

Second iteration (taking $T_{wb} = 44.8$):

$$p_{wb} = 9489 T_{wb} = 317.99\ \text{K} = 44.84°C$$

The iteration has converged.

***Example 12-9 Calculation of Psychrometric Properties of Acetone/Nitrogen Mixture*** A mixture of nitrogen $N_2$ and acetone $CH_3COCH_3$ is found from the heat and mass balance to be at 60°C (333 K) and 0.025 kg/kg (25 g/kg) absolute humidity (same conditions as in Example 12-7). Calculate the other main parameters for the mixture. The system is under vacuum at 100 mbar (0.1 bar, 10,000 Pa).

Additional data for acetone and nitrogen are obtained from *The Properties of Gases and Liquids* (Prausnitz et al.). Molecular weight (molal mass) $M_g$ for nitrogen = 28.01 kg/kmol; for acetone $M_v$ = 58.08 kg/kmol. Antoine coefficients for acetone are 16.6513, 2940.46, and 35.93, with $p_s$ in mmHg and $T$ in K. Specific heat capacity of nitrogen is approximately 1.014 kJ/(kg·K). Latent heat of acetone is 501.1 kJ/kg at the boiling point. The psychrometric ratio for the nitrogen-acetone system is not given, but the diffusion coefficient $D$ can be roughly evaluated as $1.34 \times 10^{-5}$, compared to $2.20 \times 10^{-5}$ for water in air. As the psychrometric ratio is linked to $D^{2/3}$, it can be estimated as 0.72, which is in line with tabulated values for similar organic solvents (e.g., propanol).

*Method:* Consult item (vi) in Table 12-5 for the calculation methodology.

From the terminology, specific humidity $Y_W = 0.02439$ kg/kg, the same as in Example 12-7. Mole ratio $z = 0.0121$ kmol/kmol, mole fraction $y = 0.01191$ kmol/kmol—lower than in Example 12-7 because molecular weights are different.

From the Antoine equation (12-5),

$$\ln p_s = C_0 - \frac{C_1}{T - C_2} = 16.6513 - \frac{2940.46}{T - 35.93}$$

Since $T = 60°C$, $\ln p_s = 6.758$, $p_s = 861.0$ mmHg. Hence $p_s = 1.148$ bar $= 1.148 \times 10^5$ Pa. The saturation vapor pressure is higher than atmospheric pressure; this means that acetone at 60°C must be above its normal boiling point. Check: $T_{bp}$ for acetone = 56.5°C.

Vapor pressure $p = yP = 0.01191 \times 10{,}000 = 119.1$ Pa (0.001191 bar)—much lower than before because of the reduced total pressure. This is 0.89 mmHg. Volumetric humidity $Y_v = 0.0025$ kg/m$^3$—again substantially lower than at 1 atm.

Dew point is the temperature where $p_s$ equals $p'$. From the reversed Antoine equation (12-5),

$$T = \frac{C_1}{C_0 - \ln p_s} + C_2$$

so

$$T_{dp} = \frac{2940}{16.6513 - \ln 0.89} + 35.93 = 211.27\ \text{K} = -61.88°C$$

This very low dew point is due to the low boiling point of acetone and the low concentration.

Relative humidity is the ratio of actual vapor pressure to saturation vapor pressure at dry-bulb temperature. So $p = 119.1$ Pa, $p_s = 1.148 \times 10^5$ Pa, RH = 0.104 percent—again very low.

A special psychrometric chart would need to be constructed for the acetone-nitrogen system to get first estimates (this can be done using PSYCHIC, as shown in Fig. 12-7). A humidity of 0.025 kg/kg at $T = 60°C$ lies just below the adiabatic saturation line for −40°C. The wet-bulb temperature will not be the same as $T_{as}$ for this system; since the psychrometric ratio $\beta$ is less than 1, $T_{wb}$ should be significantly above $T_{as}$. However, let us assume no good first estimate is available and simply take $T_{wb}$ to be 0°C initially.

When using the psychrometer equation, we will need to use Eq. (12-13) to obtain the value of the psychrometer coefficient. Using the tabulated values above, we obtain $A = 0.00135$, about double the value for air-water. We must remember that the

estimate will be very rough because of the uncertainty in the value of β. Refining the estimate of $T_{wb}$ by using the psychrometer equation and iterating gives

$$p_{wb} = 119.1 + 1.35 \times 10^{-3} (10^4) (60 - 0) = 932.3 \text{ Pa} = 7.0 \text{ mmHg}$$

From the Antoine equation,

$$T_{wb} = 2940/(16.6513 - \ln 7) + 35.93 = 235.84 \text{ K} = -37.3°\text{C}$$

Second iteration:

$$p_{wb} = 119.1 + 1.35 \times 10^{-3} (10^4) (60 + 37.3) = 1433 \text{ Pa} = 10.7 \text{ mmHg}$$
$$T_{wb} = 241.85 \text{ K} = -31.3°\text{C}$$

Third iteration:

$$p_{wb} = 119.1 + 1.35 \times 10^{-3} (10^4) (60 + 31.3) = 1352 \text{ Pa} = 10.1 \text{ mmHg}$$
$$T_{wb} = 241.0 \text{ K} = -32.1°\text{C}$$

The iteration has converged successfully, despite the poor initial guess. The wet-bulb temperature is −32°C; given the levels of error in the calculation, it will be meaningless to express this to any greater level of precision.

In a similar way, the adiabatic saturation temperature can be calculated from Eq. (12-6) by taking the first guess as −40°C and assuming the humid heat to be 1.05 kJ/(kg · K) including the vapor:

$$Y_{as} = Y + \frac{C_s}{\lambda_{as}} (T - T_{as})$$
$$= 0.025 + \left(\frac{1.05}{501.1}\right)(60 + 40) = 0.235 \text{ kg/kg}$$

From Table 12-2,

$$p_{as} = 1018 \text{ Pa} = 7.63 \text{ mmHg}$$

From the Antoine equation,

$$T_{as} = 237.05 \text{ K} = -36.1°\text{C}$$

Second iteration:

$$Y_{as} = 0.025 + (1.05/501.1)(60 + 36.1) = 0.226 \text{ kg/kg} \quad p_{as} = 984 \text{ Pa} = 7.38 \text{ mmHg}$$

From the Antoine equation,

$$T_{as} = 236.6 \text{ K} = -36.6°\text{C}$$

This has converged. A more accurate figure could be obtained with more refined estimates for $C_s$ and $\lambda_{wb}$.

## MEASUREMENT OF HUMIDITY

**Hygrometers** *Electric hygrometers* have been the fastest-growing form of humidity measurement in recent years and are now the most commonly used sensors for process measurement. They measure the electrical resistance, capacitance, or impedance of a film of moisture-absorbing materials exposed to the gas. A wide variety of sensing elements are used. Normally, relative humidity is measured, with a corresponding temperature measurement and conversion to absolute humidity.

*Mechanical hygrometers* utilizing materials such as human hair, wood fiber, and plastics have been used to measure humidity. These methods rely on a change in dimension with humidity. They are not suitable for process use.

Other hygrometric techniques in process and laboratory use include electrolytic and piezoelectric hygrometers, infrared and mass spectroscopy, and vapor pressure measurement, e.g., by a Pirani gauge.

The *gravimetric method* is accepted as the most accurate humidity-measuring technique. In this method a known quantity of gas is passed over a moisture-absorbing chemical such as phosphorus pentoxide, and the increase in weight is determined. It is mainly used for calibrating standards and measurements of gases with $SO_x$ present.

**Dew Point Method** The dew point of wet air is measured directly by observing the temperature at which moisture begins to form on an artificially cooled, polished surface.

Optical dew point hygrometers employing this method are often used as a fundamental technique for determining humidity. Uncertainties in temperature measurement of the polished surface, gradients across the surface, and the appearance or disappearance of fog have been much reduced in modern instruments. Automatic mirror cooling, e.g., Peltier thermoelectric, is more accurate and reliable than older methods using evaporation of a low-boiling solvent such as ether, or external coolants (e.g., vaporization of solid carbon dioxide or liquid air, or water cooling). Contamination effects have also been reduced or compensated for, but regular recalibration is still required, at least once a year.

**Wet-Bulb/Dry-Bulb Method** In the past, probably the most commonly used method for determining the humidity of a gas stream was the measurement of wet- and dry-bulb temperatures. The wet-bulb temperature is measured by contacting the air with a thermometer whose bulb is covered by a wick saturated with water. If the process is adiabatic, the thermometer bulb attains the wet-bulb temperature. When the wet- and dry-bulb temperatures are known, the humidity is readily obtained from charts such as Figs. 12-1 through 12-4. To obtain reliable information, care must be exercised to ensure that the wet-bulb thermometer remains wet and that radiation to the bulb is minimized. The latter is accomplished by making the relative velocity between wick and gas stream high [a velocity of 4.6 m/s (15 ft/s) is usually adequate for commonly used thermometers] or by the use of radiation shielding. In the *Assmann psychrometer,* the air is drawn past the bulbs by a motor-driven fan. Making sure that the wick remains wet is a mechanical problem, and the method used depends to a large extent on the particular arrangement. Again, as with the dew point method, errors associated with the measurement of temperature can cause difficulty.

For measurement of atmospheric humidities, the *sling* or *whirling psychrometer* was widely used in the past to give a quick and cheap, but inaccurate, estimate. A wet- and dry-bulb thermometer is mounted in a sling which is whirled manually to give the desired gas velocity across the bulb.

In addition to the mercury-in-glass thermometer, other temperature-sensing elements may be used for psychrometers. These include resistance thermometers, thermocouples, bimetal thermometers, and thermistors.

# EVAPORATIVE COOLING

**General References:** ASHRAE is the American Society of Heating, Refrigeration and Air Conditioning Engineers: www.ashrae.org; *ASHRAE Handbook of Fundamentals,* "Climatic Design Information," chap. 14, ASHRAE, Atlanta, Ga., 2013. Cooling Technology Institute: www.cti.org. ASHRAE and CTI are both professional organizations and both websites contain technical resources and contacts for engineers.

## INTRODUCTION

Evaporative cooling, using recirculated cooling water systems, is the method most widely used throughout the process industries for employing water to remove process waste heat, rejecting that waste heat into the environment. Maintenance considerations (water-side fouling control), through control of makeup water quality and control of cooling water chemistry, form one reason for this preference. Environmental considerations—by minimizing consumption of potable water, minimizing the generation and release of contaminated cooling water, and controlling the release into the environment of chemicals from leaking heat exchangers—form the second major reason.

Local ambient climatic conditions, particularly the maximum summer wet-bulb temperature, determine the design of the evaporative equipment. Typically, the wet-bulb temperature used for design is the 0.4 percent value, as listed in the *ASHRAE Handbook of Fundamentals,* equivalent to 35-h exceedance per year on average.

The first subsection below presents the classic *cooling tower* (CT), the evaporative cooling technology most widely used today. The second subsection presents the *wet surface air cooler* (WSAC), a more recent technology, combining within one piece of equipment the functions of cooling tower, circulated cooling water system, and heat exchange tube bundle. The most common application for WSACs is in the direct cooling of process streams. However, the closed-circuit cooling tower, employing WSACs for cooling the circulated cooling water (replacing the CT), is an important alternative WSAC application, presented at the end of this section.

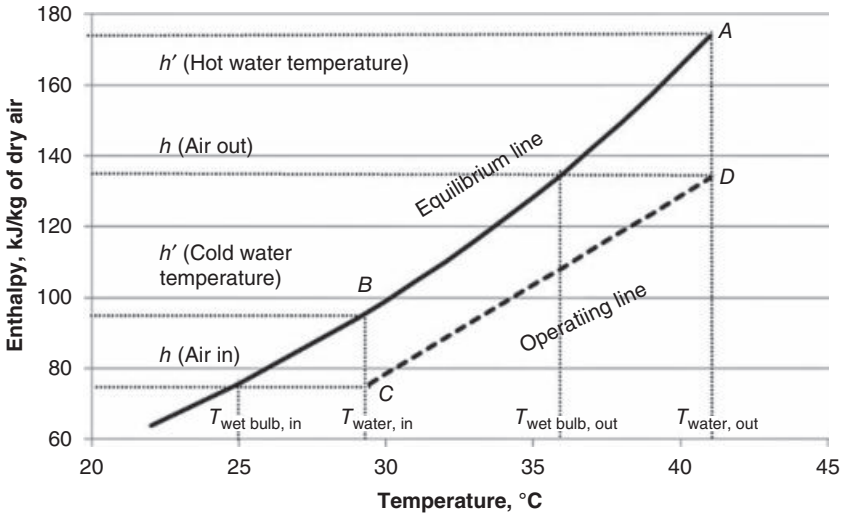

**FIG. 12-8** Cooling-tower process heat balance and solution to Example 12-10.

To minimize the total annualized costs for evaporative cooling is a complex engineering task in itself, separate from classic process design. The evaluation and the selection of the best option for process cooling impact many aspects of how the overall project will be optimally designed (utilities supply, reaction and separations design, pinch analyses, 3D process layout, plot plan, etc.). Therefore, evaluation and selection of the evaporative cooling technology system should be performed at the start of the project design cycle, during conceptual engineering (Sec. 9, Process Economics, Value Improving Practices), when the potential to influence project costs is at a maximum value (Sec. 9, VIP Fig. 9-26). The relative savings achievable for selection of the optimum heat rejection technology option can frequently exceed 25 percent, for the installed cost for the technology alone.

## PRINCIPLES

The processes of cooling water are among the oldest known. Usually water is cooled by exposing its surface to air. Some of the processes are slow, such as the cooling of water on the surface of a pond; others are comparatively fast, such as the spraying of water into air. These processes all involve the exposure of water surface to air in varying degrees.

The heat-transfer process involves (1) latent heat transfer owing to vaporization of a small portion of the water and (2) sensible heat transfer owing to the difference in temperatures of water and air. Approximately 80 percent of this heat transfer is due to latent heat and 20 percent to sensible heat.

## COOLING TOWERS

**General References:** Hensley, *Cooling Tower Fundamentals,* 2d ed., Marley Cooling Technologies,* Bridgewater, N.J., 1998. McAdams, *Heat Transmission,* 3d ed., McGraw-Hill, New York, 1954, pp. 356–365. Extensive information can be found online at the following websites: www.cti.org; www.ashrae.org; www.marleyct.com; www.spxcooling.com.

**Process Description** A cooling tower is a simultaneous heat- and mass-transfer device that cools a hot process water stream directly by evaporation into ambient air. The water is pumped up to the top of the tower and sprayed into flowing ambient air. The tower contains a packing (called *fill*) to increase the surface area of contact of the water with the air as it falls to the cool water collection basin. The fill is commonly made from wood slats or PVC.

Theoretical possible heat removal per unit mass of air circulated in a cooling tower depends on the temperature and moisture content of air. An indication of the moisture content of the air is its wet-bulb temperature. Ideally, then, the wet-bulb temperature is the lowest theoretical temperature to which the water can be cooled. Practically, the cold water temperature approaches but does not equal the air wet-bulb temperature in a cooling tower; this is so because it is impossible to contact all the water with fresh air as the water drops through the wetted fill surface to the basin. The magnitude of the approach to the wet-bulb temperature is dependent on the tower design. Important factors are air-to-water contact time, amount of fill surface, and breakup of water into droplets. In actual practice, cooling towers are seldom designed for approaches closer than 2.8°C (5°F).

**Cooling Tower Theory** The most generally accepted theory of the cooling tower heat-transfer process is that developed by Merkel [Merkel, *Z. Ver. Dtsch. Ing. Forsch.,* no. 275 (1925)]. The theory is developed using the same approach as the HTU-NTU model for mass or heat transfer in packed columns. Mass and energy balances are constructed within a differential vertical increment and then integrated over the height of the tower. The Merkel equation combines the mass- and heat-transfer processes to arrive at one driving force—enthalpy to capture the simultaneous heat- and mass-transfer processes in one equation. Both the Chilton-Colburn analogy and the fact that the Lewis number is near unity (see Psychrometry subsection) for air-water systems are used to derive the equation; this treatment is only valid for air-water systems. See Wankat, *Equilibrium Staged Separations*, Elsevier, 1988, pp. 674–688 for a lucid and detailed description of this equation and a worked example.

In the integrated form, the Merkel equation is given by

$$\frac{Ka\,V}{L} = \int_{T_2}^{T_1} \frac{C_L\,dT}{h' - h} \tag{12-14}$$

where $K$ = mass-transfer coefficient, kg water/(m$^2$ · s); $a$ = contact area, m$^2$/m$^3$ tower volume; $V$ = active cooling volume, m$^3$/m$^2$ of plan area; $L$ = water rate, kg/(m$^2$ · s); $C_L$ = heat capacity of water, J/(kg · °C); $h'$ = enthalpy of saturated air at water temperature, J/kg; $h$ = enthalpy of airstream, J/kg; and $T_1$ and $T_2$ = entering and leaving water temperatures, °C.

The right-hand side of Eq. (12-14) is entirely in terms of air and water properties and is independent of tower dimensions. The left-hand side is the "tower characteristic," $KaV/L$, which can be determined by integration. To predict tower performance, it is necessary to know the required tower characteristics for fixed ambient and water conditions.

Figure 12-8 illustrates water and air relationships and the driving potential which exist in a counterflow tower, where air flows parallel but opposite in direction to water flow. An understanding of this diagram is important in visualizing the cooling tower process and evaluating the integral in the Merkel equation.

Figure 12-8 is an enthalpy-temperature diagram, containing two lines: an equilibrium line and an operating line. The equilibrium line is shown by *AB*. This line represents the enthalpy of saturated water vapor. It can be plotted using the definition of humid enthalpy in the Psychrometry subsection.

$$h' = (C_{P,g} + C_{P,y} \cdot Y)(T - T_0) + \lambda_0 Y \tag{12-15}$$

If we choose a reference temperature of 0°C, then $\lambda_0$ = 2501 kJ/kg. The absolute humidity at saturation is found first by calculating the vapor

*The contributions of Ken Mortensen and coworkers of Marley Cooling Technologies, Overland Park, Kansas, toward the review and update of this subsection are gratefully acknowledged.

pressure (at $T$) using Eq. (12-5) and then by using the following relationship from Table 12-1:

$$Y = \frac{0.622 \cdot p}{P - p} \tag{12-16}$$

The operating line describes the enthalpy of the air moving through the tower and is given by line *CD*. The highest temperature is that of the water entering (point *D*), and the lowest is that of the water leaving (point *C*). This difference is called the *range*. The difference between the wet-bulb temperature of the air entering and the temperature of the water exiting is called the *approach*. The operating line is given by

$$h - h_{\text{wet bulb, air in}} = \left(\frac{L}{G} \cdot C_{p,\,\text{water}}\right) \cdot (T - T_{\text{water, out}}) \tag{12-17}$$

The enthalpy of the wet-bulb temperature is on the equilibrium line, and it is found by using the same procedure as outlined above. Mechanical draft cooling towers normally are designed for $L/G$ ratios ranging from 0.75 to 1.50; accordingly, the values of $KaV/L$ vary from 0.50 to 2.50.

The tower characteristic contains the kinetic information in the design, which is affected by the nature of the fill and the velocity of the air. A useful discussion on optimization of cooling towers is found in Picardo, J. R., *Energy Conversion and Management* **57:** 167–172 (2012). Some practical guidelines on the height and cross-sectional area are given below.

***Example 12-10 Calculation of Mass-Transfer Coefficient Group*** Determine the theoretically required $KaV/L$ value for a cooling duty from 41°C inlet water, 29.4°C outlet water, 25°C ambient wet-bulb temperature, and an $L/G$ ratio of 1.2.

We first evaluate the equilibrium and operating lines over the temperature range of interest. These are plotted as Fig. 12-8. The enthalpy $h$ of the air at the wet-bulb temperature equals 74.75 kJ/kg, using Eqs. (12-5), (12-15), and (12-16). Numerical integration of the Merkel equation using a spreadsheet gives $KaV/L = 2.32$.

**Cooling Tower Equipment** The airflow in a cooling tower is driven by fans or by natural convection. When fans are used, it is called a *mechanical draft tower*. Two types are in use today, the forced-draft and the induced-draft towers. In the forced-draft tower, the fan is mounted at the base, and air is forced in at the bottom and discharged at low velocity through the top. This arrangement has the advantage of locating the fan and drive outside the tower, where it is convenient for inspection, maintenance, and repairs. Since the equipment is out of the hot, humid top area of the tower, the fan is not subjected to corrosive conditions. However, because of the low exit-air velocity, the forced-draft tower is subjected to excessive recirculation of the humid exhaust vapors back into the air intakes. Since the wet-bulb temperature of the exhaust air is considerably higher than the wet-bulb temperature of the ambient air, there is a decrease in performance evidenced by an increase in cold (leaving) water temperature.

The induced-draft tower is the most common type used in the United States. It is further classified into counterflow and cross-flow design, depending on the relative flow directions of water and air. Thermodynamically, the counterflow arrangement is more efficient, since the coldest water contacts the coldest air, thus obtaining maximum enthalpy potential. The greater the cooling ranges and the more difficult the approaches, the more distinct are the advantages of the counterflow type. The cross-flow tower manufacturer may effectively reduce the tower characteristic at very low approaches by increasing the air quantity to give a lower $L/G$ ratio. The increase in airflow is not necessarily achieved by increasing the air velocity, but primarily by lengthening the tower to increase the airflow cross-sectional area. It appears then that the cross-flow fill can be made progressively longer in the direction perpendicular to the airflow and shorter in the direction of the airflow until it almost loses its inherent potential-difference disadvantage. However, as this is done, fan power consumption increases.

Ultimately, the economic choice between counterflow and cross-flow is determined by the effectiveness of the fill, design conditions, water quality, and costs of tower manufacture.

Performance of a given type of cooling tower is governed by the ratio of the weights of air to water and the time of contact between water and air. In commercial practice, the variation in the ratio of air to water is first obtained by keeping the air velocity constant at about 1148 m/(min · m$^2$) of active tower area [350 ft/(min · ft$^2$ of active tower area)] and varying the water concentration, L/(min · m$^2$ of ground area) [gal/(min · ft$^2$ of tower area)]. As a secondary operation, air velocity is varied to make the tower accommodate the cooling requirement.

The time of contact between water and air is governed largely by the time required for the water to discharge from the nozzles and fall through the tower to the basin. The time of contact is therefore obtained in a given type of unit by varying the height of the tower. Should the time of contact be insufficient, no amount of increase in the ratio of air to water will produce the desired cooling. It is therefore necessary to maintain a certain minimum height of cooling tower. When a wide approach of 8 to 11°C (15 to 20°F) to the wet-bulb temperature and a 13.9 to 19.4°C (25 to 35°F) cooling range are required, a relatively low cooling tower will suffice. A tower in which the water travels 4.6 to 6.1 m (15 to 20 ft) from the distributing system to the basin is sufficient. When a moderate approach and a cooling range of 13.9 to 19.4°C (25 to 35°F) are required, a tower in which the water travels 7.6 to 9.1 m (25 to 30 ft) is adequate. Where a close approach of 4.4°C (8°F) with a 13.9 to 19.4°C (25 to 35°F) cooling range is required, a tower is required in which the water travels from 10.7 to 12.2 m (35 to 40 ft). It is usually not economical to design a cooling tower with an approach of less than 2.8°C (5°F).

The cooling performance of any tower containing a given depth of fill varies with the water concentration. It has been found that maximum contact and performance are obtained with a tower having a water concentration of 80 to 200 L/(min · m$^2$ of ground area) [2 to 5 gal/(min · ft$^2$ of ground area)]. Thus the problem of calculating the size of a cooling tower becomes one of determining the proper concentration of water required to obtain the desired results. Once the necessary water concentration has been established, the tower area can be calculated by dividing the liters per minute circulated by the water concentration in liters per minute per square meter. The required tower size then is a function of the following:

1. Cooling range (hot water temperature minus cold water temperature)
2. Approach to wet-bulb temperature (cold water temperature minus wet-bulb temperature)
3. Quantity of water to be cooled
4. Wet-bulb temperature
5. Air velocity through the cell
6. Tower height

These considerations in combination with the Markel equation can help engineers with basic conceptual designs that can be used in conjunction with vendors for process design.

**Cooling Tower Operation: Water Makeup** It is the open nature of evaporative cooling systems, bringing in external air and water continuously, that determines the unique water problems these systems exhibit. Cooling towers (1) concentrate solids by the mechanisms described above and (2) wash air. The result is a buildup of dissolved solids, suspended contaminants, organics, bacteria, and their food sources in the circulating cooling water. These unique evaporative water system problems must be specifically addressed to maintain cooling equipment in good working order.

Makeup requirements for a cooling tower consist of the sum of evaporation loss, drift loss, and blowdown. Therefore,

$$W_m = W_e + W_d + W_b \tag{12-18}$$

where $W_m$ = makeup water, $W_e$ = evaporation loss, $W_d$ = drift loss, and $W_b$ = blowdown (consistent units: m$^3$/h or gal/min).

Evaporation loss can be estimated by

$$W_e = 0.00085 W_c (T_1 - T_2) \tag{12-19}$$

where $W_c$ = circulating water flow, m$^3$/h or gal/min, at tower inlet and $T_1 - T_2$ = inlet water temperature minus outlet water temperature, °F. The 0.00085 evaporation constant is a good rule-of-thumb value. The actual evaporation rate will vary by season and climate.

Drift loss can be estimated by

$$W_d = 0.0002 W_c \tag{12-20}$$

Drift is entrained water in the tower discharge vapors. Drift loss is a function of the drift eliminator design and is typically less than 0.02 percent of the water supplied to the tower given the new developments in eliminator design.

Blowdown discards a portion of the concentrated circulating water due to the evaporation process in order to lower the system solids concentration. The amount of blowdown can be calculated according to the number of cycles of concentration required to limit scale formation. The *cycles of concentration* are the ratio of dissolved solids in the recirculating water to dissolved solids in the makeup water. Since chlorides remain soluble on concentration, cycles of concentration are best expressed as the ratio of the chloride contents of the circulating and makeup waters. Thus, the blowdown quantities required are determined from

$$\text{Cycles of concentration} = \frac{W_e + W_b + W_d}{W_b + W_d} \tag{12-21}$$

or

$$W_b = \frac{W_e - (\text{cycles} - 1)\, W_d}{\text{cycles} - 1} \tag{12-22}$$

**TABLE 12-6 Blowdown (Percent)**

| Range, °F | 2X | 3X | 4X | 5X | 6X |
|---|---|---|---|---|---|
| 10 | 0.83 | 0.41 | 0.26 | 0.19 | 0.15 |
| 15 | 1.26 | 0.62 | 0.41 | 0.30 | 0.24 |
| 20 | 1.68 | 0.83 | 0.55 | 0.41 | 0.32 |
| 25 | 2.11 | 1.04 | 0.69 | 0.51 | 0.41 |
| 30 | 2.53 | 1.26 | 0.83 | 0.62 | 0.49 |

Cycles of concentration involved with cooling tower operation normally range from 3 to 5 cycles. For water qualities where operating water concentrations must be below 3 to control scaling, blowdown quantities will be large. The addition of acid or scale-inhibiting chemicals can limit scale formation at higher cycle levels and will allow substantially reduced water usage for blowdown.

The blowdown equation (12-22) translates to calculated percentages of the cooling system circulating water flow exiting to drain, as listed in Table 12-6. The blowdown percentage is based on the cycles targeted and the cooling range. The range is the difference between the system hot water and cold water temperatures.

***Example 12-11 Calculation of Makeup Water*** Determine the amount of makeup required for a cooling tower with the following conditions:

| | |
|---|---|
| Inlet water flow, $m^3/h$ (gal/min) | 2270 (10,000) |
| Inlet water temperature, °C (°F) | 37.77 (100) |
| Outlet water temperature, °C (°F) | 29.44 (85) |
| Drift loss, percent | 0.02 |
| Concentration cycles | 5 |

Evaporation loss [using Eq. (12-19)]:

$$W_e, \text{ m}^3/\text{h} = 0.00085 \times 2270 \times (37.77 - 29.44) \times (1.8°\text{F}/°\text{C}) = 28.9$$
$$W_e, \text{ gal/min} = 127.5$$

Drift loss

$$W_d, \text{ m}^3/\text{h} = 2270 \times 0.0002 = 0.45$$
$$W_d, \text{ gal/min} = 2$$

Blowdown

$$W_b, \text{ m}^3/\text{h} = 6.8$$
$$W_b, \text{ gal/min} = 29.9$$

Makeup

$$W_m, \text{ m}^3/\text{h} = 28.9 + 0.45 + 6.8 = 36.2$$
$$W_m, \text{ gal/min} = 159.4$$

**Fans and Pumps** The fan and pump power requirements are important considerations in system design since they impact cost and performance. The power requirement of the fan depends on the configuration and the pressure drop/air velocity characteristics of the fill. The power requirement and pressure rating on the pump depend on the tower height and how the incoming water is distributed over the fill.

**Fogging and Plume Abatement** A phenomenon that occurs in cooling tower operation is fogging, which produces a highly visible plume and possible icing hazards. Fogging results from mixing warm, highly saturated tower discharge air with cooler ambient air that lacks the capacity to absorb all the moisture as vapor. While in the past visible plumes have not been considered undesirable, properly locating towers to minimize possible sources of complaints has now received the necessary attention. In some instances, high fan stacks have been used to reduce ground fog. Although tall stacks minimize the ground effects of plumes, they can do nothing about water vapor saturation or visibility (which can be a safety matter). The persistence of plumes is much greater in periods of low ambient temperatures.

Special care must be taken regarding the placement of cooling towers relative to other buildings to ensure a fresh air supply.

Environmental aspects have caused public awareness and concern over any visible plume, although many laypersons misconstrue cooling tower discharge as harmful. This has resulted in a new development for plume abatement known as a *wet-dry cooling tower configuration*. Reducing the relative humidity or moisture content of the tower discharge stream will reduce the frequency of plume formation. Figure 12-9 shows a "parallel path" arrangement that has been demonstrated to be technically sound but at substantially increased tower investment. Ambient air travels in parallel streams through the top dry-surface section and the evaporative section. Both sections benefit thermally by receiving cooler ambient air with the wet and dry airstreams mixing after leaving their respective sections. Water flow is arranged in series, flowing first to the dry coil section and then to the evaporation fill section. A "series path" airflow arrangement, in which dry coil sections can be located before or after the air traverses the evaporative section, also can be used. However, series-path airflow has the disadvantage of water impingement, which could result in coil scaling and restricted airflow.

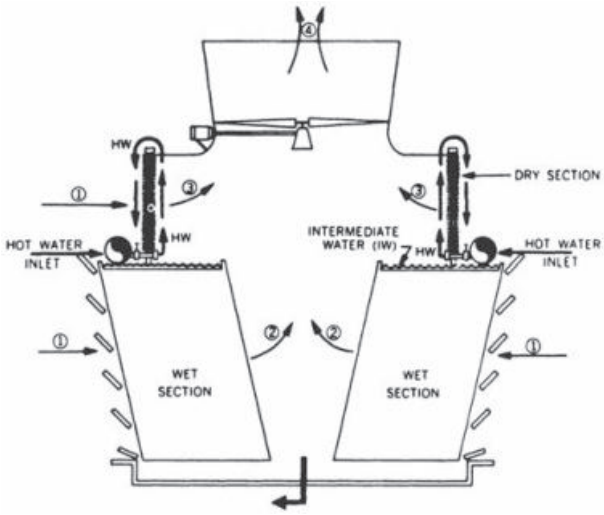

**FIG. 12-9** Parallel-path cooling-tower arrangement for plume abatement. (*Marley Co.*)

**Natural Draft Towers, Cooling Ponds, and Spray Ponds** Natural draft towers are primarily suited to very large cooling water quantities, and the reinforced concrete structures used are as large as 80 m (260 ft) in diameter and 105 m (340 ft) high.

When large ground areas are available, large cooling ponds offer a satisfactory method of removing heat from water. A pond may be constructed at a relatively small investment by pushing up earth in an earth dike 2 to 3 m (6 to 9 ft) high.

Spray ponds provide an arrangement for lowering the temperature of water by evaporative cooling and in so doing greatly reduce the cooling area required in comparison with a cooling pond.

Natural draft towers, cooling ponds, and spray ponds are infrequently used in new construction today in the chemical processing industry. Additional information may be found in the 7th edition of Perry's Handbook.

## WET SURFACE AIR COOLERS (WSACs)

**General References:** Kals, "Wet Surface Aircoolers," *Chem. Engg.* July 1971; Kals, "Wet Surface Aircoolers: Characteristics and Usefulness," AIChE-ASME Heat Transfer Conference, Denver, CO., August 6–9, 1972; Elliott and Kals, "Air Cooled Condensers," *Power,* January 1990; Kals, "Air Cooled Heat Exchangers: Conventional and Unconventional," *Hydrocarbon Processing*, August 1994; Hutton, "Properly Apply Closed Circuit Evaporative Cooling," *Chem. Progress*, October 1996; Hutton, "Improved Plant Performance through Evaporative Steam Condensing," ASME 1998 International Joint Power Conference, Baltimore, Md., August 23–26, 1998; http://www.niagarablower.com/; http://www.baltimoreaircoil.com.

**Principles** Rejection of waste process heat through a cooling tower (CT) requires transferring the heat in two devices in series, using two different methods of heat transfer. This requires two temperature driving forces in series: first, sensible heat transfer from the process stream across the *heat exchanger* (HX) into the cooling water, and, second, sensible and latent heat transfer from the cooling water to atmosphere across the CT. Rejecting process heat with a wet surface air cooler transfers the waste heat in a single device by using a single-unit operation. The single required temperature driving force is lower because the WSAC does not require the use of cooling water sensible heat to transfer heat from the process stream to the atmosphere. A WSAC tube cross section (Fig. 12-10) shows the characteristic external tube surface having a continuous flowing film of evaporating water, which cascades through the WSAC tube bundle.

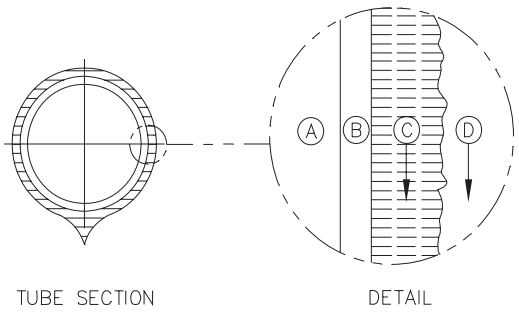

**FIG. 12-10** WSAC tube cross section. Using a small *T*, heat flows from (A) the process stream, through (B) the tube, through (C) the flowing film of evaporating water, into (D) flowing ambient air.

Consequently, process streams can be economically cooled to temperatures much closer to the ambient wet-bulb temperature, as low as to within 2.2°C (4°F), depending on the process requirements and economics for the specific application.

**Wet Surface Air Cooler Basics** The theory and principles for the design of WSACs are a combination of those known for evaporative cooling tower design and for HX design. However, the design practices for engineering WSAC equipment remain a largely proprietary, technical art, and the details are not presented here. Any evaluation of the specifics and economics for a particular application requires direct consultation with a reputable vendor.

Because ambient air is contacted with evaporating water within a WSAC, from a distance a WSAC has a similar appearance to a CT (Fig. 12-11). Economically optimal plot plan locations for WSACs can vary: integrated into, or with, the process structure, remote to it, in a pipe rack, etc.

In the WSAC the evaporative cooling occurs on the wetted surface of the tube bundle. The wetting of the tube bundle is performed by recirculating water the short vertical distance from the WSAC collection basin, through the spray nozzles, and onto the top of the bundle (Fig. 12-12). The tube bundle is completely deluged with this cascading flow of water. Using water application rates between 12 and 24 $(m^3/h)/m^2$ (5 and 10 $gpm/ft^2$), the tubes have a continuous, flowing external water film, minimizing the potential for water-side biological fouling, sediment deposition, etc. Process inlet temperatures are limited to a maximum of about 85°C (185°F), to prevent external water-side mineral scaling. However, higher process inlet temperatures can be accepted by incorporating bundles of dry, air-cooled finned tubing within the WSAC unit, to reduce the temperature of the process stream to an acceptable level before it enters the wetted evaporative tube bundles.

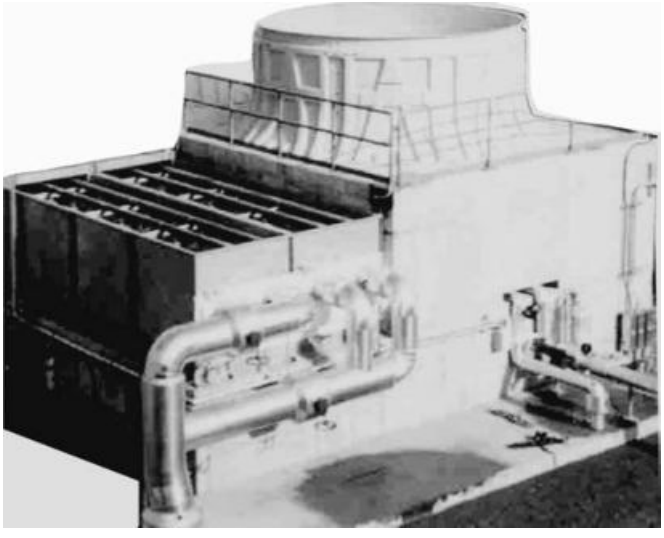

**FIG. 12-11** Overhead view of a single-cell WSAC.

**FIG. 12-12** Nozzles spraying onto wetted tube bundle in a WSAC unit.

The WSAC combines within one piece of equipment the functions of cooling tower, circulated cooling water system, and water-cooled HX. In the basic WSAC configuration (Fig. 12-13), ambient air is drawn in and down through the tube bundle. This airflow is cocurrent with the evaporating water flow, recirculated from the WSAC collection basin sump to be sprayed over the tube bundles. This downward cocurrent flow pattern minimizes the generation of water mist (drift). At the bottom of the WSAC, the air changes direction through 180°, disengaging entrained fine water droplets. Drift eliminators can be added to meet very low drift requirements. Because heat is extracted from the tube surfaces by water latent heat (and not sensible heat), only about 75 percent as much circulating water is required in comparison to an equivalent CT-cooling water heat exchange application.

The differential head of the circulation water pump is relatively small, since dynamic losses are modest (short vertical pipe and a low $\Delta P$ spray nozzle) and the hydraulic head is small, only about 6 m (20 ft) from the basin to the elevation of the spray header. Combined, the pumping energy demand is about 35 percent that for an equivalent CT application. The capital cost for this complete water system is also relatively small. The pumps and motors are smaller, the piping has a smaller diameter and is much shorter, and the

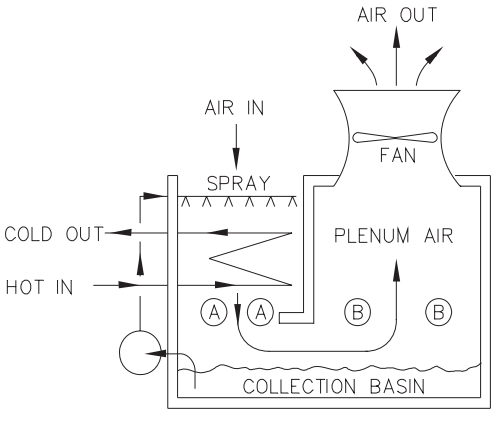

**FIG. 12-13** Basic WSAC configuration.

required piping structural support is almost negligible, compared to an equivalent CT application. WSAC fan horsepower is typically about 25 percent less than that for an equivalent CT.

A WSAC is inherently less sensitive to water-side fouling. This is so because the deluge rate prevents the adhesion of waterborne material which can cause fouling within a HX. A WSAC can accept relatively contaminated makeup water, such as CT blowdown, treated sewage plant effluent, etc. WSACs can endure more cycles of concentration without fouling than can a CT application. This higher practical operating concentration reduces the relative volume for the evaporative cooling blowdown, and therefore it also reduces the relative volume of required makeup water. For facilities designed for zero liquid discharge, the higher practical WSAC blowdown concentration reduces the size and the operating costs for the downstream water treatment system. Since a hot process stream provides the unit with a heat source, a WSAC has intrinsic freeze protection while operating.

**Common WSAC Applications and Configurations** Employment of a WSAC can reduce process system operating costs that are not specific to the WSAC unit itself. A common WSAC application is condensation of compressed gas (Fig. 12-14). A compressed gas can be condensed in a WSAC at a lower pressure, by condensing at a temperature closer to the ambient wet-bulb temperature, typically 5.5°C (10°F) above the wet-bulb temperature. This reduced condensation pressure reduces costs, by reducing the gas compressor motor operating horsepower. Consequently, WSACs are widely applied for condensing refrigerant gases, for HVAC, process chillers, ice makers, gas-turbine inlet air cooling, chillers, etc. WSACs are also used directly to condense lower-molecular-weight hydrocarbon streams, such as ethane, ethylene, propylene, and LPG. A related WSAC application is the cooling of compressed gases ($CO_2$, $N_2$, methane, LNG, etc.), which directly reduces gas compressor operating costs (inlet and interstage cooling) and indirectly reduces downstream condensing costs (after cooling the compressed gas to reduce the downstream refrigeration load).

For combined-cycle electric power generation, employment of a WSAC increases steam turbine efficiency. Steam turbine exhaust can be condensed at a lower pressure (higher vacuum) by condensing at a temperature closer to the ambient wet-bulb temperature, typically 15°C (27°F) above the wet-bulb temperature. This reduced condensation pressure results in a lower turbine discharge pressure, increasing electricity generation by increasing output shaft power (Fig. 12-15). Due to standard WSAC configurations, a second cost advantage is gained at the turbine itself. The steam turbine can be placed at grade, rather than being mounted on an elevated platform, by venting horizontally into the WSAC, rather than venting downward to condensers located below the platform elevation, as is common for conventional water-cooled vacuum steam condensers.

A WSAC can eliminate chilled water use, for process cooling applications with required temperatures close to and just above the ambient wet-bulb temperature, typically about 3.0 to 5.5°C (5 to 10°F) above the wet-bulb temperature. This WSAC application can eliminate both chiller capital and operating costs. In such an application, either the necessary process temperature is below the practical CT water supply temperature, or they are so close to it that the use of CT water is uneconomical (a low-HX log-mean temperature difference).

WSACs can be designed to simultaneously cool several process streams in parallel separate tube bundles within a single cell of a WSAC (Fig. 12-16). Often one of the streams is closed-circuit cooling water to be used for remote cooling applications. These might be applications not compatible with a WSAC (rotating seals, bearings, cooling jackets, internal reactor cooling coils, etc.) or merely numerous, small process streams in small HXs.

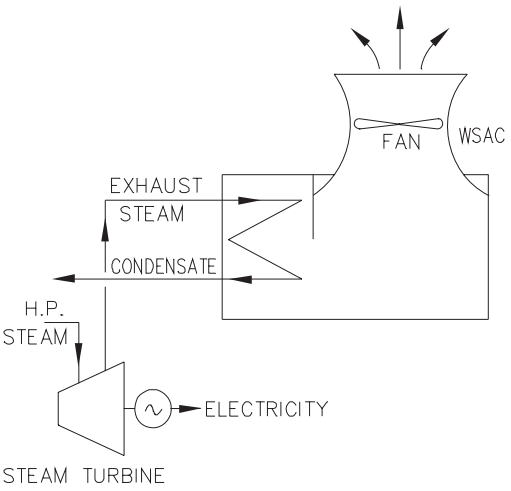

**FIG. 12-15** WSAC configuration with electricity generation. A lower steam condensing pressure increases the turbine horsepower extracted.

**WSAC for Closed-Circuit Cooling Systems** A closed-circuit cooling system as defined by the Cooling Technology Institute (CTI) (www.cti.org) employs a closed loop of circulated fluid (typically water) remotely as a cooling medium. By definition, this medium is cooled by water evaporation involving no direct fluid contact between the air and the enclosed circulated cooling medium. Applied in this manner, a WSAC can be used as the evaporative device to cool the circulated cooling medium, used remotely to cool process streams. This configuration completely isolates the cooling water (and the hot process streams) from the environment (Fig. 12-17).

The closed circuit permits complete control of the cooling water chemistry, which permits minimizing the cost for water-side materials of construction and eliminating water-side fouling of, and fouling heat-transfer resistance in, the heat exchangers (or jackets, reactor coils, etc.). Elimination of water-side fouling is particularly helpful for high-temperature cooling applications, especially where heat recovery may otherwise be impractical (quench oils, low-density polyethylene reactor cooling, etc.).

Closed-circuit cooling minimizes circulation pumping horsepower, which must overcome only dynamic pumping losses. This results through recovery of the returning circulated cooling water hydraulic head. A closed-circuit system can be designed for operation at elevated pressures, to guarantee that any process heat-transfer leak will be into the process. Such high-pressure operation is economical, since the system overpressure is not lost during return flow to the circulation pump.

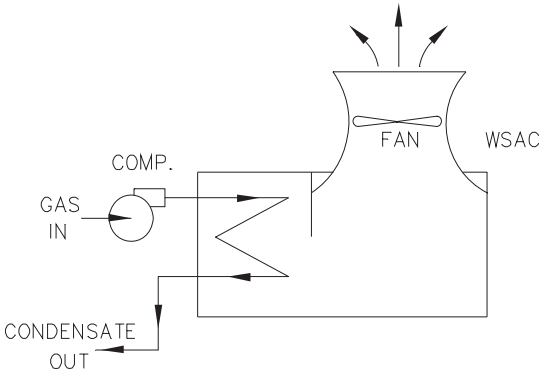

**FIG. 12-14** WSAC configuration for condensing a compressed gas. A lower condensing pressure reduces compressor operating horsepower.

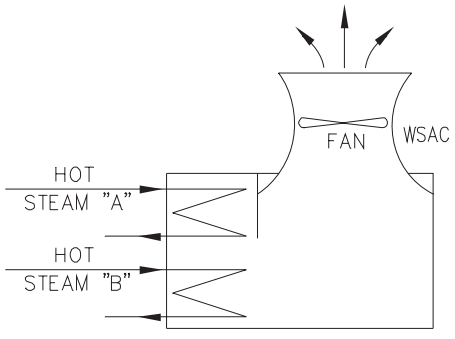

**FIG. 12-16** WSAC configuration with parallel streams.

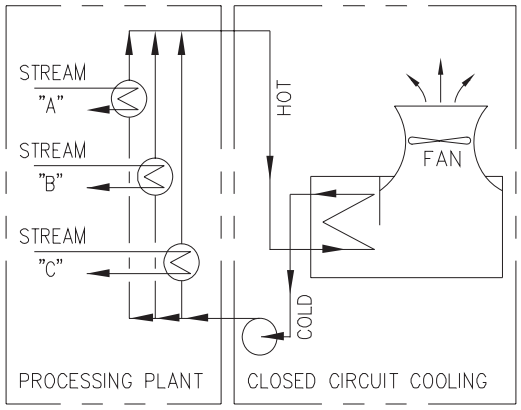

**FIG. 12-17** WSAC configuration with no direct fluid contact.

Closed-circuit cooling splits the water chemistry needs into two isolated systems: the evaporating section, exposed to the environment, and the circulated cooling section, isolated from the environment. Typically, this split reduces total water chemistry costs and water-related operations and maintenance problems. However, the split permits the effective use of a low-quality or contaminated makeup water for evaporative cooling, or a water source having severe seasonal quality problems, such as high sediment loadings.

If highly saline water is used for the evaporative cooling, a reduced flow of makeup saline water would need to be supplied to the WSAC. This reduction results from using latent cooling rather than sensible cooling to reject the waste heat. This consequence reduces the substantial capital investment required for the saline water supply and return systems (canal structures) and pump stations, and the saline supply pumping horsepower. (When saline water is used as the evaporative medium, special attention is paid to materials of construction and spray water chemical treatment due to the aggravated corrosion and scaling tendencies of this water.)

**Water Conservation Applications—"Wet-Dry" Cooling** A modified and hybridized form of a WSAC can be used to provide what is called *wet-dry* cooling for water conservation applications (Fig. 12-18). A hybridized combination of air-cooled dry finned tubes, standard wetted bare tubes, and wet deck surface area permits the WSAC to operate without water in cold weather, reducing water consumption by about 75 percent of the total for an equivalent CT application.

Under design conditions of maximum summer wet-bulb temperature, the unit operates with spray water deluging the wetted tube bundle. The exiting water then flows down into and through the wet deck surface, where the water is cooled adiabatically to about the wet-bulb temperature and then to the sump.

As the wet-bulb temperature drops, the process load is shifted from the wetted tubes to the dry finned tubes. By bypassing the process stream around the wetted tubes, cooling water evaporation (consumption) is proportionally reduced.

When the wet-bulb temperature drops to the switch point, the process bypassing has reached 100 percent. This switch point wet-bulb temperature is at or above 5°C (41°F). As the ambient temperature drops further, adiabatic evaporative cooling continues to be used, to lower the dry-bulb temperature to below the switch point temperature. This guarantees that the entire cooling load can be cooled in the dry finned tube bundle.

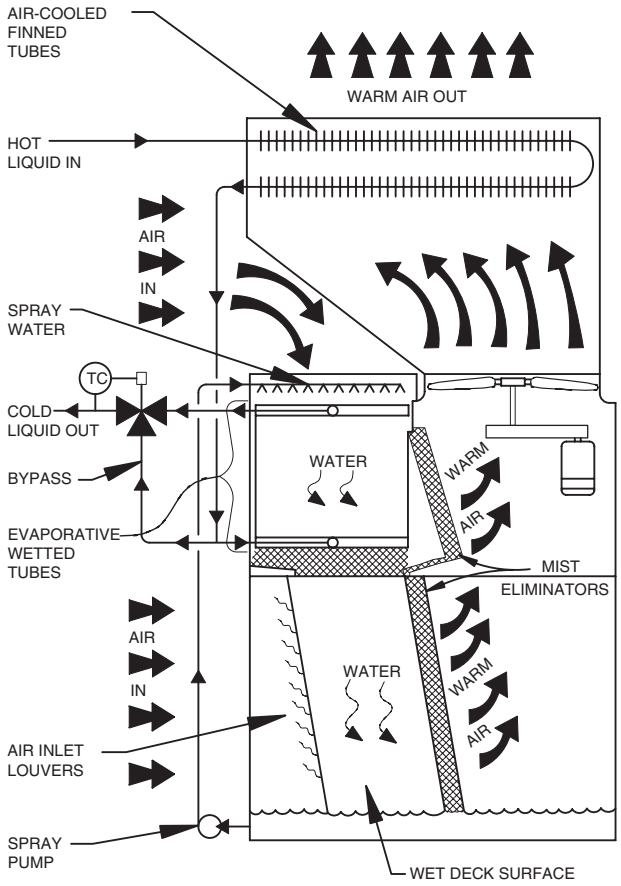

**FIG. 12-18** As seasonal ambient temperatures drop, the "wet-dry" configuration for a WSAC progressively shifts the cooling load from evaporative to convective cooling.

The use of water is discontinued after ambient dry-bulb temperatures fall below the switch point temperature, since the entire process load can be cooled using only cold fresh ambient air. By using this three-step load-shifting practice, total wet-dry cooling water consumption is about 25 percent of that consumption total experienced with an equivalent CT application.

Wet-dry cooling permits significant reduction of water consumption, which is useful where makeup water supplies are limited or where water treatment costs for blowdown are high. Because a WSAC (unlike a CT) has a heat source (the hot process stream), wet-dry cooling avoids various cold-weather-related CT problems. Fogging and persistent plume formation can be minimized or eliminated during colder weather. Freezing and icing problems can be eliminated by designing a wet-dry system for water-free operation during freezing weather, typically below 5°C (41°F). In the arctic, or regions of extreme cold, elimination of freezing fog conditions is realized by not evaporating any water during freezing weather.

## INTRODUCTION

Drying is the process by which volatile materials, usually water, are evaporated from a material to yield a solid product. Drying is a heat- and mass-transfer process. Heat is necessary to evaporate water. The latent heat of vaporization of water is about 2500 J/g, which means that the drying process requires a significant amount of energy. Simultaneously, the evaporating material must leave the drying material by diffusion and/or convection.

Heat transfer and mass transfer are not the only concerns when one is designing or operating a dryer. The product quality (color, particle density, hardness, texture, flavor, etc.) is also very strongly dependent on the drying conditions and the physical and chemical transformations occurring in the dryer.

Understanding and designing a drying process involves measurement and/or calculation of the following:

1. Mass and energy balances
2. Thermodynamics
3. Mass- and heat-transfer rates
4. Product quality considerations

The subsection below explains how these factors are measured and calculated and how the information is used in engineering practice.

## TERMINOLOGY

Generally accepted terminology and definitions are given alphabetically in the following paragraphs.

*Absolute humidity* is the mass ratio of water vapor (or other solvent mass) to dry air.

*Activity* is the ratio of the fugacity of a component in a system relative to the standard-state fugacity. In a drying system, it is the ratio of the vapor pressure of a solvent (e.g., water) in a mixture to the pure solvent vapor pressure at the same temperature. Boiling occurs when the vapor pressure of a component in a liquid exceeds the ambient total pressure.

*Bound moisture* in a solid is that liquid which exerts a vapor pressure less than that of the pure liquid at the given temperature. Liquid may become bound by retention in small capillaries, by solution in cell or fiber walls, by homogeneous solution throughout the solid, by chemical or physical adsorption on solid surfaces, and by hydration of solids.

*Capillary flow* is the flow of liquid through the interstices and over the surface of a solid, caused by liquid-solid molecular attraction.

*Constant-rate period (unhindered)* is that drying period during which the rate of water removal per unit of drying surface is constant, assuming the driving force is also constant.

*Convection* is heat or mass transport by bulk flow.

*Critical moisture content* is the average moisture content when the constant-rate period ends, assuming the driving force is also constant.

*Diffusion* is the molecular process by which molecules, moving randomly due to thermal energy, migrate from regions of high chemical potential (usually concentration) to regions of lower chemical potential.

*Dry basis* expresses the moisture content of wet solid as kilograms of water per kilogram of bone-dry solid.

*Equilibrium moisture content* is the limiting moisture to which a given material can be dried under specific conditions of air temperature and humidity.

*Evaporation* is the transformation of material from a liquid state to a vapor state.

*Falling-rate period (hindered drying)* is a drying period during which the instantaneous drying rate continually decreases.

*Free moisture content* is that liquid which is removable at a given temperature and humidity. It may include bound and unbound moisture.

*Hygroscopic material* is material that may contain bound moisture.

*Initial moisture distribution* refers to the moisture distribution throughout a solid at the start of drying.

*Latent heat of vaporization* is the specific enthalpy change associated with evaporation.

*Moisture content* of a solid is usually expressed as moisture quantity per unit weight of the dry or wet solid.

*Moisture gradient* refers to the distribution of water in a solid at a given moment in the drying process.

*Nonhygroscopic material* is material that can contain no bound moisture.

*Permeability* is the resistance of a material to bulk or convective, pressure-driven flow of a fluid through it.

*Relative humidity* is the partial pressure of water vapor divided by the vapor pressure of pure water at a given temperature. In other words, the relative humidity describes how close the air is to saturation.

*Sensible heat* is the energy required to increase the temperature of a material without changing the phase.

*Unaccomplished moisture change* is the ratio of the free moisture present at any time to that initially present.

*Unbound moisture* in a hygroscopic material is that moisture in excess of the equilibrium moisture content corresponding to saturation humidity. All water in a nonhygroscopic material is unbound water.

*Vapor pressure* is the partial pressure of a substance in the gas phase that is in equilibrium with a liquid or solid phase of the pure component.

*Wet basis* expresses the moisture in a material as a percentage of the weight of the wet solid. Use of a dry-weight basis is recommended since the percentage change of moisture is constant for all moisture levels. When the wet-weight basis is used to express moisture content, a 2 or 3 percent change at high moisture contents (above 70 percent) actually represents a 15 to 20 percent change in evaporative load. See Fig. 12-19 for the relationship between the dry- and wet-weight bases.

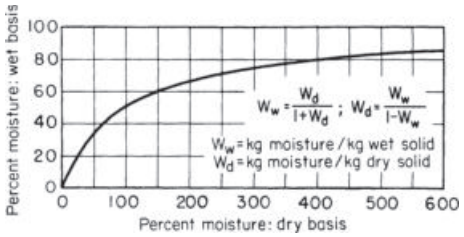

**FIG. 12-19** Relationship between wet-weight and dry-weight bases.

## THERMODYNAMICS

The thermodynamic driving force for evaporation is the difference in chemical potential or water activity between the drying material and the gas phase. Although drying of water is discussed in this subsection, the same concepts apply analogously for solvent drying.

For a pure water drop, the driving force for drying is the difference between the vapor pressure of water and the partial pressure of water in the gas phase. The rate of drying is proportional to this driving force; please see the discussion on drying kinetics later in this section.

$$\text{Rate} \propto \left( p_{\text{pure}}^{\text{sat}} - p_{w,\text{air}} \right) \tag{12-23}$$

The *activity* of water in the gas phase is defined as the ratio of the partial pressure of water to the vapor pressure of pure water, which is also related to the definition of *relative humidity*.

$$a_w^{\text{vapor}} = \frac{p_w}{p_{\text{pure}}^{\text{sat}}} = \frac{\%\text{RH}}{100} \tag{12-24}$$

The *activity* of water in a mixture or solid is defined as the ratio of the vapor pressure of water in the mixture to that of a reference, usually the vapor pressure of pure water. In solids drying or drying of solutions, the vapor pressure (or water activity) is lower than that for pure water. Therefore, the water activity value equals 1 for pure water and is less than 1 when binding is occurring. This is caused by thermodynamic interactions between the water and the drying material. In many standard drying references, this is called *bound water.*

$$a_w^{\text{solid}} = \frac{p_{\text{mixture}}^{\text{sat}}}{p_{\text{pure}}^{\text{sat}}} \tag{12-25}$$

When a solid sample is placed into a humid environment, water will transfer from the solid to the air or vice versa until equilibrium is established. At thermodynamic equilibrium, the water activity is equal in both phases:

$$a_w^{\text{vapor}} = a_w^{\text{solid}} = a_w \tag{12-26}$$

Sorption isotherms quantify how tightly water is bound to a solid. This is a result of chemical interactions, such as hydrogen bonding, between the solid and the water. The goal of obtaining a sorption isotherm for a given solid is to measure the equilibrium relationship between the percentage of water in the sample and the vapor pressure of the mixture. The sorption isotherm describes how dry a product can get if contacted with humid air for an infinite amount of time. An example of a sorption isotherm is shown in Fig. 12-20. In the sample isotherm, a feed material dried with 50 percent relative humidity air ($a_w = 0.5$) will approach a moisture content of 10 percent on a dry basis. Likewise, a material kept in a sealed container will create a headspace humidity according to the isotherm; a 7 percent moisture sample in the example below will create a 20 percent relative humidity ($a_w = 0.2$) headspace in a sample jar or package.

Strictly speaking, the equilibrium moisture content of the sample in a given environment should be independent of the initial condition of

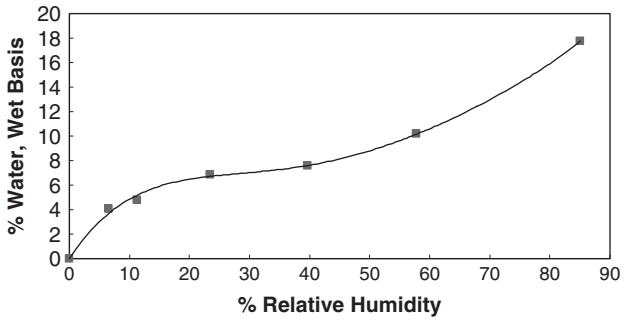

**FIG. 12-20** Example of a sorption isotherm (coffee at 22°C).

the sample. However, in some cases the sorption isotherm of an initially wet sample (sometimes called a *desorption isotherm*) is different from that of an identical, but initially dry sample. This is called *hysteresis* and can be caused by irreversible changes in the sample during wetting or drying, micropore geometry in the sample, and other factors. Paper products are notorious for isotherm hysteresis. Most materials show little or no hysteresis.

Sorption isotherms cannot generally be predicted from theory. They need to be measured experimentally. The simplest method of measuring a sorption isotherm is to generate a series of controlled-humidity environments by using saturated salt solutions, allow a solid sample to equilibrate in each environment, and then analyze the solid for moisture content.

The basic apparatus is shown in Fig. 12-21, and a table of salts is shown in Table 12-7. It is important to keep each chamber sealed and to be sure that crystals are visible in the salt solution to ensure that the liquid is saturated. Additionally, the solid should be ground into a powder to facilitate mass transfer. Equilibration can take 2 to 3 weeks. Successive moisture measurements should be used to ensure that the sample has equilibrated, i.e., achieved a steady value. Care must be taken when measuring the moisture content of a sample; this is described later in this section.

Another common method of measuring a sorption isotherm is to use a dynamic vapor sorption device. This machine measures the weight change of a sample when exposed to humidity-controlled air. A series of humidity points are programmed into the unit, and it automatically delivers the proper humidity to the sample and monitors the weight. When the weight is stable, an equilibrium point is noted and the air humidity is changed to reflect the next setting in the series. When one is using this device, it is critical to measure and record the starting moisture of the sample, since the results are often reported as a percentage of change rather than a percentage of moisture.

There are several advantages to the dynamic vapor sorption device. First, any humidity value can be dialed in, whereas salt solutions are not available for every humidity value and some are quite toxic. Second, since the weight is monitored as a function of time, it is clear when equilibrium is reached; however, this can be a slow process, so care must be taken to ensure equilibrium is actually achieved. The dynamic devices also give the sorption/desorption rates, although these can easily be misused (see the drying kinetics subsection later). The salt solution method, however, is significantly less expensive to buy and maintain. Samples created in salt solution chambers can also be qualitatively assessed for physical characteristics such as stickiness, flowability, or deliquescence.

An excellent reference on all aspects of sorption isotherms is that by Bell and Labuza, *Moisture Sorption,* 2d ed., American Association of Cereal Chemists, St. Paul, Minnesota, 2000.

**FIG. 12-21** Sorption isotherm apparatus. A saturated salt solution is in the bottom of the sealed chamber; samples sit on a tray in the headspace.

**TABLE 12-7 Maintenance of Constant Humidity**

| Saturated salt solution | | % Relative humidity at 25°C |
|---|---|---|
| Lithium bromide | LiBr | 6.37 |
| Lithium chloride | LiCl | 11.30 |
| Potassium acetate | $KC_2H_3O_2$ | 22.51 |
| Sodium iodide | NaI | 38.17 |
| Sodium bromide | NaBr | 57.57 |
| Sodium chloride | NaCl | 75.29 |
| Potassium chloride | KCl | 84.34 |

## MECHANISMS OF MOISTURE TRANSPORT WITHIN SOLIDS

Drying requires moisture to travel to the surface of a material. There are several mechanisms by which this can occur:

1. *Diffusion of moisture through solids.* Diffusion is a molecular process, brought about by random wanderings of individual molecules. If all the water molecules in a material are free to migrate, they tend to diffuse from a region of high moisture concentration to one of lower moisture concentration, thereby reducing the moisture gradient and equalizing the concentration of moisture.
2. *Convection of moisture within a liquid or slurry.* If a flowable solution is drying into a solid, then liquid motion within the material brings wetter material to the surface.
3. *Evaporation of moisture within a solid and gas transport out of the solid by diffusion and/or convection.* Evaporation can occur within a solid if it is boiling or porous. Subsequently vapor must move out of the sample.
4. *Capillary flow of moisture in porous media.* The reduction of liquid pressure within small pores due to surface tension forces causes liquid to flow in porous media by capillary action.

## DRYING KINETICS

This subsection discusses the rate of drying. The kinetics of drying dictate the size of industrial drying equipment, which directly affects the capital and operating costs of a process involving drying. The rate of drying can also influence the quality of a dried product since other simultaneous phenomena, such as heat transfer, shrinkage, microstructure development, and chemical reactions, are often affected by the moisture and temperature history of the material.

The most classical drying kinetics problem is that of a pure water drop drying in air, as shown in Example 12-12.

***Example 12-12 Drying of a Pure Water Drop*** See Marshall, *Atomization & Spray Drying,* 1986. Calculate the time to dry a drop of water, given the air temperature and relative humidity as a function of drop size.

*Solution* Assume that the drop is drying at the wet-bulb temperature. Begin with an energy balance [Eq. (12-27)]

$$\text{Mass flux} = \frac{h\,(T_{\text{air}} - T_{\text{drop}})}{\Delta H_{\text{vap}}} \tag{12-27}$$

Next, a mass balance is performed on the drop. The change in mass equals the flux times the surface area.

$$\frac{\rho\, dV_{\text{droplet}}}{dt} = -A \times \text{mass flux} \tag{12-28}$$

Evaluating the area and volume for a sphere gives

$$\rho \cdot 4\pi R^2 \frac{dR}{dt} = -4\pi R^2 \times \text{mass flux} \tag{12-29}$$

Combining Eqs. (12-28) and (12-29) and simplifying give

$$\rho \frac{dR}{dt} = \frac{-h\,(T_{\text{air}} - T_{\text{drop}})}{\Delta H_{\text{vap}}} \tag{12-30}$$

A standard correlation for heat transfer to a sphere is given by Ranz and Marshall, "Evaporation from Drops," *Chem. Eng. Prog.* **48**(3): 141–146 and **48**(4): 173–180 (1952), as

$$\text{Nu} = \frac{h(2R)}{k_{\text{air}}} = 2 + 0.6\,\text{Re}^{0.5}\text{Pr}^{0.33} \tag{12-31}$$

For small drop sizes or for stagnant conditions, the Nusselt number has a limiting value of 2.

$$\text{Nu} = \frac{h(2R)}{k_{\text{air}}} = 2 \tag{12-32}$$

$$h = \frac{k_{\text{air}}}{R} \tag{12-33}$$

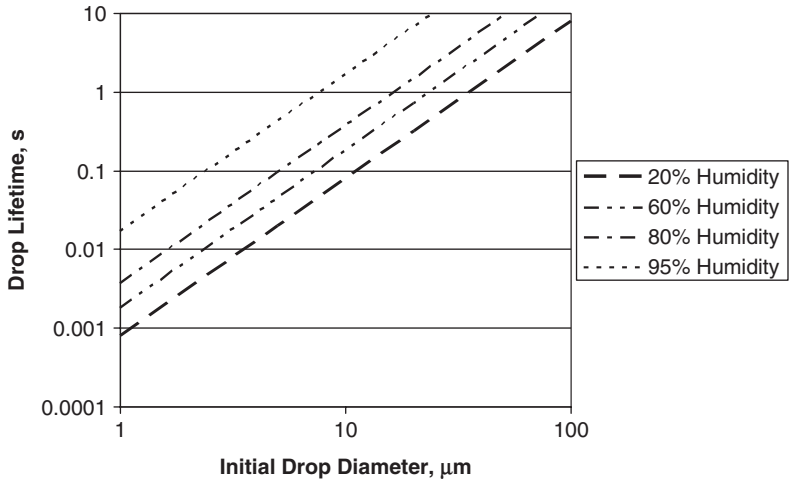

**FIG. 12-22** Drying time of pure water drops as function of relative humidity at 25°C.

Insertion into Eq. (12-30) gives

$$R\frac{dR}{dt} = \frac{k_{air}(T_{air} - T_{drop})}{\rho\,\Delta H_{vap}} \tag{12-34}$$

Integration yields

$$\frac{R_0^2}{2} - \frac{R^2}{2} = \frac{k_{air}(T_{air} - T_{drop})\cdot t}{\rho \Delta H_{vap}} \tag{12-35}$$

where $R_0$ = initial drop radius, m.

Now the total lifetime of a drop can be calculated from Eq. (12-35) by setting $R = 0$:

$$t = \frac{\rho\,\Delta H_{vap}\,R_0^2}{2k_{air}(T_{air} - T_{drop})} \tag{12-36}$$

The effects of drop size and air temperature are readily apparent from Eq. (12-36). The temperature of the drop is the wet-bulb temperature and can be obtained from a psychrometric chart, as described in the previous subsection. Sample results are plotted in Fig. 12-22.

The above solution for drying of a pure water drop cannot be used to predict the drying rates of drops containing solids. Drops containing solids will not shrink uniformly and will develop internal concentration gradients (falling-rate period) in most cases.

**Drying Curves and Periods of Drying** The most basic and essential kinetic information on drying of solid materials is a *drying curve*. A drying curve describes the drying kinetics and how they change during drying. The drying curve is affected by the material properties, size or thickness of the drying material, and drying conditions. In this subsection, the general characteristics of drying curves and their uses are described. Experimental techniques to obtain drying curves are discussed in the Experimental Methods subsection.

Several representations of a typical drying curve are shown in Fig. 12-23. The top plot, Fig. 12-23*a,* is the moisture content (dry basis) as a function of time. The middle plot, Fig. 12-23*b,* is the drying rate as a function of time, the derivative of the top plot. The bottom plot, Fig. 12-23*c,* is the drying rate as affected by the average moisture content of the drying material. Since the material loses moisture as time passes, the progression of time in this bottom plot is from right to left.

Some salient features of the drying curve show the different periods of drying. These are common periods, but not all occur in every drying process. The first period of drying is called the *induction* period. This period occurs when material is being heated early in drying. The second period of drying is called the *constant-rate* period. During this period, the surface remains wet enough to maintain the vapor pressure of water on the surface. Once the surface dries sufficiently, the drying rate decreases and the falling-rate period occurs. This period can also be referred to as *hindered drying.*

Figure 12-23 shows the transition between constant- and falling-rate periods of drying occurring at the critical point. The *critical point* refers to the average moisture content of a material at this transition. This is a useful concept, but the critical point can depend on drying conditions.

The subsections below show examples of drying curves and the phenomena that give rise to different common types.

**Introduction to Internal and External Mass-Transfer Control—Drying of a Slab** The concepts in drying kinetics are best illustrated with a simple example—air drying of a slab. Consider a thick slab of homogeneous wet material, as shown in Fig. 12-24. In this particular example, the slab is dried on an insulating surface under constant conditions. The heat for drying is carried to the surface with hot air, and air carries water vapor

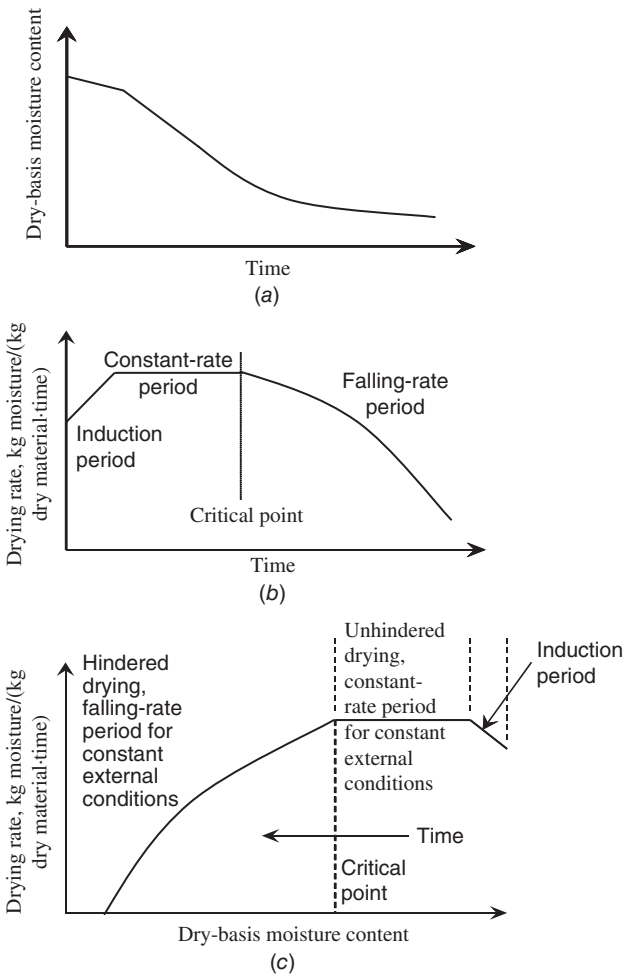

**FIG. 12-23** Several common representations of a typical drying curve.

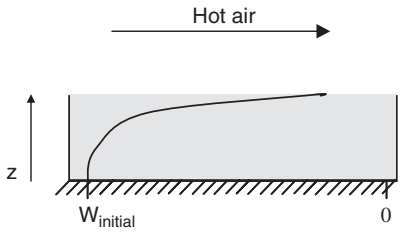

**FIG. 12-24** Drying of a slab.

from the surface. At the same time, a moisture gradient forms within the slab, with a dry surface and a wet interior. The curved line is the representation of the gradient. At the bottom of the slab ($z = 0$), the material is wet and the moisture content is drier at the surface.

The following processes must occur to dry the slab:

1. Heat transfer from the air to the surface of the slab
2. Mass transfer of water vapor from the surface of the slab to the bulk air
3. Mass transfer of moisture from the interior of the slab to the surface of the slab

Depending on the drying conditions, thickness, and physical properties of the slab, any of the above steps can be rate-limiting. Figure 12-25 shows two examples of rate-limiting cases. Example 12-14 shows how to compute these from physical property data and how the same material can exhibit different drying curves.

The top example shows the situation of *external rate control*. In this situation, the heat transfer to the surface and/or the mass transfer from the surface to the vapor phase is slower than mass transfer to the surface from the bulk of the drying material. In this limiting case, the moisture gradient in the material is minimal, and the rate of drying will be constant as long as the average moisture content remains high enough to maintain a high water activity (see the subsection on thermodynamics for a discussion of the relationship between moisture content and water vapor pressure). External rate control leads to the observation of a constant-rate period drying curve.

The bottom example shows the opposite situation: *internal rate control*. In the case of heating from the top, internal control refers to a slow rate of mass transfer from the bulk of the material to the surface of the material. Diffusion, convection, and capillary action (in the case of porous media) are possible mechanisms for mass transfer of moisture to the surface of the slab. In the internal rate control situation, moisture is removed from the surface by the air faster than moisture is transported to the surface. This regime is caused by relatively thick layers or high values of the mass- and heat-transfer coefficients in the air. Internal rate control leads to the observation of a falling-rate period drying curve.

Generally speaking, drying curves show both behaviors. When drying begins, the surface is often wet enough to maintain a constant-rate period and is therefore externally controlled. But as the material dries, the mass-transfer rate of moisture to the surface often slows, causing the rate to decrease since the lower moisture content on the surface causes a lower water vapor pressure. However, some materials begin dry enough that there is no observable constant-rate period.

Note that falling-rate periods do sometimes occur when drying is externally controlled. The drying rate depends on the water activity at the surface of the material, and the rate, by itself, is not a measure of an internal moisture gradient. The observation of falling-rate periods with external rate control is more likely during drying of powder, where moisture can be tightly bound but the distance for diffusion to the drying surface is small.

**Concept of a Characteristic Drying Rate Curve** In 1958, van Meel observed that the drying rate curves, during the falling-rate period, for a specific material often show the same shape (Fig. 12-26), so that a single characteristic drying curve can be drawn for the material being dried. Strictly speaking, the concept should only apply to materials of the same specific size (surface area to material ratio) and thickness, but Keey (1992) shows evidence that it applies over a somewhat wider range with reasonable accuracy. In the absence of experimental data, a linear falling-rate curve is often a reasonable first guess for the form of the characteristic function (good approximation for milk powder, fair for ion-exchange resin and silica gel). At each volume-averaged free moisture content, it is assumed that there is a corresponding specific drying rate relative to the unhindered drying rate in the first drying period that is independent of the external drying conditions. *Volume-averaged* means averaging over the volume (distance cubed for a sphere) rather than just the distance. The *relative drying rate* is defined as

$$f = \frac{N}{N_m} \tag{12-37}$$

where $N$ is the drying rate, $N_m$ is the rate in the constant-rate period, and the characteristic moisture content becomes

$$\Phi = \frac{\overline{X} - X_e}{X_{cr} - X_e} \tag{12-38}$$

where $\overline{X}$ is the volume-averaged moisture content, $X_{cr}$ is the moisture content at the critical point, and $X_e$ is that at equilibrium. Thus, the drying curve is normalized to pass through the point (1, 1) at the critical point of transition in drying behavior and the point (0, 0) at equilibrium.

This representation leads to a simple lumped-parameter expression for the drying rate in the falling-rate period, namely,

$$N = fN_m = f[k\phi_m(Y_W - Y_G)] \tag{12-39}$$

Here $k$ is the external mass-transfer coefficient, $\phi_m$ is the humidity-potential coefficient (corrects for the humidity not being a strictly true representation of the driving force; close to unity most of the time), $Y_W$ is the humidity above a fully wetted surface, and $Y_G$ is the bulk-gas humidity. Equation (12-39) has been used extensively as the basis for understanding the behavior of industrial drying plants owing to its simplicity and the separation of the parameters

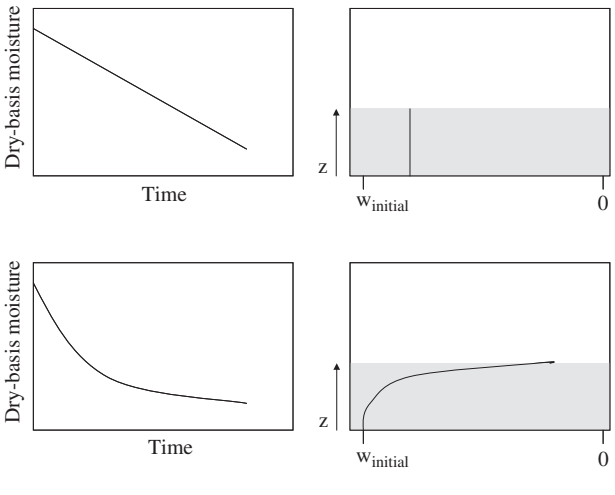

**FIG. 12-25** Drying curves and corresponding moisture gradients for situations involving external heat- and mass-transfer control and internal mass-transfer control.

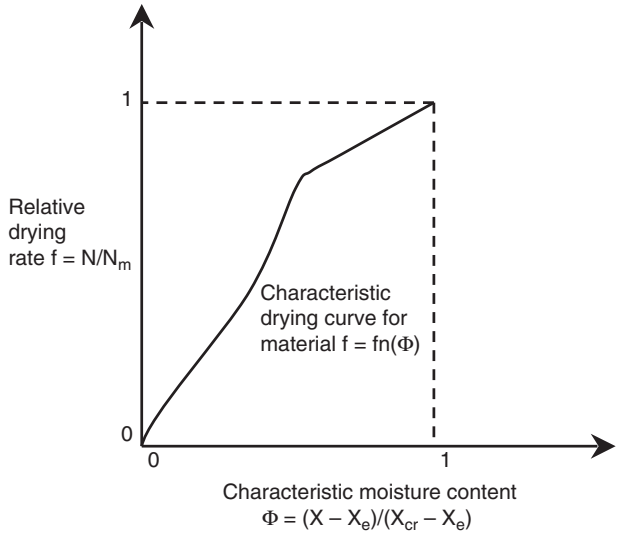

**FIG. 12-26** Characteristic drying curve.

that influence the drying process: the material itself *f*, the design of the dryer *k*, and the process conditions $\phi_m(Y_W - Y_G)f$.

***Example 12-13 Characteristic Drying Curve Application*** Suppose (with nonhygroscopic solids, $X_e$ = 0 kg/kg) that we have a linear falling-rate curve, with a maximum drying rate $N_m$ of 0.5 kg moisture/(kg dry solids · s) from an initial moisture content of 1 kg moisture/kg dry solids. If the drying conditions around the sample are constant, what is the time required to dry the material to a moisture content of 0.2 kg moisture/kg dry solids?

The linear falling-rate drying curve is given by this relationship:

$$N = -\frac{dX}{dt} = X \cdot 0.5 \frac{\text{kg}}{\text{kg}} \frac{1}{\text{s}} \tag{12-40}$$

where $N$ = the drying rate, kg/(kg · s) and $X$ = average dry basis moisture content. Rearranging and integrating Eq. (12-40) gives

$$\int_1^{0.2} \frac{dX}{X} = \ln\left(\frac{0.2}{1}\right) = -0.5 \cdot \frac{\text{kg}}{\text{kg}} \frac{1}{\text{s}} \cdot t \tag{12-41}$$

$$t = 3.21 \text{ s}$$

The characteristic drying curve, however, is clearly a gross approximation. A common drying curve will be found only if the volume-averaged moisture content reflects the moistness of the surface in some fixed way. An additional worked example using a linear falling-rate drying curve is in the Continuous Agitated Dryer subsection.

For example, in the drying of impermeable timbers, for which the surface moisture content reaches equilibrium quickly, there is unlikely to be any significant connection between the volume-averaged and the surface moisture contents, so the concept is unlikely to apply. While the concept might not be expected to apply to the same material with different thickness, Pang finds that it applies for different thicknesses in the drying of softwood timber (Keey, 1992), and its applicability appears to be wider than the theory might suggest. A paper by Kemp and Oakley (2002) explains that many of the errors in the assumptions in this method often cancel out, meaning that the concept has wide applicability.

## DRYER MODELING, DESIGN, AND SCALE-UP

**General Principles** Models and calculations on dryers can be categorized in terms of (1) the level of complexity used and (2) the purpose or type of calculation (design, or scale-up). A fully structured approach to dryer modeling can be developed from these principles, as described below and in greater detail by Kemp and Oakley (2002).

In this section, we cover the principles and refer the reader to specific examples relevant for each type of dryer in the Drying Equipment subsection.

**Levels of Dryer Modeling** Modeling can be carried out at four different levels, depending on the amount of data available and the level of detail and precision required in the answer.

Level 1. *Heat and mass balances.* These balances give information on the material and energy flows to and from the dryer, but do not address the kinetics or required size of the equipment.

Level 2. *Scoping.* Approximate or scoping calculations give rough sizes and throughputs (mass flow rates) for dryers, using simple data and making some simplifying assumptions. Either heat-transfer control or first-order drying kinetics is assumed.

Level 3. *Scaling.* Scaling calculations give overall dimensions and performance figures for dryers by scaling up drying curves from small-scale or pilot-plant experiments.

Level 4. *Detailed.* Rigorous or detailed methods aim to track the temperature and drying history of the solids and find local conditions inside the dryer. Naturally, these methods use more complex modeling techniques with many more parameters and require many more input data.

***Types of Dryer Calculations*** The user may wish to design a new dryer, dry a different formulation, or improve the performance of an existing dryer. Three types of calculations are possible:

- Design of a new dryer to perform a given duty, using information from the process flowsheet and physical properties databanks
- Performance calculations for an existing dryer at a new set of operating conditions or to dry a different material
- Scale-up from laboratory-scale or pilot-plant experiments to a full-scale dryer

Solids drying is very difficult to model reliably, particularly in the falling-rate period which usually has the main effect on determining the overall drying time. Falling-rate drying kinetics depend strongly on the internal moisture transport within a solid. This is highly dependent on the internal structure, which in turn varies with the upstream process, the solids formation step, and often between individual batches. Hence, many key drying parameters within solids (e.g., diffusion coefficients) cannot be predicted from theory alone, or obtained from physical property databanks; practical measurements are required. Because of this, experimental work is almost always necessary to design a dryer accurately, and scale-up calculations are more reliable than design based only on thermodynamic data. The experiments are used to verify the theoretical model and find the difficult-to-measure parameters; the full-scale dryer can then be modeled more realistically.

**Heat and Mass Balance** The heat and mass balance on a generic continuous dryer is shown schematically in Fig. 12-27. In this case, mass flows and moisture contents are given on a dry basis.

The *mass balance* is usually performed on the principal solvent and gives the evaporation rate $E$ (kg/s). In a contact or vacuum dryer, this is approximately equal to the exhaust vapor flow, apart from any noncondensibles. In a convective dryer, this gives the increased outlet humidity of the exhaust. For a continuous dryer at steady-state operating conditions,

$$E = F(X_I - X_O) = G(Y_O - Y_I) \tag{12-42}$$

This assumes that the dry gas flow $G$ and dry solids flow $F$ do not change between dryer inlet and outlet. Mass balances can also be performed on the overall gas and solids flows to allow for features such as air leaks and solids entrainment in the exhaust gas stream.

In a design calculation (including scale-up), the required solids flow rate, inlet moisture content $X_I$, and outlet moisture $X_O$ are normally specified, and the evaporation rate and outlet gas flow are calculated. In a performance calculation, this is normally reversed; the evaporation rate under new operating conditions is found, and the new solids throughput or outlet moisture content is back-calculated.

For a batch dryer with a dry mass $m$ of solids, a mass balance only gives a snapshot at one point during the drying cycle and an instantaneous drying rate, given by

$$E = m\left(\frac{-dX}{dt}\right) = G(Y_O - Y_I) \tag{12-43}$$

The *heat balance* on a continuous dryer takes the generic form

$$GI_{GI} + FI_{SI} + Q_{\text{in}} = GI_{GO} + FI_{SO} + Q_{wl} \tag{12-44}$$

Here $I$ is the enthalpy (kJ/kg dry material) of the solids or gas plus their associated moisture. Enthalpy of the gas includes the latent heat term for the vapor. Expanding the enthalpy terms gives

$$\begin{aligned} G(C_{sI}T_{GI} + \lambda Y_I) + F(C_{PS} + X_I C_{PL})T_{SI} + Q_{\text{in}} \\ = G(C_{SO}T_{GO} + \lambda Y_O) + F(C_{PS} + X_O C_{PL})T_{SO} + Q_{wl} \end{aligned} \tag{12-45}$$

Here $C_s$ is the humid heat $C_{PG} + YC_{PY}$. In convective dryers, the left-hand side is dominated by the sensible heat of the hot inlet gas $GC_{sI}T_{GI}$; in contact dryers, the heat input from the jacket $Q_{\text{in}}$ is dominant. In both cases, the largest single term on the right-hand side is the latent heat of the vapor $G\lambda Y_O$. Other terms are normally below 10 percent. *This shows why the operating line of a convective dryer on a psychrometric chart is roughly parallel to a constant-enthalpy line.*

The corresponding equation for a batch dryer is

$$GI_{GI} + Q_{\text{in}} = GI_{GO} + m\frac{dI_s}{dt} + Q_{wl} \tag{12-46}$$

Further information on heat and mass balances, including practical advice on industrial dryers, is given later in this section. Worked examples are shown in the continuous band and tunnel dryer, pneumatic conveying dryer, and spray dryer subsections.

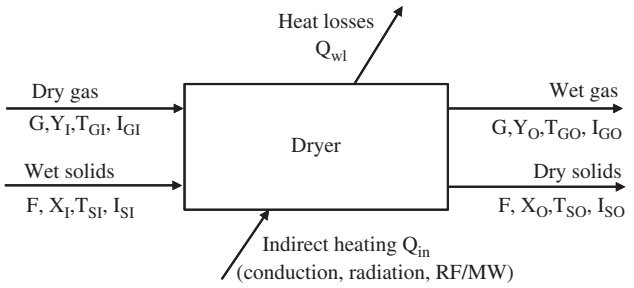

**FIG. 12-27** Heat and material flows around a continuous dryer.

**Scoping Design Calculations** In scoping calculations, some approximate dryer dimensions and drying times are obtained based mainly on a heat and mass balance, without measuring a drying curve or other experimental drying data. They allow the cross-sectional area of convective dryers and the volume of batch dryers to be estimated quite accurately, but are less effective for other calculations and can yield overoptimistic results.

Some examples of scoping calculations are shown later in the batch agitated dryer, spray drying, drum dryer, and sheet dryer subsections.

**Scaling Models** These models use experimental data from drying kinetics tests in a laboratory, pilot-plant or full-scale dryer, and are thus more accurate and reliable than methods based only on estimated drying kinetics. They treat the dryer as a complete unit, with drying rates and air velocities averaged over the dryer volume, except that, if desired, the dryer can be subdivided into a small number of sections. These methods are used for layer dryers (tray, oven, horizontal-flow band, and vertical-flow plate types) and for a simple estimate of fluidized-bed dryer performance. For batch dryers, they can be used for scale-up by refining the scoping design calculation.

The basic principle is to take an experimental drying curve and perform two transformations: (1) from test operating conditions to full-scale operating conditions and (2) from test dimensions to full-scale dryer dimensions. If the operating conditions of the test (e.g., temperature, gas velocity, agitation rate) are the same as those for the full-scale plant, then the first correction is not required.

Scaling models are the main design method traditionally used by dryer manufacturers. Pilot-plant test results are scaled to a new set of conditions on a dryer with greater airflow or surface area by empirical rules, generally based on the external driving forces (temperature, vapor pressure, or humidity driving forces). By implication, therefore, a characteristic drying curve concept is again being used, scaling the external heat and mass transfer and assuming that the internal mass transfer changes in proportion. A good example is the set of rules described under Fluidized-Bed Dryers, which include the effects of temperature, gas velocity, and bed depth on drying time in the initial test and the full-scale dryer. A worked example is shown in the fluidized-bed drying subsection.

***Specific Drying Rate Concept*** An intuitive, useful method for scale-up of layer dryers from experimental data has been developed and reported by C. Moyers [*Drying Technol.* **12**(1 & 2): 393–417 (1994)]. The method defines a *specific drying rate* (SDR) as

$$\text{SDR} = \frac{m_s}{A_c} = \frac{\rho_s z}{(1+X_1)\tau} \tag{12-47}$$

where $\rho_s$ is the bulk density of the dry solids, $z$ is the layer thickness, $X_1$ is the initial moisture content, $\tau$ is the drying time, and $A_c$ is the surface area of contact.

The method assumes that the SDR is constant between scales. The article presents practical examples using laboratory data for continuous rotating shelf dryers, plate dryers, and continuous paddle dryers.

**Detailed or Rigorous Models** These models aim to predict local conditions within the dryer and the transient condition of the particles and gas in terms of temperature, moisture content, velocity, etc. Naturally, they require many more input data on the dryer equipment and material properties as well as computational tools (hardware and software) to solve the equations. There are many published models of this type in the academic literature. They give the possibility of more-detailed results, but the potential cumulative errors are also greater. Two types are discussed here: incremental models and *computational fluid dynamics* (CFD) models.

***Incremental Model*** The one-dimensional incremental model is a key analysis tool for several types of dryers. A set of simultaneous equations is solved at a given location (Fig. 12-28), and the simulation moves along the dryer axis in a series of steps or increments, hence the name. A spreadsheet or other computer program is needed, and any number (sometimes thousands) of increments may be used.

Examples of incremental models are shown later in the pneumatic conveying drying, sheet drying, and electromagnetic drying subsections.

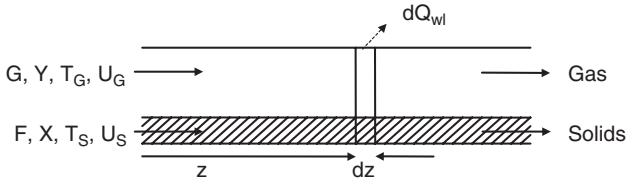

**FIG. 12-28** Principle of the incremental model.

Increments may be stated in terms of time ($dt$), length ($dz$), or moisture content ($dX$). A set of six simultaneous equations is then solved, and ancillary calculations are also required, e.g., to give local values of gas and solids properties. The generic set of equations ( for a time increment $\Delta t$) is as follows:

Heat transfer to particle: $$Q_P = h_{PG} A_P (T_G - T_S) \tag{12-48}$$

Mass transfer from particle:

$$\frac{-dX}{dt} = \text{function}\,(X, Y, T_P, T_G, h_{PG}, A_P) \tag{12-49}$$

Mass balance on moisture: $$G\,\Delta Y = -F\,\Delta X = F\,\frac{-dX}{dt}\,\Delta t \tag{12-50}$$

Heat balance on particle: $$\Delta T_S = \frac{Q_P\,\Delta t - \lambda_{ev} m_P\,\Delta X}{m_P (C_{PS} + C_{PL} X)} \tag{12-51}$$

Heat balance for increment:

$$-\Delta T_G = \frac{F(C_{PS} + C_{PL} X)\,\Delta T_S + G(\lambda_0 + C_{PY} T_G)\,\Delta Y + \Delta Q_{WI}}{G(C_{PG} + C_{PY} Y)} \tag{12-52}$$

Particle transport: $$\Delta z = U_S\,\Delta t \tag{12-53}$$

The mass and heat balance equations are the same for any type of dryer, but the particle transport equation is completely different, and the heat- and mass-transfer correlations are also somewhat different as they depend on the environment of the particle in the gas (i.e., single isolated particles, agglomerates, clusters, layers, fluidized beds, or packed beds). The mass-transfer rate from the particle is regulated by the drying kinetics and is thus obviously material-dependent (at least in falling-rate drying).

The model is effective and appropriate for dryers where both solids and gas are approximately in axial plug flow, such as pneumatic conveying and cascading rotary dryers. However, it runs into difficulties where there is recirculation or radial flow.

The incremental model is also useful for measuring variations in local conditions such as temperature, solids moisture content, and humidity along the axis of a dryer (e.g., plug-flow fluidized bed), through a vertical layer (e.g., tray or band dryers), or during a batch drying cycle (using time increments, not length).

Any fundamental mathematical model of drying contains mass and energy balances, constitutive equations for mass- and heat-transfer rates, and physical properties. Table 12-8 shows the differential mass balance equations that can be used for common geometries and solved as incremental models. Note there are two sets of differential mass balances—one including shrinkage and one not including shrinkage. When moisture leaves a drying material, the material can either shrink, or develop porosity, or both.

The equations in Table 12-8 are insufficient on their own. Some algebraic relationships are needed to formulate a complete problem, as illustrated in Example 12-14. Equations for the mass- and heat-transfer coefficients are also needed for the boundary conditions presented in Table 12-8. These require the physical properties of the air, the object geometry, and the Reynolds number.

Analytical solutions exist for the equations on the left-hand side of Table 12-8 in the special case of a constant diffusion coefficient. These can be found in Crank, J., *Mathematics of Diffusion,* 2d ed., Oxford University Press, Oxford, UK, 1975. However, the values of the water-solid diffusion coefficient often vary 1 to 3 orders of magnitude with the local moisture content, and so use of these analytical solutions is not recommended. Some data and some theories are available in the literature on the variation of a moisture (or solvent)/solid diffusion coefficient with moisture level; see, e.g., Zielinski, J. M., and Duda, J. L., *AIChE Journal* **38**(3): 405–413 (1992).

Example 12-14 shows the solution for a problem using numerical modeling. This example shows some of the important qualitative characteristics of drying.

***Example 12-14 Air Drying of a Thin Layer of Paste*** Simulate the drying kinetics of 100 μm of paste initially containing 50 percent moisture (wet-basis) with dry air at 60°C, 0 percent relative humidity air at velocities of 0.1, 1.0, or 10 m/s. The diffusion coefficient of water in the material depends on the local moisture content. The length of the layer in the airflow direction is 2.54 cm (Fig. 12-29).

**TABLE 12-8 Mass-Balance Equations for Drying Modeling When Diffusion Is Mass-Transfer Mechanism of Moisture Transport**

| Case | Mass balance without shrinkage | Mass balance with shrinkage |
|---|---|---|
| Slab geometry | $\frac{\partial C_w}{\partial t}=\frac{\partial}{\partial z}\left[\mathscr{D}(w)\frac{\partial C_w}{\partial z}\right]$ | $\frac{\partial u}{\partial t}=\frac{\partial}{\partial s}\left[\mathscr{D}(w)\frac{\partial u}{\partial s}\right]\quad \frac{\partial s}{\partial z}=\rho_s$ |
| | At top surface, $-\mathscr{D}(w)\frac{\partial C_w}{\partial z_{\text{top surface}}}=k_p\frac{P_w^{\text{bulk}}-P_w^{\text{surface}}}{P-P_w^{\text{surface}}}$ | At top surface, $-\mathscr{D}(w)\frac{\partial u}{\partial s_{\text{top surface}}}=k_p\frac{P_w^{\text{bulk}}-P_w^{\text{surface}}}{P-P_w^{\text{surface}}}$ |
| | At bottom surface, $\frac{\partial C_w}{\partial z_{\text{bottom surface}}}=0$ | At bottom surface, $\frac{\partial u}{\partial s_{\text{bottom surface}}}=0$ |
| Cylindrical geometry | $\frac{\partial C_w}{\partial t}=\frac{1}{r}\frac{\partial}{\partial r}\left[r\mathscr{D}(w)\frac{\partial C_w}{\partial r}\right]$ | $\frac{\partial u}{\partial t}=\frac{\partial}{\partial s}\left[\rho_s^2\mathscr{D}(w)\frac{\partial u}{\partial s}\right]\quad \frac{\partial s}{\partial z}=r\rho_s$ |
| | At surface, $-\mathscr{D}(w)\frac{\partial C_w}{\partial r_{\text{surface}}}=k_p\frac{P_w^{\text{bulk}}-P_w^{\text{surface}}}{P-P_w^{\text{surface}}}$ | At surface, $-\mathscr{D}(w)r\frac{\partial uC_w}{\partial s_{\text{surface}}}=k_p\frac{P_w^{\text{bulk}}-P_w^{\text{surface}}}{P-P_w^{\text{surface}}}$ |
| | At center, $\frac{\partial C_w}{\partial r_{\text{center}}}=0$ | At center, $\frac{\partial u}{\partial s_{\text{surface}}}=0$ |
| Spherical geometry | $\frac{\partial C_w}{\partial t}=\frac{1}{r^2}\frac{\partial}{\partial r}\left[r^2\mathscr{D}(w)\frac{\partial C_w}{\partial r}\right]$ | $\frac{\partial u}{\partial t}=\frac{\partial}{\partial s}\left[\rho_s^4\mathscr{D}(w)\frac{\partial u}{\partial s}\right]\quad \frac{\partial s}{\partial z}=r^2\rho_s$ |
| | At surface, $-\mathscr{D}(w)\frac{\partial C_w}{\partial r_{\text{surface}}}=k_p\frac{P_w^{\text{bulk}}-P_w^{\text{surface}}}{P-P_w^{\text{surface}}}$ | At surface, $-\mathscr{D}(w)r^2\frac{\partial u}{\partial s_{\text{surface}}}=k_p\frac{P_w^{\text{bulk}}-P_w^{\text{surface}}}{P-P_w^{\text{surface}}}$ |
| | At center, $\frac{\partial C_w}{\partial r_{\text{center}}}=0$ | At center, $\frac{\partial u}{\partial s_{\text{bottom surface}}}=0$ |

The variable μ is the dry-basis moisture content. The equations that include shrinkage are taken from Van der Lijn, doctoral thesis, Wageningen (1976).

***Physical Property Data*** Sorption isotherm data fit well to the following equation:

$$w=3.10\left(\frac{\%\text{RH}}{100}\right)^5-6.21\left(\frac{\%\text{RH}}{100}\right)^4+4.74\left(\frac{\%\text{RH}}{100}\right)^3 -1.70\left(\frac{\%\text{RH}}{100}\right)^2+0.378\left(\frac{\%\text{RH}}{100}\right) \tag{12-54}$$

$$\text{Solid density}=1150\ \text{kg/m}^3$$
$$\text{Heat of vaporization}=2450\ \text{J/g}$$
$$\text{Solid heat capacity}=2.5\ \text{J/(g}\cdot\text{K)}$$
$$\text{Water heat capacity}=4.184\ \text{J/(g}\cdot\text{K)}$$

*Solution* The full numerical model needs to include shrinkage since the material is 50 percent water initially and the thickness will decrease from 100 to 46.5 mm during drying. Assuming the layer is viscous enough to resist convection in the liquid, diffusion is the dominant liquid-phase transport mechanism.

Table 12-8 gives the mass balance equation:

$$\frac{\partial u}{\partial t}=\frac{\partial}{\partial s}\left[\mathscr{D}(u)\frac{\partial u}{\partial s}\right]\quad \frac{\partial s}{\partial z}=\rho_s$$

At top surface,

$$-\mathscr{D}(u)\frac{\partial u}{\partial s}=k_p\left(\frac{p_w^{\text{bulk}}-p_w^{\text{surface}}}{P-p_w^{\text{surface}}}\right) \tag{12-55}$$

At bottom surface,

$$\frac{\partial u}{\partial s_{\text{top surface}}}=0 \tag{12-56}$$

The temperature is assumed to be uniform through the thickness of the layer.

$$(C_{p,\text{solids}}+C_{p,\text{water}}\cdot w_{\text{avg,dry-basis}})\cdot m_{\text{solids}}\cdot\frac{dT_{\text{layer}}}{dt}=[h\cdot(T_{\text{air}}-T_{\text{layer}})-F\cdot\Delta H_{\text{vap}}]\cdot A \tag{12-57}$$

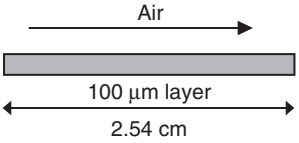

**FIG. 12-29** Drying of a thin layer of paste.

Mass- and heat-transfer coefficients are given by

$$\text{Nu}=\frac{hL}{k_{\text{air}}}=0.664\ \text{Re}^{0.5}\ \text{Pr}^{0.333} \tag{12-58}$$

$$\text{Sh}=\frac{k_cL}{D_{\text{air/water}}}=0.664\ \text{Re}^{0.5}\ \text{Sc}^{0.333} \tag{12-59}$$

$$k_p=k_c\cdot\rho_{\text{air}} \tag{12-60}$$

The Reynolds number uses the length of the layer $L$ in the airflow direction:

$$\text{Re}=\frac{VL\rho_{\text{air}}}{\mu_{\text{air}}} \tag{12-61}$$

where $V$ = air velocity.

The Prandtl and Schmidt numbers, Pr and Sc, respectively, for air are given by

$$\text{Pr}=\frac{C_{p,\text{air}}\mu_{\text{air}}}{k_{\text{air}}}=0.70\qquad \text{Sc}=\frac{\mu_{\text{air}}}{\rho_{\text{air}}D_{\text{air/water}}}=0.73 \tag{12-62}$$

The following algebraic equations are also needed:

$$\frac{1}{\rho}=\frac{w}{\rho_w^\circ}+\frac{1-w}{\rho_s^\circ}\ \text{density of wet material (assumes volume additivity)} \tag{12-63}$$

$$C_w=w\cdot\rho\quad \text{concentration of water} \tag{12-64}$$

$$\rho_s=(1-w)\rho\quad \text{concentration of solids} \tag{12-65}$$

$$\frac{\%\text{RH}}{100}=\frac{P_{w,\text{surface}}}{P_{w,\text{sat}}}\quad \text{definition of relative humidity}$$

The Antoine equation for vapor pressure of water is

$$\ln(P_{w,\text{ sat}})=23.1963-\frac{3816.44}{(T+273.15)-46.13} \tag{12-66}$$

Equation (12-67) is the dependence of diffusion coefficient on moisture content for maltodextrin from Raderer, M., et al., *Chemical Engineering Journal* **86:** 185–191 (2002). For dry-basis moisture contents of 1, 0.5, and 0.25, the values of $\mathscr{D}$ are $1.88\times10^{-10}$, $6.28\times10^{-11}$, and $1.11\times10^{-11}$ m$^2$/s, respectively.

$$\mathscr{D}(u)=\exp\left(-\frac{35.8+215\cdot u}{1+10.2\cdot u}\right) \tag{12-67}$$

*Result:* The results of simulations for air velocities of 0.1, 1.0, and 10 m/s are shown in Fig. 12-30. The top plot shows the average moisture content of the layer as a function of time, the middle plot shows the drying rate as a function of time, and the bottom plot shows the moisture gradient in each layer after 60 s of drying.

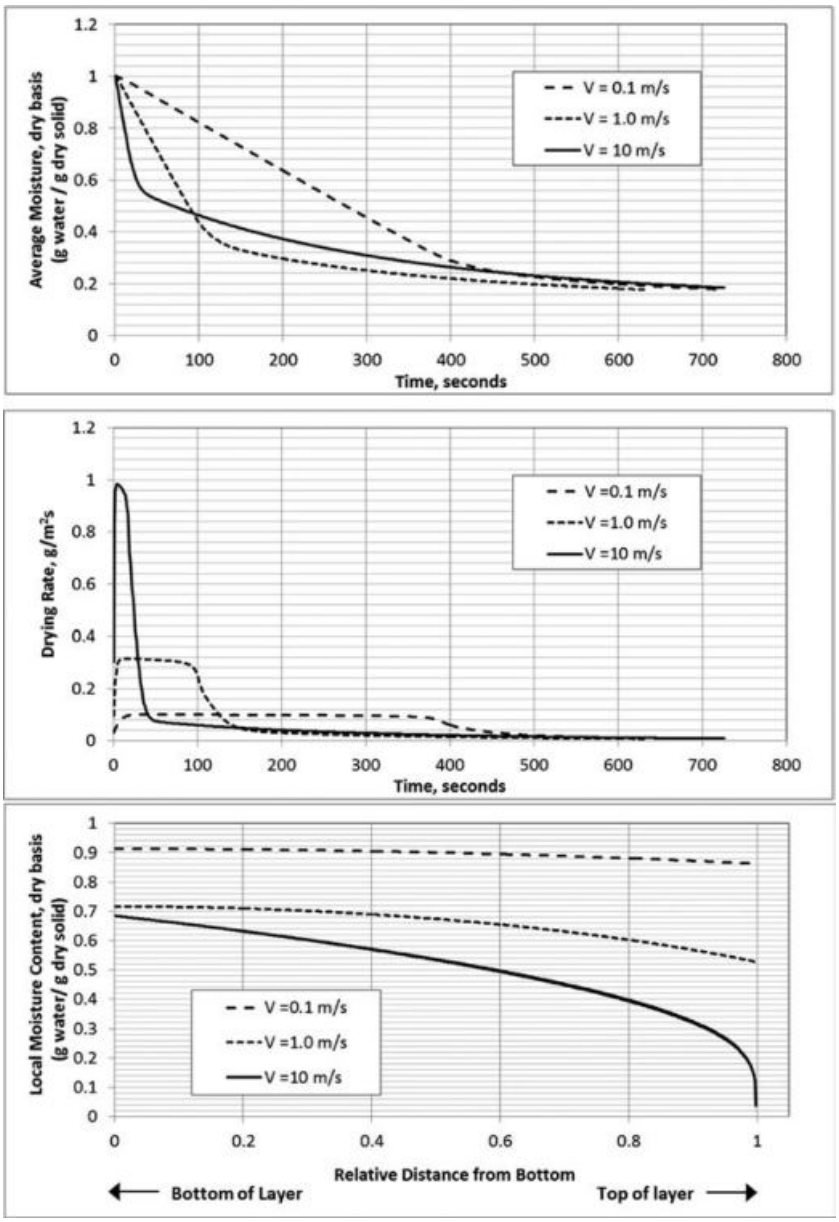

**FIG. 12-30** Simulation results for thin-layer drying example.

These results illustrate the relationships between the external air conditions, drying rate, and moisture gradient. In each case, drying begins in a constant-rate period and then moves to a falling-rate period. The drying rates in the constant-rate period are controlled by the air velocity, which affects the external heat- and mass-transfer coefficients [Eqs. (12-58) and (12-59)]. The surface dries, reaching a critical moisture content, and the falling-rate period begins in each case. In the falling-rate period, the rate-limiting step is internal diffusion so the rate becomes independent of air velocity. The plot of the internal moisture gradient at 60 s (bottom plot) illustrates that the falling-rate period has begun for the 10 m/s case, but not yet for the 1.0 and 0.1 m/s cases. The equation set in this example was solved by using a differential algebraic equation solver called gPROMS from Process Systems Enterprises (www.pse.com). It can also be solved with other software and programming languages such as FORTRAN. Example 12-14 is too complicated to be done on a spreadsheet.

***Computational Fluid Dynamics*** CFD provides a very detailed and accurate model of the gas phase, including three-dimensional effects and swirl. Where localized flow patterns have a major effect on the overall performance of a dryer and the particle history, CFD can yield immense improvements in modeling and in the understanding of physical phenomena. Conversely, where the system is well mixed or drying is dominated by falling-rate kinetics and local conditions are unimportant, CFD modeling will give little or no advantage over conventional methods, but will incur a vastly greater cost in computing time.

CFD has been extensively applied in recent years to spray dryers (Langrish and Fletcher, 2001), but it has also been useful for other local three-dimensional swirling flows, e.g., around the feed point of pneumatic conveying dryers (Kemp et al., 1991), and for other cases where airflows affect drying significantly, e.g., local overdrying and warping in timber stacks (Langrish, 1999). See Jamaleddine, T., and Ray, M., *Drying Technology* **28:** 120–154 (2010), for a comprehensive review on how CFD has been used for a wide variety of drying problems.

CFD software packages specialize in their treatment of the turbulence and other details of airflows. However, the differential equations that describe transport within the solid material in the dryer are usually greatly simplified into algebraic relationships so they can be called as user-defined functions within the solver.

Usually, one cannot simultaneously employ a detailed treatment of the equipment and the product at the same time. The engineer must decide which level of detail will enable the designs or business decisions.

**TABLE 12-9 Sample Techniques for Various Dryer Types**

| Dryer type | Sampling method |
|---|---|
| Fluid bed dryer | Sampling cup (see Fig. 12-31) |
| Sheet dryer | Collect at end of dryer. Increase speed to change the drying time. |
| Tray dryer | Record initial moisture and mass of tray with time. |
| Indirect dryer | Decrease residence time with higher flow rate and sample at exit. |
| Spray dryer | Residence time of product is difficult to determine and change. Special probes have been developed to sample partially dried powder in different places within the dryer (ref. Langrish). |

## EXPERIMENTAL METHODS

Lab-, pilot-, and plant-scale experiments all play important roles in drying research. Lab-scale experiments are often necessary to study product characteristics and physical properties; pilot-scale experiments are often used in proof-of-concept process tests and to generate larger quantities of sample material; and plant-scale experiments are often needed to diagnose processing problems and to start or change a full-scale process. Quite often, however, plant data are difficult to obtain since plants are not generally designed to facilitate experimental measurements.

**Measurement of Drying Curves** Measuring and using experimental drying curves can be difficult. Typically, this is a three-step process. The first step is to collect samples at different times of drying, the second step is to analyze each sample for moisture, and the third step is to interpret the data to make process decisions.

Solid sample collection techniques depend on the type of dryer. Since a drying curve is the moisture content as a function of time, it must be possible to obtain material before the drying process is complete. There are several important considerations when sampling material for a drying curve:

1. The sampling process needs to be fast relative to the drying process. Drying occurring during or after sampling can produce misleading results. Samples must be sealed prior to analysis. Plastic bags do not provide a sufficient seal.
2. In heterogeneous samples, the sample must be large enough to accurately represent the composition of the mixture.

Table 12-9 outlines some sampling techniques for various dryer types.

Moisture measurement techniques are critical to the successful collection and interpretation of drying data. The key message of this subsection is that the moisture value almost certainly depends on the measurement technique and that it is essential to have a *consistent technique* when measuring moisture. Table 12-10 compares and contrasts some different techniques for moisture measurement.

The most common method is gravimetric ("loss on drying"). A sample is weighed in a sample pan or tray and placed into an oven or heater at some high temperature for a given length of time. The sample is weighed again after drying. The difference in weight is then assumed to be due to the complete evaporation of water from the sample. The sample size, temperature, and drying time are all important factors. A very large or thick sample may not dry completely in the given time; a very small sample may not accurately represent the composition of a heterogeneous sample. A low temperature can fail to completely dry the sample, and a temperature that is too high can burn the sample, causing an artificially high loss of mass.

Usually solid samples are collected as described, but in some experiments, it is more convenient to measure the change in humidity of the air due to drying. This technique requires a good mass balance of the system and is more common in lab-scale equipment than pilot- or plant-scale equipment.

**Performing a Mass and Energy Balance on a Large Industrial Dryer** Measuring a mass and energy balance on a large dryer is often necessary to understand how well the system is operating and how much additional capacity may be available. This exercise can also be used to detect and debug gross problems, such as leaks and product buildup.

There are four steps to this process.

1. Draw a sketch of the overall process including all the flows of mass into and out of the system. Look for places where air can leak into or out of the system. There is no substitute for physically walking around the equipment to get this information.
2. Decide on the envelope for the mass and energy balance. Some dryer systems have hot-air recycle loops and/or combustion or steam heating systems. It is not always necessary to include these to understand the dryer operation.
3. Decide on places to measure airflows and temperatures and to take feed and product samples. Drying systems and other process equipment are frequently not equipped for such measurements; the system may need minor modification, such as the installation of ports into pipes for pitot tubes or humidity probes. These ports must not leak when a probe is in place.
4. Take the appropriate measurements and calculate the mass and energy balances. In continuous operations, these measurements should be taken when the process is at a steady-state condition; data from different locations should be coordinated to be collected within a narrow time window. Care should be taken to seal samples effectively and analyze them quickly, ideally during the course of the experiment.

The measurements are inlet and outlet temperatures, humidities, and flow rates of the air inlets and outlets as well as the moisture and temperature of the feed and dry solids. The following are methods for each of the measurements:

***Airflow Rate*** This is often the most difficult to measure. Fan curves are frequently available for blowers but are not always reliable. A small pitot tube can be used (see Sec. 22, Waste Management, in this text) to measure the local velocity. The best location for use of a pitot tube is in a straight section of pipe. Measurements at multiple positions in the cross section of the pipe or duct are advisable, particularly in laminar flow or near elbows and other flow disruptions.

***Air Temperature*** A simple thermocouple can be used in most cases, but in some cases special care must be taken to ensure that wet or sticky material does not build up on the thermocouple. A wet thermocouple will yield a low temperature from evaporative cooling.

***Air Humidity*** Humidity probes need to be calibrated before use, and the absolute humidity needs (or both the relative humidity and temperature need) to be recorded. If the probe temperature is below the dew point of the air in the process, then condensation on the probe will occur until the probe heats.

***Feed and Exit Solids Rate*** These are generally known, particularly for a unit in production. Liquids can be measured by using a bucket and stopwatch. Solids can be measured in a variety of ways.

**TABLE 12-10 Moisture Determination Techniques**

| Method | Principle | Advantages | Disadvantages |
|---|---|---|---|
| Gravimetric (loss on drying) | Water evaporates when sample is held at a high temperature. Difference in mass is recorded. | Simple technique. No extensive calibration methods are needed. Lab equipment is commonly available. | Method is slow. Measurement time is several minutes to overnight (depending on material and accuracy). Generally not suitable for process control. Does not differentiate between water and other volatile substances. |
| IR/NIR | Absorption of infrared radiation by water is measured. | Fast method. Suitable for very thin layers or small particles. | Only surface moisture is detected. Extensive calibration is needed. |
| RF/microwave | Absorption of RF or microwave energy is measured. | Fast method. Suitable for large particles. | Extensive calibration is needed. |
| Equilibrium relative humidity (ERH) | The equilibrium relative humidity headspace above sample in a closed chamber is measured. Sorption isotherm is used to determine moisture. | Relatively quick method. Useful particularly if a final moisture specification is in terms of water activity (to retard microorganism growth). | May give misleading results since the surface of the material will equilibrate with the air. Large particles with moisture gradients can give falsely low readings. Measurement of relative humidity can be imprecise. |
| Karl Fischer titration | Chemical titration that is water-specific. Material can be either added directly to a solvent or heated in an oven, with the headspace purged and bubbled through solvent. | Specific to water only and very precise. Units can be purchased with an autosampler. Measurement takes only a few minutes. | Equipment is expensive and requires solvents. Minimal calibration required. Sample size is small, which may pose a problem for heterogeneous mixtures. |

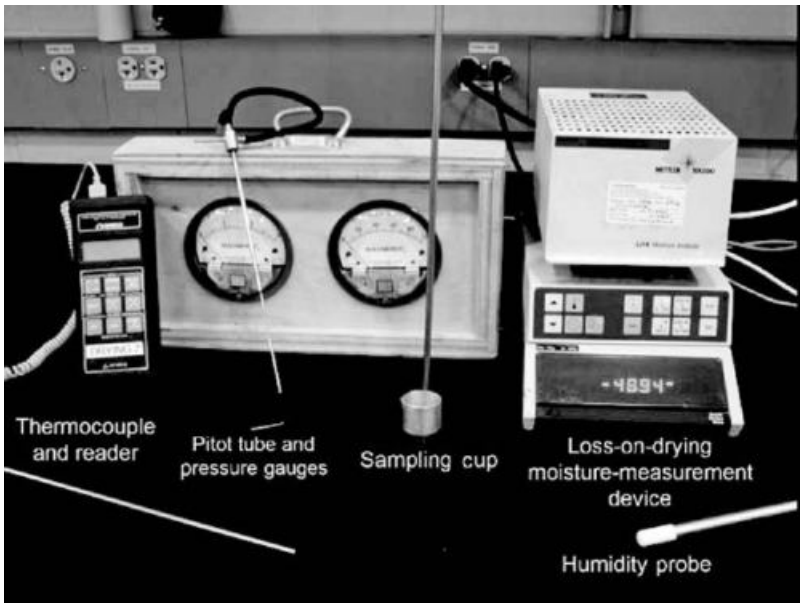

**FIG. 12-31** Variety of tools used to measure mass and energy balances on dryers.

***Feed and Exit Solids Moisture Content*** These need to be measured by using an appropriate technique, as described above. Use the same method for both the feed and exit solids. Don't rely on formula sheets for feed moisture information.

Figure 12-31 shows some common tools used in these measurements.

## DRYING OF NONAQUEOUS SOLVENTS

**Practical Considerations** Removal of nonaqueous solvents from a material presents several practical challenges. First, solvents are often flammable and require drying either in an inert environment, such as superheated steam or nitrogen, or in a gas phase comprised solely of solvent vapor. The latter will occur in indirect or vacuum drying equipment. Second, the solvent vapor must be collected in an environmentally acceptable manner.

An additional practical consideration is the remaining solvent content that is acceptable in the final product. Failure to remove all the solvent can lead to problems such as toxicity of the final solid or can cause the headspace of packages, such as drums, to accumulate solvent vapor.

**Physical Properties** The physical properties that are important in solvent drying are the same as those for an aqueous system. The vapor pressure of a solvent is the most important property since it provides the thermodynamic driving force for drying. Acetone (BP 57°C), for example, can be removed from a solid at atmospheric pressure readily by boiling, but glycerol (BP 200°C) will dry only very slowly. Like water, a solvent may become bound to the solid and have a lower vapor pressure. This effect should be considered when one is designing a solvent-drying process.

Diffusion of nonaqueous solvents through a material can be slow. The diffusion coefficient is directly related to the size of the diffusing molecule, so molecules larger than water typically have diffusion coefficients that have a much lower value. This phenomenon is known as *selective diffusion.* Large diffusing molecules can become kinetically trapped in the solid matrix. Solvents with a lower molecular weight will often evaporate from a material faster than a solvent with a higher molecular weight, even if the vapor pressure of the larger molecule is higher. Some encapsulation methods rely on selective diffusion; an example is instant coffee production using spray drying, where volatile flavor and aroma components are retained in particles more than water, even though they are more volatile than water, as shown in Fig. 12-32.

## PRODUCT QUALITY CONSIDERATIONS

**Overview** The drying operation usually has a very strong influence on final product quality and product performance measures. And the final product quality strongly influences the value of the product. Generally, a specific particle or unit size, a specific density, a specific color, and a specific target moisture are desired. Naturally every product is somewhat different, but these are usually the first things we need to get right.

***Target Moisture*** This seems obvious, but it's very important to determine the right moisture target before we address other drying basics. Does biological activity determine the target, flowability of the powder, shelf life, etc.? Sometimes a very small (1 to 2 percent) change in the target moisture will have a profound impact on the size of dryer required. This is especially true for difficult-to-dry products with flat falling-rate drying characteristics. Therefore, spend the time necessary to get clear on what really determines the moisture target. And as noted earlier in this subsection, care should be taken to define a moisture measurement method since results are often sensitive to the method.

***Particle Size*** Generally a customer or consumer wants a very specific particle size—and the narrower the distribution, the better. No one wants lumps or dust. The problem is that some attrition and sometimes agglomeration occur during the drying operation. We may start out with the right particle size, but we must be sure the dryer we've selected will not adversely affect particle size to the extent that it becomes a problem. Some dryers will

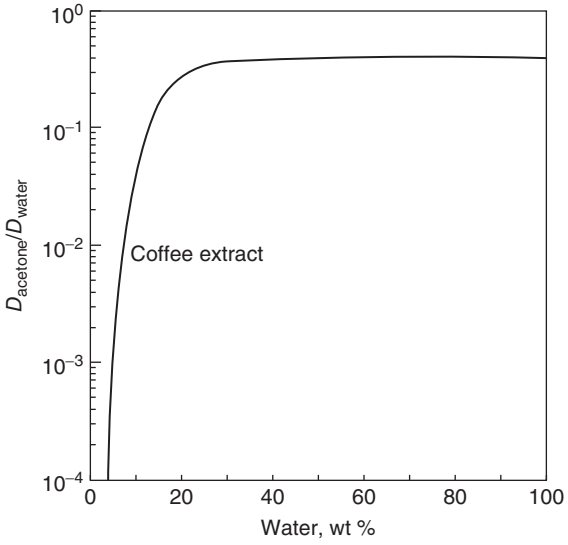

**FIG. 12-32** The ratio of the diffusion coefficients of acetone to water in instant coffee as a function of moisture content (taken from Thijssen et al., *De Ingenieur,* JRG, 80, Nr. 47 (1968)]. Acetone has a much higher vapor pressure than water, but is selectively retained in coffee during drying.

treat particles more gently than others. Particle size is also important from a segregation standpoint. See Sec. 18, Liquid-Solid Operations and Equipment. Fine particles can also increase the risk of fire or explosion.

***Density*** Customers and consumers are generally very interested in getting the product density they have specified or expect. If the product is a consumer product and is going into a box, then the density needs to be correct to fill the box to the appropriate level. If density is important, then product shrinkage during drying can be an important harmful transformation to consider. This is particularly important for biological products for which shrinkage can be very high. This is why freeze drying can be the preferred dryer for many of these materials.

***Solubility*** Many dried products are rewet either during use by the consumer or by a customer during subsequent processing. Shrinkage can again be a very harmful transformation. Often shrinkage is a virtually irreversible transformation that creates an unacceptable product morphology. Case hardening is a phenomenon that occurs when the outside of the particle or product initially shrinks to form a very hard and dense skin that does not easily rewet. A common cause is capillary collapse, discussed along with shrinkage below.

***Flowability*** If we're considering particles, powders, and other products that are intended to flow, then this is a very important consideration. These materials need to easily flow from bins, from hoppers, and out of boxes for consumer products. Powder flowability is a measurable characteristic using rotational shear cells (Peschl, Freeman) or translational shear cells (Jenike) in which the powder is consolidated under various normal loads; then the shear force is measured, enabling a complete yield locus curve to be constructed. This can be done at various powder moistures to create a curve of flowability versus moisture content. Some minimal value is necessary to ensure free flow. Additional information on these devices and this measure can be found in Sec. 21, Solids Processing and Particle Technology.

***Color*** Product color is usually a very important product quality attribute, and a change in color can be caused by several different transformations.

**Transformations Affecting Product Quality** Drying, as with any other unit operation, has both productive and harmful transformations that occur. The primary productive transformation is water removal of course, but there are many harmful transformations that can occur and adversely affect product quality. The most common of these harmful transformations includes product shrinkage; attrition or agglomeration; loss of flavor, aroma, and nutritional value; browning reactions; discoloration; stickiness; and flowability problems. These issues were discussed briefly above, but are worth a more in-depth review.

***Shrinkage*** Shrinkage is a particularly important transformation with several possible mechanisms to consider. It's usually especially problematic with food and other biological materials, but is a very broadly occurring phenomenon. Shrinkage generally affects solubility, wettability, texture and morphology, and absorbency. It can be observed when drying lumber when it induces stress cracking and during the drying of coffee beans prior to roasting. Tissue, towel, and other paper products undergo some shrinkage during drying. And many chemical products shrink as water evaporates, creating voids and capillaries prone to collapse as additional water evaporates. As we consider capillary collapse, there are several mechanisms worth mentioning.

*Surface tension.* The capillary suction created by a receding liquid meniscus can be extremely high.

*Plasticization.* An evaporating solvent which is also a plasticizer of polymer solute product will lead to greater levels of collapse and shrinkage.

*Electric charge effects.* The van der Waals and electrostatic forces can also be a strong driver of collapse and shrinkage.

***Surface Tension*** These effects are very common and worthy of a few more comments. Capillary suction created by a receding liquid meniscus can create very high pressures for collapse. The quantitative expression for the pressure differential across a liquid-fluid interface was first derived by Laplace in 1806. The meniscus, which reflects the differential, is affected by the surface tension of the fluid. Higher surface tensions create greater forces for collapse. These strong capillary suction pressures can easily collapse a pore. We can reduce these suction pressures by using low-surface-tension fluids or by adding surfactants, in the case of water, which will also significantly reduce surface tension ( from 72 to 30 dyn/cm).

The collapse can also be reduced with some dryer types. Freeze drying and heat pump drying can substantially reduce collapse, but the capital cost of these dryers is sometimes prohibitive. At the other extreme, dryers that rapidly flash off the moisture can reduce collapse. This mechanism can also be affected by particle size such that the drying is primarily boundary-layer-controlled. When the particle size becomes sufficiently small, moisture can diffuse to the surface at a rate sufficient to keep the surface wetted. This has been observed in a gel-forming food material when the particle size reached 150 to 200 μm (Genskow, "Considerations in Drying Consumer Products," *Proceedings International Drying Symposium,* Versailles, France, 1988).

***Biochemical Degradation*** Biochemical degradation is another harmful transformation that occurs with most biological products. There are four key reactions to consider: lipid oxidation, Maillard browning, protein denaturation, and various enzyme reactions. These reactions are both heat- and moisture-dependent such that control of temperature and moisture profiles can be very important during drying.

*Lipid oxidation* Lipid oxidation is normally observed as a product discoloration and can be exacerbated with excessive levels of bleach. It is catalyzed by metal ions, enzymes, and pigments. Acidic compounds can be used to complex the metal ions. Synthetic antioxidants such as butylated hydroxytoluene (BHT) and butylated hydroxyanisole (BHA) can be added to the product, but are limited and coming under increased scrutiny due to toxicology concerns. It may be preferable to use natural antioxidants such as lecithin or vitamin E or to dry under vacuum or in an inert (nitrogen, steam) atmosphere.

*Protein denaturation* Normally protein denaturation is observed as an increase in viscosity and a decrease in wettability. It is temperature-sensitive, generally occurring between 40 and 80°C. A common drying process scheme is to dry thermally and under wet-bulb drying conditions without overheating and then vacuum, heat-pump, or freeze-dry to the target moisture.

*Enzyme reactions* Enzymatic browning is caused by the enzyme polyphenol oxidase which causes phenols to oxidize to orthoquinones. The enzyme is active between pH 5 and 7. A viable process scheme again is to dry under vacuum or in an inert (nitrogen, steam) atmosphere.

*Maillard browning reaction* This nonenzymatic reaction is observed as a product discoloration, which in some products creates an attractive coloration. The reaction is temperature-sensitive, and normally the rate passes through a maximum and then falls as the product becomes drier. The reaction can be minimized by minimizing the drying temperature, reducing the pH to acidic, or adding an inhibitor such as sulfur dioxide or metabisulfate. A viable process scheme again is to dry thermally and under wet-bulb drying conditions without overheating and then vacuum, heat-pump, or freeze-dry to the target moisture.

Some of the above reactions can be minimized by reducing the particle size and using a monodisperse particle size distribution. The small particle size will better enable wet-bulb drying, and the monodisperse size will reduce overheating of the smallest particles.

***Stickiness, Lumping, and Caking*** These are not characteristics we generally want in our products. They generally connote poor product quality, but can be a desirable transformation if we are trying to enlarge particle size through agglomeration. Stickiness, lumping, and caking are phenomena that are dependent on product moisture and product temperature. The most general description of this phenomenon is created by measuring the cohesion (particle to particle) of powders, as described below. A related measure is *adhesion*—particle-to-wall interactions. Finally, the sticky point is a special case for materials that undergo glass transitions.

The sticky point can be determined by using a method developed by Lazar and later by Downton [Downton, Flores-Luna, and King, "Mechanism of Stickiness in Hygroscopic, Amorphous Powders," *I&EC Fundamentals* **21:** 447 (1982)]. In the simplest method, a sample of the product, at a specific moisture, is placed in a closed tube which is suspended in a water bath. A small stirrer is used to monitor the torque needed to "stir" the product. The water bath temperature is slowly increased until the torque increases. This torque increase indicates a sticky point temperature for that specific moisture. The test is repeated with other product moistures until the entire stickiness curve is determined. A typical curve is shown in Fig. 12-33.

As noted, a sticky point mechanism is a glass transition—the transition when a material changes from the glassy state to the rubbery liquid state. Glass transitions are well documented in food science (Levine and Slade). Roos and Karel ["Plasticizing Effect of Water on Thermal Behavior and Crystallization of Amorphous Food Models," *J. Food Sci.* **56**(1): 38–43 (1991)] have demonstrated that for these types of products, the glass transition temperature follows the sticky point curve within about 2°C. This makes it straightforward to measure the stickiness curve by using a *differential scanning calorimeter* (DSC). Somewhat surprisingly, even materials that are not undergoing glass transitions exhibit this behavior, as demonstrated with the detergent stickiness curve above.

Lumping and caking can be measured by using the rotational shear cells (Peschl, Freeman) or translational shear cells (Jenike) noted above for measuring flowability. The powder is consolidated under various normal loads, and then the shear force is measured, enabling a complete yield locus curve to be constructed. This can be done at various powder moistures to create a curve of cake strength versus moisture content. Slurries and dry solids are free-flowing, and there is a cohesion/adhesion peak at an intermediate moisture content, typically when voids between particles are largely full of liquid. A variety of other test methods for handling properties and flowability are available.

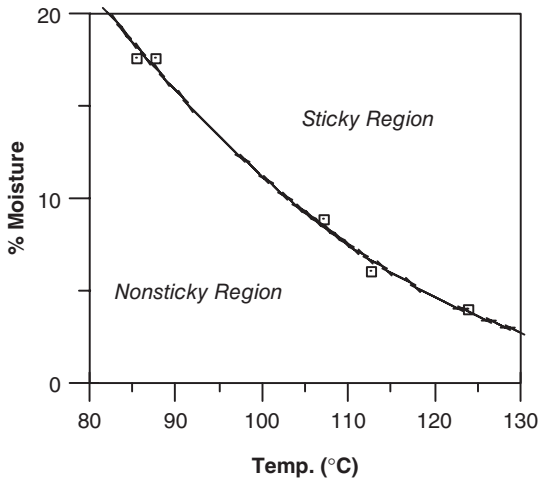

**FIG. 12-33** Detergent stickiness curve.

Product quality was addressed quite comprehensively by Evangelos Tsotsas at the 2d Nordic Drying Conference [Tsotsas, "Product Quality in Drying—Luck, Trial, Experience, or Science?" 2d Nordic Drying Conference, Copenhagen, Denmark, 2003]. Tsotsas notes that 31 percent of the papers at the 12th International Drying Symposium refer to product quality. The top five were color (12 percent), absence of chemical degradation (10 percent), absence of mechanical damage (9 percent), bulk density (8 percent), and mechanical properties (7 percent). All these properties are reasonably straightforward to measure. They are physical properties, and we are familiar with them for the most part. However, down the list at a rank of 20 with only 2 percent of the papers dealing with it, we have sensory properties.

This is the dilemma—sensory properties should rank very high, but they don't because we lack the tools to measure them effectively. For the most part, these quality measures are subjective rather than objective, and frequently they require direct testing with consumers to determine the efficacy of a particular product attribute. So the issue is really a lack of physical measurement tools that directly assess the performance measures important to the consumer of the product. The lack of objective performance measures and unknown mechanistic equations also makes mathematical modeling very difficult for addressing quality problems.

The good news is that there has been a shift from the macro to the meso and now to the micro scale in drying science. We have some very powerful analytical tools to help us understand the transformations that are occurring at the meso scale and micro scale.

## CLASSIFICATION AND SELECTION OF DRYERS

Drying equipment may be classified in several ways. Effective classification is vital in selection of the most appropriate dryer for the task and in understanding the key principles on which it operates. The main drying-process attributes are as follows:

1. Form of feed and product—particulate (solid or liquid feed), sheet, slab
2. Mode of operation—batch or continuous
3. Mode of heat transfer—convective (direct), conductive (indirect), radiative, or dielectric
4. Condition of solids—static bed, moving bed, fluidized or dispersed
5. Gas-solids contacting—parallel flow, perpendicular flow, or through-circulation
6. Gas flow pattern—cross-flow, cocurrent, or countercurrent

Other important features of the drying system are the type of carrier gas (air, inert gas, or superheated steam/solvent), use of gas or solids recycle, type of heating (indirect or direct-fired), and operating pressure (atmospheric or vacuum).

However, in the selection of a group of dryers for preliminary consideration in a given drying problem, the most important factor is often category 1, the form, handling characteristics, and physical properties of the wet material.

Table 12-11 shows the major categories of drying equipment, organized by feed type. This section compares these types in general terms. Each dryer type listed in Table 12-11 is discussed in greater detail in the Drying Equipment subsection.

**Description of Dryer Classification and Selection Criteria**

1. *Form of Feed and Product* Dryers are specifically designed for particular feed and product forms; dryers handling films, sheets, slabs, and bulky artifacts form a clear subset. Most dryers are for particulate products, but the feed may range from a solution or slurry ( free-flowing liquid) through a sticky paste to wet filter cakes, powders, or granules (again relatively free-flowing). The ability to successfully mechanically handle the feed and product is a key factor in dryer selection (see Table 12-11).

The drying kinetics also depend strongly on solids properties, particularly particle size and porosity. The surface area/volume ratio and the internal pore structure control the extent to which an operation is diffusion-limited, i.e., diffusion into and out of the pores of a given solids particle, not through the voids among separate particles.

2. *Mode of Operation* Batch dryers are typically used for low throughputs (under 50 kg/h), for long drying times, or where the overall process is predominantly batch. Continuous dryers dominate for high throughputs, high evaporation rates, and where the rest of the process is continuous. Dryers that are inherently continuous can be operated in semibatch mode (e.g., small-scale spray dryers) and vice versa.

3. *Mode of Heat Transfer*

*Direct (convective) dryers* These are the general operating characteristics of direct dryers.

*a.* Direct contacting of hot gases with the solids is employed for solids heating and vapor removal. Note, in some cases, hot exhaust gas from combustion containing CO and $CO_2$ should not contact the product and this exhaust gas heats fresh air that contacts the product using a separate heat exchanger; these are still considered "direct" dryers.

**TABLE 12-11 Classification of Commercial Dryers Based on Feed Materials Handled**

| Type of dryer | Liquids | Slurries | Pastes and sludges | Free-flowing | Granular, crystalline, or fibrous solids | Large solids, special forms and shapes | Continuous sheets | Discontinuous sheets |
|---|---|---|---|---|---|---|---|---|
| | True and colloidal solutions; emulsions. Examples: inorganic salt solutions, extracts, milk, blood, waste liquors, rubber latex | Pumpable suspensions. Examples: pigment slurries, soap and detergents, calcium carbonate, bentonite, clay slip, lead concentrates | Examples: filter-press cakes, sedimentation sludges, centrifuged solids, starch, detergents | 100-mesh (150-μm) or less. Relatively free-flowing in wet state. Dusty when dry. Examples: centrifuged precipitates | Larger than 100-mesh (150 μm). Examples: rayon staple, salt crystals, sand, ores, potato strips, synthetic rubber | Examples: pottery, brick, rayon cakes, shotgun shells, hats, painted objects, rayon skeins, lumber, pet food, croutons | Examples: paper, impregnated fabrics, cloth, cellophane, plastic sheets | Examples: veneer, wallboard, photographic prints, leather, foam rubber sheets |
| **Batch tray dryers** Material is loaded onto a static tray and dried without agitation. Includes vacuum drying. | Not applicable | Not applicable | Suitable only if material can be preformed. Suited to batch operation. | Not applicable | Usually not suited for materials smaller than 30-mesh (0.5 mm). Suited to small capacities. | Primarily useful for small objects. | Not applicable | Not applicable |
| **Continuous tray and gravity dryers** Material dries on trays and moves between successive trays by gravity. | Not applicable | Not applicable | Suitable for small-scale and large-scale production. | See comments under Pastes and Sludges. Vertical turbo-tray applicable | Suitable for large particles (>500 μm) or small discrete objects. | Not suitable for large or fragile objects. | Not applicable | Not applicable |
| **Continuous band and tunnel dryers** Material is loaded on a continuous band or belt and is dried by convection, conduction, or radiant heat. | Not applicable | Only crystal filter dryer or centrifuge dryer may be suitable. | Suitable for materials that can be preformed. Will handle large capacities | Not applicable | Usually not suited for materials smaller than 30-mesh (0.5 mm). Material does not tumble or mix. | Suited to a wide variety of shapes and forms. Can be used to convey materials through heated zones. | Not applicable | Special designs are required. Suited to veneers. |
| **Batch agitated and rotating dryers** Batch dryer where material is moved to enhance mass- and heat-transfer rates | Atmospheric or vacuum. Suitable for small batches. Easily cleaned. Solvents can be recovered. Material agitated while dried. | See comments under Liquids. | See comments under Liquids. | See comments under Liquids. | Suitable for small batches. Easily cleaned. Material is agitated during drying, causing some degradation and/or balling up. | Not applicable | Not applicable | Not applicable |
| **Continuous agitated and rotating dryers** Material is mechanically agitated or turned over during drying. | Applicable with dry-product recirculation. | Applicable with dry-product recirculation. | Suitable only if product does not stick to walls and does not dust. Recirculation of product may prevent sticking. Generally requires recirculation of dry product. Little dusting occurs. | Suitable for most materials and especially for high capacities, provided dusting is not too severe. Chief advantage is low dust loss. Well suited to most materials and capacities, particularly those requiring drying at steam temperature | Suitable for most materials, especially for high capacities. Dusting or crystal abrasion will limit its use. Low dust loss. Material must not stick or be temperature-sensitive. | Not applicable | Not applicable | Not applicable |
| **Fluidized- and spouted-bed dryers** Particulate material is suspended/fluidized and simultaneously dried by upward-moving air. | Applicable only as fluid-bed granulator with inert bed or dry-solids recirculator. | See comments under Liquids. | See comments under Liquids. | Fluidized bed suitable, if not too dusty. Internal coils can supplement heating, especially for fine powders. Suitable for high capacities. | Fluidized bed suitable for crystals, granules, and very short fibers. Suitable for high capacities. Suitable for spouted beds for granules over 800 μm. | Only applicable for spouted beds if objects are conveyable in gas stream. | Not applicable | Not applicable |
| **Pneumatic conveying dryers** Particulate material is suspended in hot air (or superheated steam) and conveyed. | See comments under Slurries. | Can be used only if product is recirculated (backmixed) to make feed suitable for handling. | Usually requires recirculation of dry product to make suitable feed. Well suited to high capacities. Disintegration usually required. | Suitable for materials that are easily suspended in a gas stream and lose moisture readily. Well suited to high capacities. | Suitable for materials conveyable in a gas stream. Well suited to high capacities. Only surface moisture usually removed. Product may suffer physical degradation. | Not applicable | Not applicable | Not applicable |

**TABLE 12-11 Classification of Commercial Dryers Based on Feed Materials Handled** (*Continued*)

| Type of dryer | Liquids | Slurries | Pastes and sludges | Free-flowing | Granular, crystalline, or fibrous solids | Large solids, special forms and shapes | Continuous sheets | Discontinuous sheets |
|---|---|---|---|---|---|---|---|---|
| **Spray dryers** A liquid or slurry feed is atomized/sprayed, and the resulting droplets dry into particles. | Suited for large capacities. Product is usually powdery, spherical, and free-flowing. High temperatures can sometimes be used with heat-sensitive materials. Products generally have low bulk density. | See comments under Liquids. Pressure-nozzle atomizers subject to erosion. | Requires special pumping equipment to feed the atomizer. See comments under Liquids. | Not applicable unless feed is pumpable. | Not applicable | Not applicable | Not applicable | Not applicable |
| **Drum and thin-film dryers** Liquid or paste feed is distributed on the outside of a hot, slowly rotating drum. | Single, double, or twin. Atmospheric or vacuum operation. Product flaky and usually dusty. Maintenance costs may be high. | See comments under Liquids. Twin-drum dryers are widely used. | Can be used only when paste or sludge can be made to flow. See comments under Liquids. | Not applicable | Not applicable | Not applicable | Not applicable | Not applicable |
| **Sheet dryers** Discrete or continuous solid sheets are dried by blowing air or steam through them or over them. Heat can be added by multiple methods. | Not applicable | Not applicable | Not applicable | Not applicable | Not applicable | Not applicable | See description for applications. Web can be controlled with tension. | See description for applications. Items being dried need to be positioned or held in place. |
| **Freeze dryers** Air is removed from the system. Energy must be supplied via conduction or radiation. | Expensive. Usually used only for high-value products such as pharmaceuticals; products which are heat-sensitive and readily oxidized. | See comments under Liquids. | See comments under Liquids. | See comments under Liquids. | Expensive. Usually used on pharmaceuticals and related products which cannot be dried successfully by other means. Applicable to fine chemicals. | See comments under Granular Solids. | Applicable in special cases such as emulsion-coated films. | See comments under Granular Solids. |
| **Electromagnetic drying (infrared, radiofrequency, microwave)** Batch or continuous operation. Electromagnetic energy added to material. | Can be used in combination with other dryers such as drum. Infrared: only for thin films. Microwave/ radio-frequency: expensive, specialty applications. | See comments under Liquids. | See comments under Liquids. | Infrared: only for thin layers Radiofrequency/microwave | Primarily suited to drying surface moisture. Not suited for thick layers. | Especially suited for drying and baking paint and enamels. | Infrared. Useful for laboratory work or in conjunction with other methods. Radiofrequency/ microwave: successful for foam rubber. | See comments under Continuous Sheets. |

*b.* Drying temperatures may range up to 750°C, the limiting temperature for most common structural metals. At higher temperatures, radiation becomes an important heat-transfer mechanism.

*c.* At gas temperatures below the boiling point, the vapor content of gas influences the rate of drying and the final moisture content of the solid. With gas temperatures above the boiling point throughout, the vapor content of the gas has only a slight retarding effect on the drying rate and final moisture content. Thus, superheated vapors of the liquid being removed (e.g., steam) can be used for drying.

*d.* For low-temperature drying, dehumidification of the drying air may be required when atmospheric humidities are excessively high.

*e.* Efficiency increases with an increase in the inlet gas temperature for a constant exhaust temperature.

*f.* Because large amounts of gas are required to supply all the heat for drying, dust recovery or volatile organic compound (VOC) equipment may be very large and expensive, especially when drying very small particles.

*Indirect (contact or conductive) dryers* These differ from direct dryers with respect to heat transfer and vapor removal:

*a.* Heat is transferred to the wet material by conduction through a solid retaining wall, usually metallic.

*b.* Surface temperatures may range from below freezing in the case of freeze dryers to above 500°C in the case of indirect dryers heated by combustion products.

*c.* Indirect dryers are suited to drying under reduced pressures and inert atmospheres, to permit the recovery of solvents and to prevent the occurrence of explosive mixtures or the oxidation of easily decomposed materials.

*d.* Indirect dryers using condensing fluids as the heating medium are generally economical from the standpoint of heat consumption, since they furnish heat only in accordance with the demand made by the material being dried.

*e.* Dust recovery and dusty or hazardous materials can be handled more satisfactorily in indirect dryers than in direct dryers.

*Electromagnetic (Infrared, Radiofrequency, Microwave)* These dryers use energy in the form of electromagnetic radiation.

*a.* Infrared dryers depend on the transfer of radiant energy to evaporate moisture. The radiant energy is supplied electrically by infrared lamps, by electric resistance elements, or by incandescent refractories heated by gas. The last method has the added advantage of convection heating. Infrared heating is not widely used in the chemical industries for the removal of moisture. Its principal use is in baking or drying paint films (curing) and in heating thin layers of materials. It is sometimes used to give supplementary heating on the initial rolls of paper machines (cylinder dryers).

*b.* Dielectric dryers (radiofrequency or microwave) have not yet found a wide field of application, but are increasingly used. Their fundamental characteristic of generating heat within the solid indicates potentialities for drying massive geometric objects such as wood, sponge-rubber shapes, and ceramics, and for reduced moisture gradients in layers of solids. Power costs are generally much higher than the fuel costs of conventional methods; a small amount of dielectric heating (2 to 5 percent) may be combined with thermal heating to maximize the benefit at minimum operating cost. The high capital costs of these dryers must be balanced against product quality and process improvements. See more in the Drying Equipment part of this subsection.

4. *Condition of Solids* In solids-gas contacting equipment, the solids bed can exist in any of the following four conditions:

*Static* This is a dense bed of solids in which each particle rests upon another at essentially the settled bulk density of the solids phase. Specifically, *there is no relative motion among solids particles* (Fig. 12-34).

*Moving* This is a slightly expanded bed of solids in which the particles are separated only enough to flow one over another. Usually the flow is downward under the force of gravity (Fig. 12-35), but upward motion by mechanical lifting or agitation may also occur within the process vessel (Fig. 12-36). In some cases, lifting of the solids is accomplished in separate equipment, and solids flow in the presence of the gas phase is downward only. The latter is a moving bed as usually defined in the petroleum industry. In this definition, *solids motion is achieved by either mechanical agitation or gravity force.*

*Fluidized* This is an expanded condition in which the solids particles are supported by drag forces caused by the gas phase passing through the interstices among the particles at some critical velocity. The superficial gas velocity upward is less than the terminal settling velocity of the solids particles; the gas velocity is not sufficient to entrain and convey continuously all the solids. Specifically, the solids phase and the gas phase are intermixed and *together behave as a boiling fluid* (Fig. 12-37).

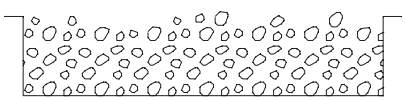

**FIG. 12-34** Solids bed in static condition (tray dryer).

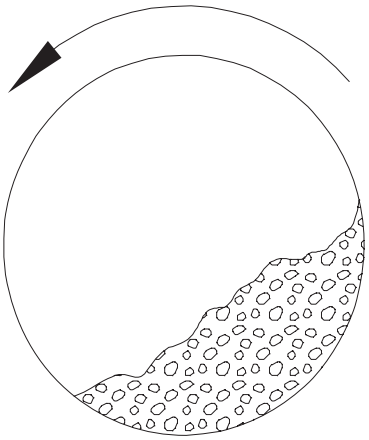

**FIG. 12-35** Horizontal moving bed.

*Dispersed or dilute* This is a fully expanded condition in which the solids particles are so widely separated that they exert essentially no influence upon one another. Specifically, the solids phase is so fully dispersed in the gas that the *density of the suspension is essentially that of the gas phase alone* (Fig. 12-38). Commonly, this situation exists when the gas velocity at all points in the system exceeds the terminal settling velocity of the solids and the particles can be lifted and continuously conveyed by the gas; however, this is not always true. Cascading rotary dryers, countercurrent-flow spray dryers, and gravity settling chambers are three exceptions in which the gas velocity is insufficient to entrain the solids completely.

Cascading (direct) rotary dryers with lifters illustrate all four types of flow in a single dryer. Particles sitting in the lifters ( flights) are a static bed. When they are in the rolling bed at the bottom of the dryer, or rolling off the top of the lifters, they form a moving bed. They form a falling curtain which is initially dense ( fluidized) but then spreads out and becomes dispersed.

Dryers where the solid forms the continuous phase (static and moving beds) are called *layer dryers*, while those where the gas forms the continuous phase ( fluidized and dispersed solids) are classified as *dispersion dryers.* Gas-particle heat and mass transfer is much faster in dispersion dryers, and so these are often favored where high drying rates, short drying times, or high solids throughput is required. Layer dryers are very suitable for slow-drying materials requiring a long residence time.

Because heat transfer and mass transfer in a gas-solids-contacting operation take place at the solids' surfaces, maximum process efficiency can be expected with a maximum exposure of solids surface to the gas phase, together with thorough mixing of gas and solids. Both are important. Within any arrangement of particulate solids, gas is present in the voids among the particles and contacts all surfaces except at the points of particle contact. When the solids are fluidized or dispersed, the gas moves past them rapidly, and external heat- and mass-transfer rates are high. When the solids bed is in a static or slightly moving condition, however, gas within the voids is cut off from the main body of the gas phase and can easily become saturated, so that local drying rates fall to low or zero values. Some transfer of energy

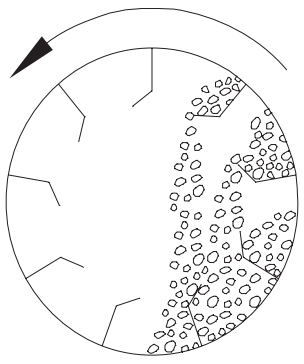

**FIG. 12-36** Moving solids bed in a rotary dryer with lifters.

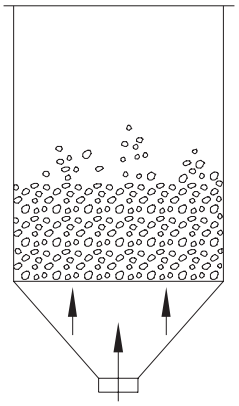

**FIG. 12-37** Fluidized solids bed.

and mass may occur by diffusion, but it is usually insignificant. The problem can be much reduced by using through-circulation of gas instead of cross-circulation, or by agitating and mixing the solids.

*Solids Agitation and Mixing* There are four alternatives:

1. No agitation, e.g., tray and band dryers. This is desirable for friable materials. However, drying rates can be extremely low, particularly for cross-circulation and vacuum drying.
2. Mechanical agitation, e.g., vertical pan and paddle dryers. This improves mixing and drying rates, but may give attrition depending on agitator speed; and solids may stick to the agitator. These are illustrated in Fig. 12-39.
3. Vessel rotation, e.g., double-cone and rotary dryers. Mixing and heat transfer are better than for static dryers but may be less than for mechanical agitation. Formation of balls and lumps may be a problem.
4. Airborne mixing, e.g., fluidized beds and flash and spray dryers. Generally there is excellent mixing and mass transfer, but feed must be dispersible and entrainment and gas cleaning are higher.

*Solids transport* In continuous dryers, the solids must be moved through the dryer. These are the main methods of doing this:

1. Gravity flow (usually vertical), e.g., turbo-tray, plate and moving-bed dryers, and rotary dryers (due to the slope)
2. Mechanical conveying (usually horizontal), e.g., band, tunnel, and paddle dryers
3. Airborne transport, e.g., fluidized beds and flash and spray dryers
4. Vibration

*Solids flow pattern* For most continuous dryers, the solids are basically in plug flow; backmixing is low for nonagitated dryers but can be extensive for mechanical, rotary, or airborne agitation. Exceptions are well-mixed fluidized beds, fluid-bed granulators, and spouted beds (well-mixed) and spray and spray/fluidized-bed units (complex flow patterns).

5. *Gas-Solids Contacting* Where there is a significant gas flow, it may contact a bed of solids in the following ways:

*a. Parallel flow or cross-circulation.* The direction of gas flow is parallel to the surface of the solids phase. Contacting is primarily at the interface between phases, with possibly some penetration of gas into the voids among the solids near the surface. The solids bed is usually in a static condition (Fig. 12-40).

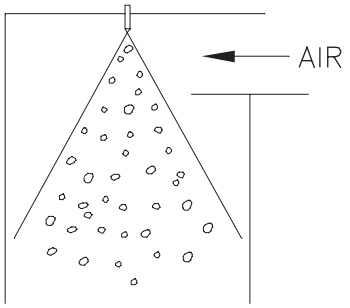

**FIG. 12-38** Solids in a dilute condition near the top of a spray dryer.

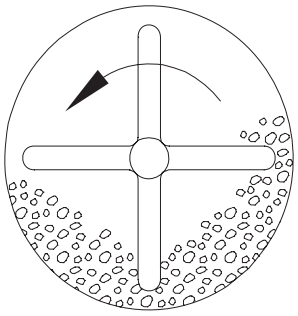

**FIG. 12-39** Paddle dryer.

*b. Perpendicular flow* or *impingement.* The direction of gas flow is normal to the phase interface. The gas impinges on the solids bed. Again the solids bed is usually in a static condition (Fig. 12-41). This most commonly occurs when the solids are a continuous sheet, film, or slab.

*c. Through circulation.* The gas penetrates and flows through interstices among the solids, circulating more or less freely around the individual particles (Fig. 12-42). This may occur when solids are in static, moving, fluidized, or dilute conditions.

6. *Gas Flow Pattern in Dryer* Where there is a significant gas flow, it may be in cross-flow, cocurrent, or countercurrent flow compared with the direction of solids movement.

*a. Cocurrent gas flow.* The gas phase and solids particles both flow in the same direction (Fig. 12-43).

*b. Countercurrent gas flow.* The direction of gas flow is exactly opposite to the direction of solids movement.

*c. Cross-flow of gas.* The direction of gas flow is at a right angle to that of solids movement, across the solids bed (Fig. 12-44).

The difference between these is shown most clearly in the gas and solids temperature profiles along the dryer. For cross-flow dryers, all solids particles are exposed to the same gas temperature, and the solids temperature approaches the gas temperature near the end of drying (Fig. 12-45). In cocurrent dryers, the gas temperature falls throughout the dryer, and the final solids temperature is much lower than that for the cross-flow dryer (Fig. 12-46). Hence cocurrent dryers are very suitable for drying heat-sensitive materials, although it is possible to get a solids temperature peak inside the dryer. Conversely, countercurrent dryers give the most even temperature gradient throughout the dryer, but the exiting solids come into contact with the hottest, driest gas (Fig. 12-47). These can be used to heat-treat the solids or to give low final moisture content (minimizing the local equilibrium moisture content) but are obviously unsuitable for thermally sensitive solids.

## SELECTION OF DRYING EQUIPMENT

**Dryer Selection Considerations** Dryer selection is a challenging task. These are some important considerations:

- Batch dryers are almost invariably used for mean throughputs below 50 kg/h, and continuous dryers are generally used above 1 ton/h; in the intervening range, either may be suitable.
- Liquid or slurry feeds, large objects, or continuous sheets and films require completely different equipment from particulate feeds.
- Particles and powders below 1 mm are effectively dried in dispersion or contact dryers, but most through-circulation units are unsuitable. Conversely, for particles of several millimeters or above, through-circulation dryers, rotary dryers, and spouted beds are very suitable.
- Through-circulation and dispersion convective dryers (including fluidized-bed, rotary, and pneumatic types) and agitated or rotary contact dryers generally give better drying rates than nonagitated cross-circulated or contact tray dryers.
- Nonagitated dryers (including through-circulation) may be preferable for fragile particles where it is desired to avoid attrition.

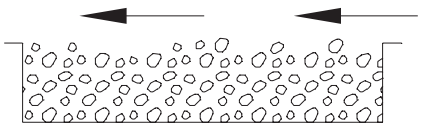

**FIG. 12-40** Parallel gas flow over a static bed of solids.

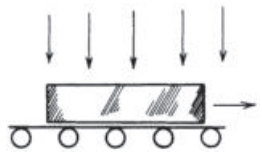

**FIG. 12-41** Circulating gas impinging on a large solid object in perpendicular flow, in a roller-conveyor dryer.

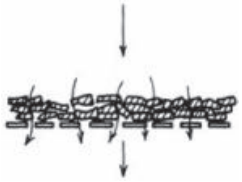

**FIG. 12-42** Gas passing through a bed of preformed solids, in through-circulation on a perforated-band dryer.

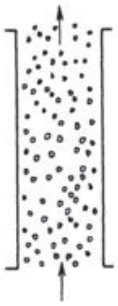

**FIG. 12-43** Cocurrent gas-solids flow in a vertical-lift dilute-phase pneumatic conveyor dryer.

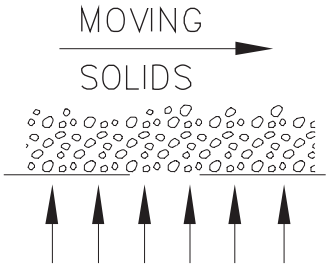

**FIG 12-44** Cross-flow of gas and solids in a fluid-bed or band dryer.

- For organic solvents or solids which are highly flammable, are toxic, or decompose easily, contact dryers are often preferable to convective dryers, as containment is better and environmental emissions are easier to control. If a convective dryer is used, a closed-cycle system using an inert carrier gas (e.g., nitrogen) is often required.
- Cocurrent, vacuum, and freeze dryers can be particularly suitable for heat-sensitive materials.

A detailed methodology for dryer selection, including the use of a rule-based expert system, has been described by Kemp [*Drying Technol.* **13**(5–7): 1563–1578 (1995) and **17**(7 and 8): 1667–1680 (1999)].

A simpler step-by-step procedure is given here.

1. *Initial selection of dryers.* Select those dryers which appear best suited to handling the wet material and the dry product, which fit into the continuity of the process as a whole, and which will produce a product of the desired physical properties. This preliminary selection can be made with the aid of Table 12-11, which classifies the various types of dryers on the basis of the materials handled.
2. *Initial comparison of dryers.* The dryers so selected should be evaluated approximately from available cost and performance data. From this evaluation, those dryers that appear to be uneconomical or unsuitable from the standpoint of performance should be eliminated from further consideration.
3. *Drying tests.* Drying tests should be conducted in those dryers still under consideration. These tests will determine the optimum operating conditions and the product characteristics and will form the basis for firm quotations from equipment vendors.
4. *Final selection of dryer.* From the results of the drying tests and quotations, the final selection of the most suitable dryer can be made.

These are the important factors to consider in the preliminary selection of a dryer:

1. Properties of the material being handled
   - *a.* Physical characteristics when wet (stickiness, cohesiveness, adhesiveness, flowability)
   - *b.* Physical characteristics when dry
   - *c.* Corrosiveness
   - *d.* Toxicity
   - *e.* Flammability
   - *f.* Particle size
   - *g.* Abrasiveness
2. Drying characteristics of the material
   - *a.* Type of moisture (bound, unbound, or both)
   - *b.* Initial moisture content (maximum and range)
   - *c.* Final moisture content (maximum and range)
   - *d.* Permissible drying temperature
   - *e.* Probable drying time for different dryers
   - *f.* Level of nonwater volatiles
3. Flow of material to and from the dryer
   - *a.* Quantity to be handled per hour (or batch size and frequency)
   - *b.* Continuous or batch operation
   - *c.* Process prior to drying
   - *d.* Process subsequent to drying

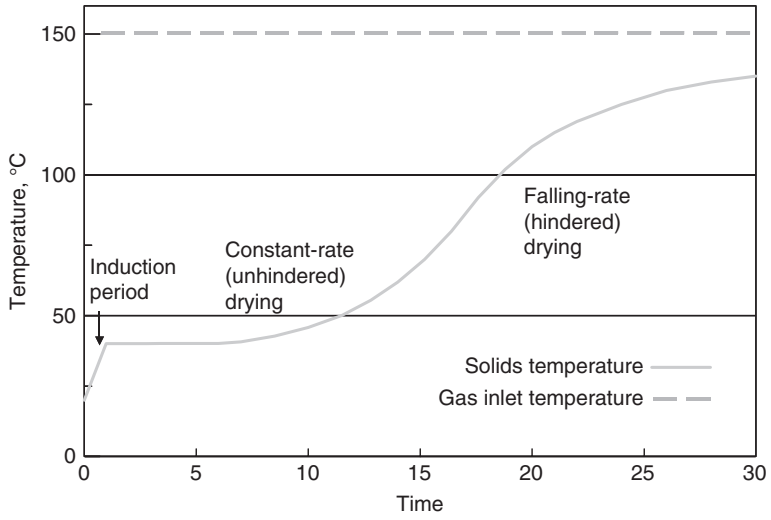

**FIG. 12-45** Temperature profiles along a continuous plug-flow dryer for cross-flow of gas and solids. (*Aspen Technology Inc.*)

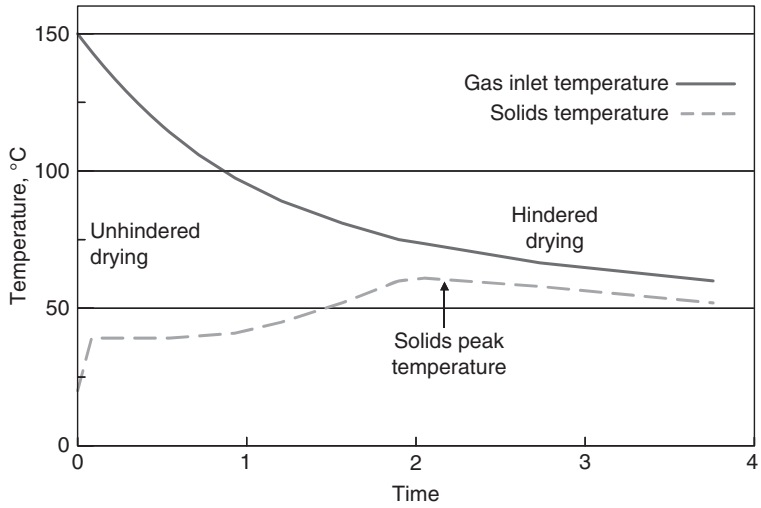

**FIG. 12-46** Temperature profiles along a continuous plug-flow dryer for cocurrent flow of gas and solids. (*Aspen Technology Inc.*)

4. Product quality
   *a.* Shrinkage
   *b.* Contamination
   *c.* Uniformity of final moisture content
   *d.* Decomposition of product
   *e.* Overdrying
   *f.* Particle size distribution (if applicable)
   *g.* Product temperature
   *h.* Bulk density
5. Recovery and environmental considerations
   *a.* Dust recovery
   *b.* Solvent recovery
6. Facilities available at site of proposed installation
   *a.* Space
   *b.* Flow rate, temperature, humidity, and cleanliness of air
   *c.* Available fuels
   *d.* Available electric power
   *e.* Permissible noise, vibration, dust, or heat losses
   *f.* Source of wet feed
   *g.* Exhaust-gas outlets/permissible VOC discharge levels

Following preliminary selection of suitable types of dryers, a rough evaluation of the size and cost should be made to eliminate those which are obviously uneconomical. Information for this evaluation can be obtained from material presented under discussion of the various dryer types. When data are inadequate, usually preliminary cost and performance data can be obtained from the equipment manufacturer. In comparing dryer performance, the factors in the preceding list which affect dryer performance should be properly weighed.

## DRYER DESCRIPTIONS

**Batch Tray Dryers**

***Examples and Synonyms*** Direct heat tray dryer, batch through-circulation dryer, vacuum shelf dryer, through-circulation drying room, vacuum oven, vacuum-shelf dryer.

***Description*** A tray or compartment dryer is an enclosed, insulated housing in which solids are placed upon tiers of trays in the case of particulate solids or stacked in piles or upon shelves in the case of large objects. Heat transfer may be *direct* from gas to solids by circulation of large volumes of hot gas or *indirect* by use of heated shelves, radiator coils,

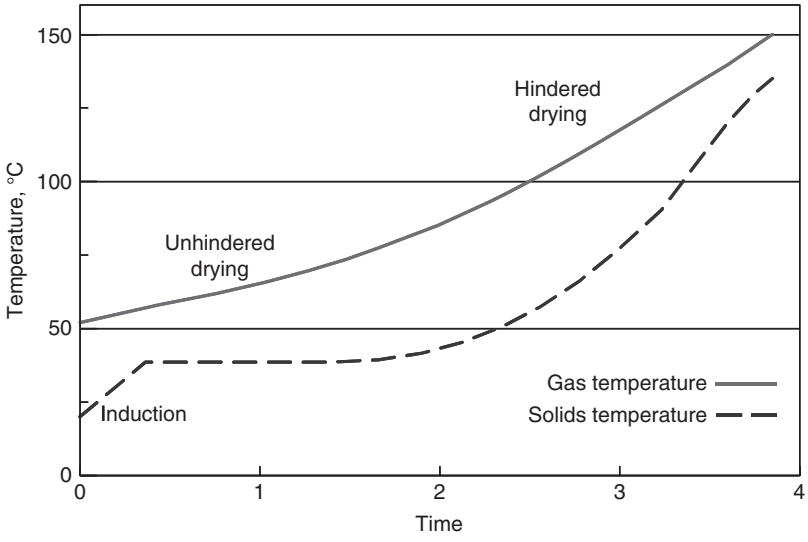

**FIG. 12-47** Temperature profiles along a continuous plug-flow dryer for countercurrent flow of gas and solids. (*Aspen Technology Inc.*)

or refractory walls inside the housing. In indirect-heat units, excepting vacuum-shelf equipment, circulation of a small quantity of gas is usually necessary to sweep moisture vapor from the compartment and prevent gas saturation and condensation. Compartment units are employed for the heating and drying of lumber, ceramics, sheet materials (supported on poles), painted and metal objects, and all forms of particulate solids.

***Field of Application*** Because of the high labor requirements usually associated with loading or unloading the compartments, batch compartment equipment is rarely economical except in the following situations:

1. A long heating cycle is necessary because the size of the solid objects or permissible heating temperature requires a long holdup for internal diffusion of heat or moisture. This case may apply when the cycle will exceed 12 to 24 h.
2. The production of several different products requires strict batch identity and thorough cleaning of equipment between batches. This is a situation existing in many small, multiproduct plants, e.g., for pharmaceuticals or specialty chemicals.
3. The quantity of material to be processed does not justify investment in more expensive, continuous equipment. This case would apply in many pharmaceutical drying operations.

Further, because of the nature of solids-gas contacting, which is usually by parallel flow and rarely by through-circulation, heat transfer and mass transfer are comparatively inefficient. For this reason, use of tray and compartment equipment is restricted primarily to ordinary drying and heat-treating operations.

***Auxiliary Equipment*** If noxious gases, fumes, or dust is given off during the operation, dust or fume recovery equipment will be necessary in the exhaust gas system. Condensers are employed for the recovery of valuable solvents from dryers. To minimize heat losses, thorough insulation of the compartment with brick or other insulating compounds is necessary. Vacuum-shelf dryers require auxiliary stream jets or other vacuum-producing devices, intercondensers for vapor removal, and occasionally wet scrubbers or (heated) bag-type dust collectors.

Uniform depth of loading in dryers and furnaces handling particulate solids is essential to consistent operation, minimum heating cycles, or control of final moisture. After a tray has been loaded, the bed should be leveled to a uniform depth. Special preform devices, noodle extruders, pelletizers, etc., are employed occasionally for preparing pastes and filter cakes so that screen bottom trays can be used and the advantages of through-circulation approached.

Control of tray and compartment equipment is usually maintained by control of the circulating air temperature (and humidity) and rarely by the solids temperature. On vacuum units, control of the absolute pressure and heating-medium temperature is utilized. In direct dryers, cycle controllers are frequently employed to vary the air temperature or velocity across the solids during the cycle; e.g., high air temperatures may be employed during a constant-rate drying period while the solids surface remains close to the air wet-bulb temperature. During the falling-rate periods, this temperature may be reduced to prevent case hardening or other degrading effects caused by overheating the solids surfaces. In addition, higher air velocities may be employed during early drying stages to improve heat transfer; however, after surface drying has been completed, this velocity may need to be reduced to prevent dusting. Two-speed circulating fans are employed commonly for this purpose.

***Direct-Heat Tray Dryers*** Satisfactory operation of tray-type dryers depends on maintaining a constant temperature and a uniform air velocity over all the material being dried.

Circulation of air at velocities of 1 to 10 m/s is desirable to improve the surface heat-transfer coefficient and to eliminate stagnant air pockets. Proper airflow in tray dryers depends on sufficient fan capacity, on the design of ductwork to modify sudden changes in direction, and on properly placed baffles. *Nonuniform airflow is one of the most serious problems in the operation of tray dryers.*

Tray dryers may be of the tray-truck or the stationary-tray type. In the former, the trays are loaded on trucks which are pushed into the dryer; in the latter, the trays are loaded directly into stationary racks within the dryer. Trays may be square or rectangular, with 0.5 to 1 $m^2$ per tray, and may be fabricated from any material compatible with corrosion and temperature conditions. When the trays are stacked in the truck, there should be a clearance of not less than 4 cm between the material in one tray and the bottom of the tray immediately above. When material characteristics and handling permit, the trays should have screen bottoms for additional drying area. Metal trays are preferable to nonmetallic trays, since they conduct heat more readily. Tray loadings range usually from 1 to 10 cm deep.

Steam is the usual heating medium, and a standard heater arrangement consists of a main heater before the circulating fan. When steam is not available or the drying load is small, electric heat can be used. For temperatures above 450 K, products of combustion can be used, or indirect-fired air heaters.

Air is circulated by propeller or centrifugal fans; the fan is usually mounted within or directly above the dryer. Total pressure drop through the trays, heaters, and ductwork is usually in the range of 2.5 to 5 cm of water. Air recirculation is generally on the order of 80 to 95 percent except during the initial drying stage of rapid evaporation. Fresh air is drawn in by the circulating fan, frequently through dust filters. In most installations, air is exhausted by a separate small exhaust fan with a damper to control air recirculation rates.

*Prediction of heat- and mass-transfer coefficients in direct heat tray dryers* In convection phenomena, heat-transfer coefficients depend on the geometry of the system, the gas velocity past the evaporating surface, and the physical properties of the drying gas. In estimating drying rates, the use of heat-transfer coefficients is preferred because they are usually more reliable than mass-transfer coefficients. In calculating mass-transfer coefficients from drying experiments, the partial pressure at the surface is usually inferred from the measured or calculated temperature of the evaporating surface. Small errors in temperature have negligible effect on the heat-transfer coefficient but introduce relatively large errors in the partial pressure and hence in the mass-transfer coefficient.

For many cases in drying, the heat-transfer coefficient is proportional to $U_g^n$, where $U_g$ is an appropriate local gas velocity. For flow parallel to plane plates, the exponent $n$ has been reported to range from 0.35 to 0.8. The differences in exponent have been attributed to differences in flow pattern in the space above the evaporating surface, particularly whether it is laminar or turbulent, and whether the length is sufficient to allow fully developed flow. In the absence of applicable specific data, the heat-transfer coefficient for the parallel-flow case can be taken, for estimating purposes, as

$$h = \frac{8.8 J^{0.8}}{D_c^{0.2}} \tag{12-68}$$

where $h$ is the heat-transfer coefficient, W/($m^2 \cdot K$); $J$ is the gas mass flux, kg/($m^2 \cdot s$); and $D_c$ is a characteristic dimension of the system. The experimental data have been weighted in favor of an exponent of 0.8 in conformity with the usual Colburn $j$ factor, and average values of the properties of air at 370 K have been incorporated. Typical values are in the range 10 to 50 W/($m^2 \cdot K$).

Experimental data for drying from flat surfaces have been correlated by using the equivalent diameter of the flow channel or the length of the evaporating surface as the characteristic length dimension in the Reynolds number. However, the validity of one versus the other has not been established. The proper equivalent diameter probably depends at least on the geometry of the system, the roughness of the surface, and the flow conditions upstream of the evaporating surface. For airflow impinging normally to the surface from slots and nozzles, the heat-transfer coefficient can be obtained from the well-known Martin correlation: Martin, "Heat and Mass Transfer Between Impinging Gas Jets and Solid Surfaces," *Advances in Heat Transfer,* vol. 13, Academic Press, 1977, pp. 1–66. This correlation uses relevant geometric properties such as the diameter of the holes, the spacing between the slots/nozzles, and the distance between the slots/nozzles and the sheet. See Example 12-23 for calculation of the heat-transfer coefficient from an array of jets.

Most efficient performance is obtained with plates having open areas equal to 2 to 3 percent of the total heat-transfer area. The plate should be located at a distance equal to four to six hole (or equivalent) diameters from the heat-transfer surface.

As with many drying calculations, the most reliable design method is to perform experimental tests and to scale up. By measuring performance on a single tray with similar layer depth, air velocity, and temperature, the specific drying rate (SDR) concept as described in the Solids Drying Fundamentals subsection can be applied to give the total area and number of trays required for the full-scale dryer.

*Performance data for direct heat tray dryers* A standard two-truck dryer is illustrated in Fig. 12-48. Adjustable baffles or a perforated distribution plate is normally employed to develop 0.3 to 1.3 cm of water pressure drop at the wall through which air enters the truck enclosure. This will enhance the uniformity of air distribution, from top to bottom, among the trays.

Performance data on some typical tray and compartment dryers are tabulated in Table 12-12. These indicate that an overall rate of evaporation of 0.0025 to 0.025 kg water/($s \cdot m^2$) of tray area may be expected from tray and tray-truck dryers. The thermal efficiency of this type of dryer will vary from 20 to 50 percent, depending on the drying temperature used and the humidity of the exhaust air. In drying to very low moisture contents under temperature restrictions, the thermal efficiency may be on the order of 10 percent. Maintenance will run from 3 to 5 percent of the installed cost per year.

***Batch Through-Circulation Dryers*** These may be either of shallow bed or deep bed type. In the first type of batch through-circulation dryer, heated air passes through a stationary permeable bed of the wet material placed on removable screen-bottom trays suitably supported in the dryer. This type is similar to a standard tray dryer *except that hot air passes through the wet solid*

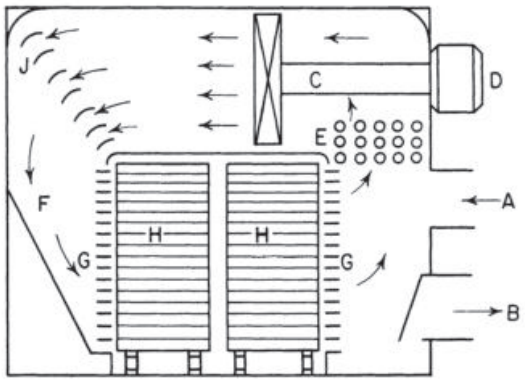

**FIG. 12-48** Double-truck tray dryer. (*A*) Air inlet duct. (*B*) Air exhaust duct with damper. (*C*) Adjustable-pitch fan, 1 to 15 hp. (*D*) Fan motor. (*E*) Fin heaters. (*F*) Plenum chamber. (*G*) Adjustable air blast nozzles. (*H*) Trucks and trays.

*instead of across it.* The pressure drop through the bed of material can be estimated using the Ergun equation [Ergun, S., "Fluid Flow through Packed Columns," *Chem. Eng. Progress* **48** (1952)] and does not usually exceed about 2 cm of water. In the second type, deep perforated-bottom trays are placed on top of plenum chambers in a closed-circuit hot air circulating system. In some food-drying plants, the material is placed in finishing bins with perforated bottoms; heated air passes up through the material and is removed from the top of the bin, reheated, and recirculated. The latter types involve a pressure drop through the bed of material of 1 to 8 cm of water at relatively low air rates. Table 12-13 gives performance data on three applications of batch through-circulation dryers. Batch through-circulation dryers are restricted in application to granular materials (particle size typically 1 mm or greater) that permit free flow-through circulation of air. Drying times are usually much shorter than in parallel-flow tray dryers. Design methods are included in the subsection Continuous Through-Circulation Dryers.

***Vacuum-Shelf Dryers*** Vacuum-shelf dryers are indirectly heated batch dryers consisting of a vacuum-tight chamber usually constructed of cast iron or steel plate; heated, supporting shelves within the chamber; a vacuum source; and usually a condenser. One or two doors are provided, depending on the size of the chamber. The doors are sealed with resilient gaskets of rubber or similar material.

Hollow shelves of flat steel plate are fastened permanently inside the vacuum chamber and are connected in parallel to inlet and outlet headers. The heating medium, entering through one header and passing through the hollow shelves to the exit header, is generally steam, ranging in pressure from 700 kPa gauge to subatmospheric pressure for low-temperature operations. Low temperatures can be provided by circulating hot water, and high temperatures can be obtained by circulating hot oil or other heat-transfer liquids. Some small dryers employ electrically heated shelves. The material to be dried is placed in pans or trays on the heated shelves. The trays are generally of metal to ensure good heat transfer between the shelf and the tray.

Vacuum-shelf dryers may vary in size from 1 to 24 shelves, the largest chambers having overall dimensions of 6 m wide, 3 m long, and 2.5 m high.

**TABLE 12-13 Performance Data for Batch Through-Circulation Dryers***

Vacuum is applied to the chamber, and vapor is removed through a large pipe which is connected to the chamber in such a manner that if the vacuum is broken suddenly, the in-rushing air will not greatly disturb the bed of material being dried. This line leads to a condenser where moisture or solvent that has been vaporized is condensed. The noncondensible exhaust gas goes to the vacuum source, which may be a wet or dry vacuum pump or a steam-jet ejector.

Vacuum-shelf dryers are used extensively for drying pharmaceuticals, temperature-sensitive or easily oxidizable materials, and materials so valuable that labor cost is insignificant. They are particularly useful for handling small batches of materials wet with toxic or valuable solvents. Recovery of the solvent is easily accomplished without danger of passing through an explosive range. Dusty materials may be dried with negligible dust loss. Hygroscopic materials may be completely dried at temperatures below that required in atmospheric dryers. The equipment is employed also for freeze-drying processes, for metallizing-furnace operations, and for the manufacture of semiconductor parts in controlled atmospheres. All these latter processes demand much lower operating pressures than do ordinary drying operations.

*Design methods for vacuum-shelf dryers* Heat is transferred to the wet material by conduction through the shelf and bottom of the tray and by radiation from the shelf above. The critical moisture content will not be necessarily the same as for atmospheric tray drying, as the heat-transfer mechanisms are different.

During the constant-rate period, moisture is rapidly removed. Often 50 percent of the moisture will evaporate in the first hour of a 6- to 8-h cycle. The drying time has been found to be proportional to between the first and second powers of the depth of loading. Vacuum-shelf dryers operate in the range of 1 to 25 mmHg pressure. For size-estimating purposes, a heat-transfer coefficient of 20 J/(m$^2$ · s · K) may be used. The area employed in this case should be the shelf area in direct contact with the trays. For the same

reason, the shelves should be kept free from scale and rust. Air vents should be installed on steam-heated shelves to vent noncondensible gases. The heating medium should not be applied to the shelves until after the air has been evacuated from the chamber, to reduce the possibility of the material's overheating or boiling at the start of drying. Case hardening ( formation of hard external layer) can sometimes be avoided by retarding the rate of drying in the early part of the cycle.

Some performance data for vacuum-shelf dryers are given in Table 12-14.

The thermal efficiency of a vacuum-shelf dryer is usually on the order of 60 to 80 percent. Table 12-15 gives operating data for one organic and two inorganic compounds.

**Continuous Tray and Gravity Dryers**

***Examples and Synonyms*** Turbo-tray dryer, plate dryer, moving-bed dryer, gravity dryer.

***Description*** Continuous tray dryers are equivalent to batch tray dryers, but with the solids moving between trays by a combination of mechanical movement and gravity. Gravity (moving-bed) dryers are normally through-circulation convective dryers with no internal trays where the solids gradually descend by gravity. In all these types, the net movement of solids is vertically downward.

***Turbo-Tray Dryers*** The turbo-tray dryer (also known as rotating tray, rotating shelf, or Wyssmont Turbo-Dryer) is a continuous dryer consisting of a stack of rotating annular shelves in the center of which turbo-type fans revolve to circulate the air over the shelves. Wet material enters through the roof, falling onto the top shelf as it rotates beneath the feed opening. After completing one rotation, the material is wiped by a stationary wiper through radial slots onto the shelf below, where it is spread into a uniform pile by a stationary leveler. The action is repeated on each shelf, with transfers occurring once in each revolution. From the last shelf, material is discharged through the bottom of the dryer (Fig. 12-49).

The rate at which each fan circulates air can be varied by changing the pitch of the fan blades. In final drying stages, in which diffusion controls or the product is light and powdery, the circulation rate is considerably lower than in the initial stage, in which high evaporation rates prevail. In the majority of applications, air flows through the dryer upward in counterflow to the material. In special cases, required drying conditions dictate that airflow be cocurrent or both countercurrent and cocurrent with the exhaust leaving at some level between solids inlet and discharge. A separate cold-air-supply fan is provided if the product is to be cooled before being discharged.

By virtue of its vertical construction, the turbo-type tray dryer has a stack effect, the resulting draft being frequently sufficient to operate the dryer with natural draft. Pressure at all points within the dryer is maintained close to atmospheric. Most of the roof area is used as a breeching, lowering the exhaust velocity to settle dust back into the dryer.

Heaters can be located in the space between the trays and the dryer housing, where they are not in direct contact with the product, and thermal efficiencies up to 3500 kJ/kg (1500 Btu/lb) of water evaporated can be obtained by reheating the air within the dryer. For materials which have a tendency to foul internal heating surfaces, an external heating system is employed.

The turbo-tray dryer can handle materials from thick slurries [1 million $N \cdot s/m^2$ (100,000 cP) and over] to fine powders. Filter-press cakes are granulated before feeding. Thixotropic materials are fed directly from a rotary filter by scoring the cake as it leaves the drum. Pastes can be extruded onto the top shelf and subjected to a hot blast of air to make them firm and free-flowing after one rotation.

The turbo-tray dryer is manufactured in sizes from package units 2 m in height and 1.5 m in diameter to large outdoor installations 20 m in height and 11 m in diameter. Tray areas range from 1 $m^2$ up to about 2000 $m^2$. The number of shelves in a tray rotor varies according to space available and the minimum rate of transfer required, from as few as 12 shelves to as many as 58 in the largest units. Standard construction permits operating temperatures up to 615 K, and high-temperature heaters permit operation at temperatures up to 925 K.

**TABLE 12-15 Performance Data for Vacuum-Shelf Dryers**

| Material | Sulfur black | Calcium carbonate | Calcium phosphate |
|---|---|---|---|
| Loading, kg dry material/$m^2$ | 25 | 17 | 33 |

| Evaporation rate, $kg/(s \cdot m^2)$ | $8.9 \times 10^{-4}$ | $7.9 \times 10^{-4}$ | $6.6 \times 10^{-4}$ |

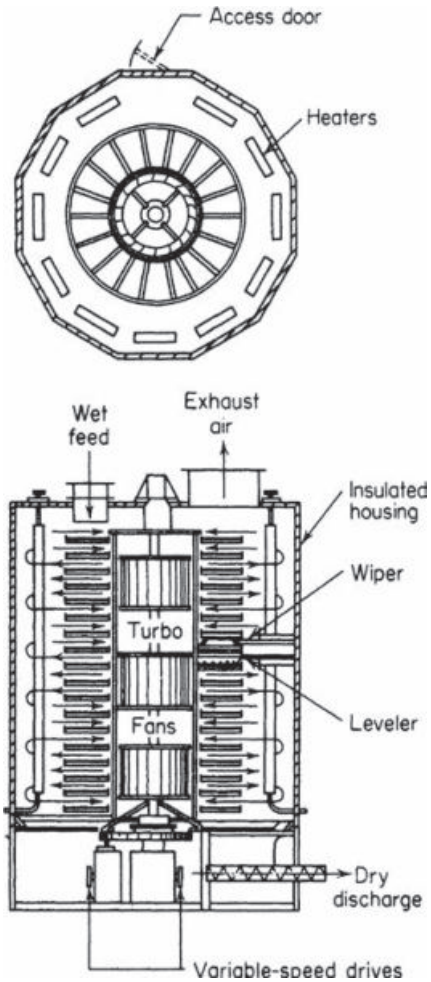

**FIG. 12-49** Turbo-Dryer. (*Wyssmont Company, Inc.*)

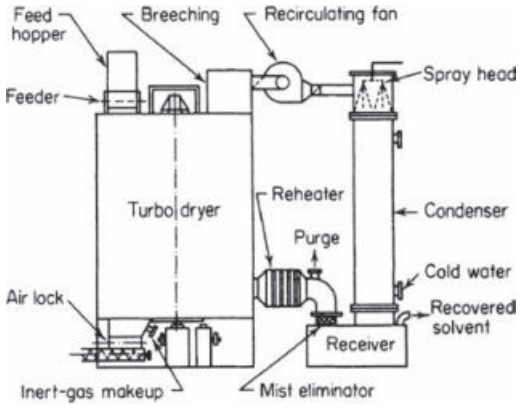

**FIG. 12-50** Turbo-Dryer in closed circuit for continuous drying with solvent recovery. (*Wyssmont Company, Inc.*)

*Design methods for turbo-tray dryers* The heat- and mass-transfer mechanisms are similar to those in batch tray dryers, except that constant turning over and mixing of the solids significantly improve drying rates. Design usually must be based on previous installations or pilot tests by the manufacturer; apparent heat-transfer coefficients are typically 30 to 60 J/(m$^2$·s·K) for dry solids and 60 to 120 J/(m$^2$·s·K) for wet solids. Turbo-tray dryers have been employed successfully for the drying and cooling of calcium hypochlorite, urea crystals, calcium chloride flakes, and sodium chloride crystals. The Wyssmont "closed-circuit" system, as shown in Fig. 12-50, consists of the turbo-tray dryer with or without internal heaters, recirculation fan, condenser with receiver and mist eliminators, and reheater. Feed and discharge are through a sealed wet feeder and lock, respectively. This method is used for continuous drying without leakage of fumes, vapors, or dust to the atmosphere. A unified approach for scaling up dryers, such as turbo-tray, plate, conveyor, or any other dryer type that forms a defined layer of solids next to a heating source, is the SDR method described by Moyers [*Drying Technol.* **12**(1 & 2): 393–417 (1994)].

*Performance and cost data for turbo-tray dryers* Performance data for four applications of closed-circuit drying are included in Table 12-16. Operating, labor, and maintenance costs compare favorably with those of direct heat rotating equipment.

***Plate Dryers*** The plate dryer is an *indirectly heated,* fully continuous dryer available for three modes of operation: atmospheric, gastight, or full vacuum. The dryer is of vertical design, with horizontal, heated plates mounted inside the housing. The plates are heated by hot water, steam, or thermal oil, with operating temperatures up to 320°C possible. The product enters at the top and is conveyed through the dryer by a product transport system consisting of a central-rotating shaft with arms and plows. (See dryer schematic, Fig. 12-51.) The thin product layer [approximately 12- mm (0.5-in) depth] on the surface of the plates, coupled with frequent product turnover by the conveying system, results in short retention times

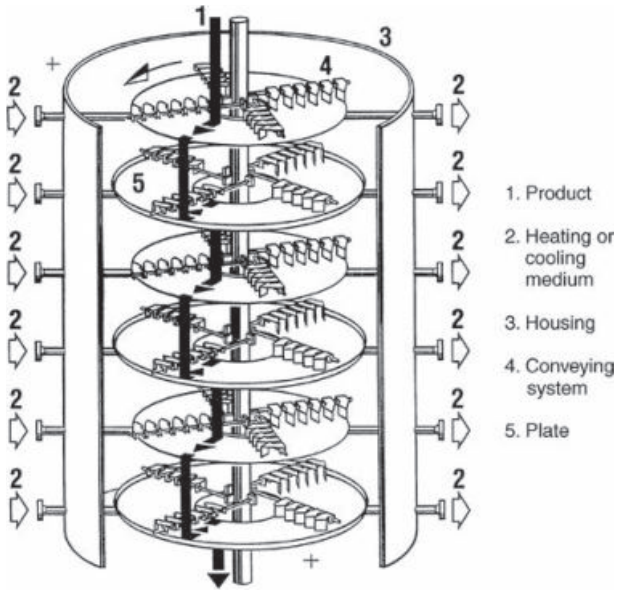

**FIG. 12-51** Indirect heat continuous plate dryer for atmospheric, gastight, or full-vacuum operation. (*Krauss Maffei.*)

(approximately 5 to 40 min), true plug flow of the material, and uniform drying. The vapors are removed from the dryer by a small amount of heated purge gas or by vacuum. The material of construction of the plates and housing is normally stainless steel, with special metallurgies also available. The drive unit is located at the bottom of the dryer and supports the central-rotating shaft. Typical speed of the dryer is 1 to 7 rpm.

The plate dryer may vary in size from 5 to 35 vertically stacked plates with a heat-exchange area between 3.8 and 175 m$^2$. Depending upon the loose-bulk density of the material and the overall retention time, the plate dryer can process up to 5000 kg/h of wet product.

The plate dryer is limited in its scope of applications only in the consistency of the feed material (the products must be friable, be free-flowing, and not undergo phase changes) and drying temperatures up to 320°C. Applications include specialty chemicals, pharmaceuticals, foods, polymers, pigments, etc. Initial moisture or volatile level can be as high as 65 percent, and the unit is often used as a final dryer to take materials to a bone-dry state, if necessary. The plate dryer can also be used for heat treatment, removal of waters of hydration (bound moisture), solvent removal, and a product cooler.

The atmospheric plate dryer is a dust-tight system. The dryer housing is an octagonal, panel construction, with operating pressure in the range of ±0.5 kPa gauge. An exhaust air fan draws the purge air through the housing for removal of the vapors from the drying process. The purge air velocity through the dryer is in the range of 0.1 to 0.15 m/s, resulting in minimal

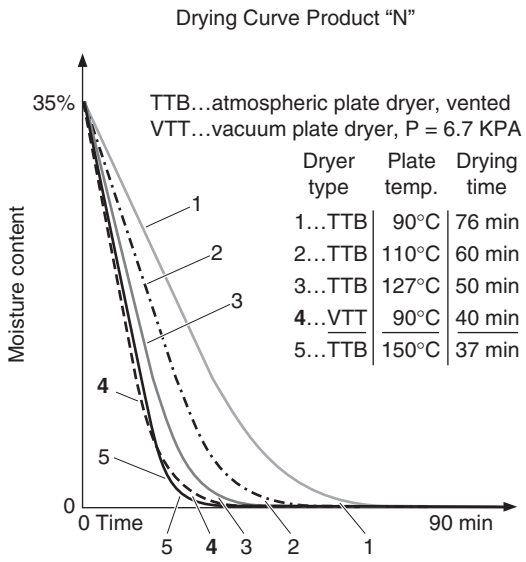

**FIG. 12-52** Plate dryer drying curves demonstrating impact of elevated temperature and/or operation under vacuum. (*Krauss Maffei.*)

dusting and small dust filters for the exhaust air. The air temperature is normally equal to the plate temperature. The gastight plate dryer, together with the components of the gas recirculation system, forms a closed system. The dryer housing is semicylindrical and is rated for a nominal pressure of 5 kPa gauge. The flow rate of the recirculating purge gas must be sufficient to absorb the vapors generated from the drying process. The gas temperature must be adjusted according to the specific product characteristics and the type of volatile. After condensation of the volatiles, the purge gas (typically nitrogen) is recirculated back to the dryer via a blower and heat exchanger. Solvents such as methanol, toluene, and acetone are normally evaporated and recovered in the gastight system.

The vacuum plate dryer is provided as part of a closed system. The vacuum dryer has a cylindrical housing and is rated for full-vacuum operation (typical pressure range of 3 to 27 kPa absolute). The exhaust vapor is evacuated by a vacuum pump and is passed through a condenser for solvent recovery. There is no purge gas system required for operation under vacuum. Of special note in the vacuum-drying system are the vacuum feed and discharge locks, which allow for continuous operation of the plate dryer under full vacuum.

***Comparison Data—Plate Dryers*** Comparative studies have been done on products under both atmospheric and vacuum drying conditions. See Fig. 12-52. These curves demonstrate (1) the improvement in drying achieved with elevated temperature and (2) the impact to the drying process obtained with vacuum operation. Note that curve 4 at 90°C, pressure at 6.7 kPa absolute, is comparable to the atmospheric curve at 150°C. Also the comparative atmospheric curve at 90°C requires 90 percent more drying time than the vacuum condition. The dramatic improvement with the use of vacuum is important to note for heat-sensitive materials.

The above drying curves have been generated via testing on a plate dryer simulator. The test unit duplicates the physical setup of the production dryer; therefore, linear scale-up from the test data can be made to the full-scale dryer. Because of the thin product layer on each plate, drying in the unit closely follows the normal type of drying curve in which the constant-rate period (steady evolution of moisture or volatiles) is followed by the falling-rate period of the drying process. This results in higher heat-transfer coefficients and specific drying capacities on the upper plates of the dryer compared to the lower plates. The average specific drying capacity for the plate dryer is in the range of 2 to 20 kg/($m^2 \cdot h$) (based on final dry product). Performance data for typical applications are shown in Table 12-17.

***Gravity or Moving-Bed Dryers*** A body of solids in which the particles, consisting of granules, pellets, beads, or briquettes, flow downward by gravity at substantially their normal settled bulk density through a vessel in contact with gases is defined frequently as a *moving-bed* or *tower dryer.* Moving-bed equipment is frequently used for grain drying and plastic pellet drying, and it also finds application in blast furnaces, shaft furnaces, and petroleum refining. Gravity beds are also employed for the cooling and drying of extruded pellets and briquettes from size enlargement processes.

A gravity dryer consists of a stationary vertical, usually cylindrical housing with openings for the introduction of solids (at the top) and removal of solids (at the bottom), as shown schematically in Fig. 12-53. Gas flow is through the solids bed and may be cocurrent or countercurrent and, in some instances, cross-flow. By definition, the rate of gas flow upward must be less than that required for fluidization.

***Fields of Application*** One of the major advantages of the gravity-bed technique is that it lends itself well to true intimate countercurrent contacting of solids and gases. This provides for efficient heat transfer and mass transfer. Gravity-bed contacting also permits the use of the solid as a heat-transfer medium, as in pebble heaters.

Gravity vessels are applicable to coarse granular free-flowing solids which are comparatively dust-free. The solids must possess physical properties in size and surface characteristics so that they will not stick together, bridge, or segregate during passage through the vessel. The presence of significant quantities of fines or dust will close the passages among the larger particles through which the gas must penetrate, increasing pressure drop. Fines may also segregate near the sides of the bed or in other areas where gas velocities are low, ultimately completely sealing off these portions of the vessel. The high efficiency of gas-solids contacting in gravity beds is due to the uniform distribution of gas throughout the solids bed; hence choice of feed and its preparation are important factors to successful operation. Preforming techniques such as pelleting and briquetting are employed frequently for the preparation of suitable feed materials.

Gravity vessels are suitable for low-, medium-, and high-temperature operation; in the last case, the housing will be lined completely with refractory brick. Dust recovery equipment is minimized in this type of operation

**TABLE 12-17 Plate Dryer Performance for Three Applications***

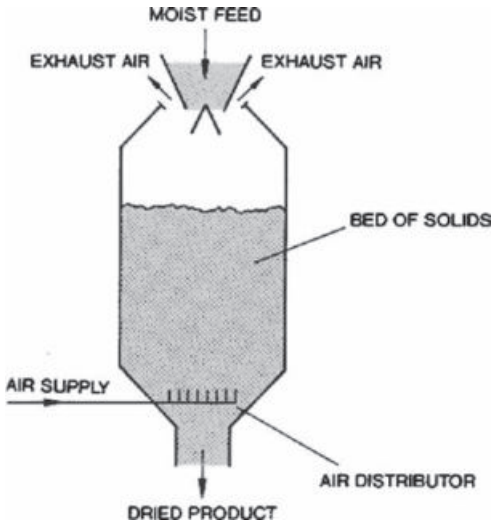

**FIG. 12-53** Moving-bed gravity dryer.

since the bed actually performs as a dust collector itself, and dust in the bed will not, in a successful application, exist in large quantities.

Other advantages of gravity beds include flexibility in gas and solids flow rates and capacities, variable retention times from minutes to several hours, space economy, ease of start-up and shutdown, the potentially large number of contacting stages, and ease of control by using the inlet and exit gas temperatures.

Maintenance of a uniform rate of solids movement downward over the entire cross-section of the bed is one of the most critical operating problems encountered. For this reason, gravity beds are designed to be as high and narrow as practical. In a vessel of large cross-section, discharge through a conical bottom and center outlet will usually result in some degree of "ratholing" through the center of the bed. Flow through the center will be rapid while essentially stagnant pockets are left around the sides. To overcome this problem, multiple outlets may be provided in the center and around the periphery; table unloaders, rotating plows, wide moving grates, and multiple-screw unloaders are employed; insertion of inverted cone baffles in the lower section of the bed, spaced so that flushing at the center is retarded, is also a successful method for improving uniformity of solids movement.

**Continuous Band and Tunnel Dryers**

***Examples and Synonyms*** Ceramic tunnel kilns, moving truck dryers, trolleys, atmospheric belt/band dryers, vibrating bed dryers, vacuum belt dryers, vibrating tray dryers, conveyor dryers, continuous-tunnel, belt-conveyor, or screen-conveyor (band) dryers.

***Description*** Continuous-tunnel dryers are batch truck or tray compartments, operated in series. The solids to be processed are placed in trays or on trucks which move progressively through the tunnel in contact with hot gases. In high-temperature operations, radiation from walls and refractory lining may be significant also. Operation is semicontinuous; when the tunnel is filled, one truck is removed from the discharge end as each new truck is fed into the inlet end.

Applications of tunnel equipment are essentially the same as those for batch tray and compartment units previously described, namely, practically all forms of particulate solids and large solid objects. Auxiliary equipment and the special design considerations discussed for batch trays and compartments apply also to tunnel equipment. For size-estimating purposes, tray and truck tunnels and furnaces can be treated in the same manner as discussed for batch equipment.

*Belt-conveyor* and *screen-conveyor (band) dryers* are truly continuous in operation, carrying a layer of solids on an endless conveyor.

Conveyor dryers are more suitable than (multiple) batch compartments for large-quantity production, usually giving investment and installation savings. Belt and screen conveyors which are truly continuous represent major labor savings over batch operations, but require additional investment for automatic feeding and unloading devices.

Airflow can be totally cocurrent, countercurrent, or a combination of both. In addition, cross-flow designs are employed frequently, with the heating air flowing back and forth across the belts in series. Reheat coils may be installed after each cross-flow pass to maintain constant-temperature operation; large propeller-type circulating fans are installed at each stage,

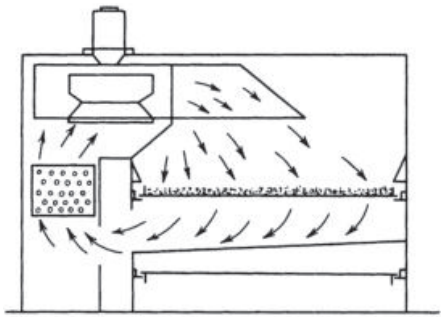

**FIG. 12-54** Section view of a continuous through-circulation conveyor dryer. (*Proctor & Schwartz, Inc.*)

and air may be introduced or exhausted at any desirable points. Conveyor dryers possess the maximum flexibility for any combination of airflow and temperature staging. Contact drying is also possible, usually under vacuum, with the bands resting on heating plates (vacuum band dryer).

*Ceramic tunnel kilns* handling large irregular-shaped objects must be equipped for precise control of temperature and humidity conditions to prevent cracking and condensation on the product. The internal mechanisms that cause cracking when drying clay and ceramics have been studied extensively. Information on ceramic tunnel kiln operation and design is reported fully in publications such as *The American Ceramic Society Bulletin, Ceramic Industry,* and *Transactions of the British Ceramic Society.*

***Continuous Through-Circulation Band Dryers*** Continuous through-circulation dryers operate on the principle of blowing hot air through a permeable bed of wet material passing continuously through the dryer. Drying rates are high because of the large area of contact and short distance of travel for the internal moisture.

The most widely used type is the horizontal conveyor dryer (also called *perforated band* or *conveying-screen* dryer), in which wet material is conveyed as a layer 2 to 15 cm deep (sometimes up to 1 m), on a horizontal mesh screen, belt, or perforated apron, while heated air is blown either upward or downward through the bed of material. This dryer consists usually of a number of individual sections, complete with fan and heating coils, arranged in series to form a housing or tunnel through which the conveying screen travels. As shown in the sectional view in Fig. 12-54, the air circulates through the wet material and is reheated before reentering the bed. It is not uncommon to circulate the hot gas upward in the wet end and downward in the dry end, as shown in Fig. 12-55. A portion of the air is exhausted continuously by one or more exhaust fans, not shown in the sketch, which handle air from several sections. Since each section can be operated independently, extremely flexible operation is possible, with high temperatures usually at the wet end, followed by lower temperatures; in some cases, a unit with cooled or specially humidified air is employed for final conditioning. The maximum pressure drop that can be taken through the bed of solids without developing leaks or air bypassing is roughly 50 mm of water.

***Example 12-15 Mass and Energy Balance on a Dryer with Partially Recycled Air*** A continuous through-air dryer is producing 648 kg/h of a coarse granular product, as illustrated in Fig. 12-56. The material enters the dryer at 40 percent moisture and exits at 10 percent moisture, on wet basis. The airflow rate is 4750 kg/h, and the ambient temperature and absolute humidity are 22°C and 0.01 kg/kg, respectively. Measurements are being taken on the system to assess performance. To check the measurements against expected values, calculate the relative humidity and dew point of the exhaust air if 85 percent of the mass flow of air exiting the dryer is recycled. Neglect heat losses and sensible heating of the solids. Use the following physical properties:

$$\Delta H_{vap} = 2257 \text{ kJ/kg}; C_{p,air} = 1.0 \text{ J/(g·K)}; C_{p,water\ vapor} = 1.9 \text{ J/(g·K)}$$

We start by calculating the dry solids flow rate into the process, which equals 648(1 – 0.4) = 389 kg/h. The dry-basis moisture content of the feed and product are then calculated to be $X_{product} = 0.111$ g water/g dry material and $X_{feed} = 0.667$ g water/g dry material. The relationship from the Solids Drying Fundamentals subsection was used: $X = w/(1 - w)$, where $X$ is the dry-basis moisture content and $w$ is the wet-basis moisture content.

The drying rate of the system equals the dry mass flow rate times the difference in the dry-basis moisture contents:

$$\text{Drying rate} = \dot{m}_{dry}(X_{feed} - X_{product}) = 216 \text{ kg/h}$$

Now a series of steady-state mass balance equations can be written. Dry airflow rates (kg/h) are denoted by $a$, and water vapor flow rates (kg/h) are denoted by $w$. Subscripts refer to streams.

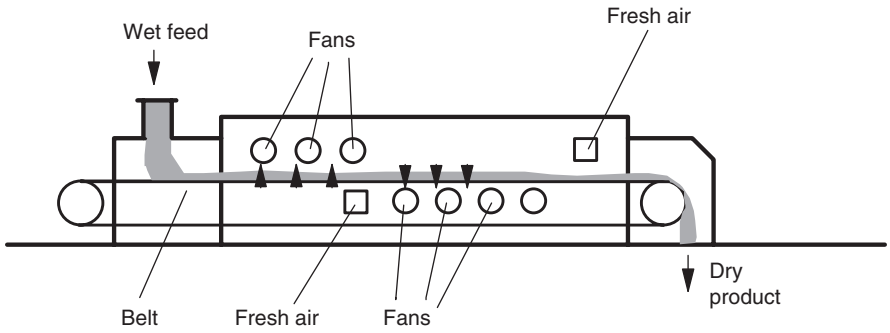

**FIG. 12-55** Longitudinal view of a continuous through-circulation conveyor dryer with intermediate airflow reversal.

Air mass balances:

$$a_4 = a_5 = a_6 \quad a_4 = a_1 + a_2 \quad a_5 = a_2 + a_3 \quad \frac{a_2}{a_5} = \text{recycle ratio}$$

Water vapor mass balances:

$$w_5 = w_4 + \text{drying rate} \quad w_4 = w_1 + w_2 \quad w_5 = w_2 + w_3 \quad w_4 = w_6 \quad \frac{w_2}{w_5} = \text{recycle ratio}$$

Energy balances:

$$a_4 Cp_4 (T_4 - T_5) = \dot{m} \cdot \Delta H_{vap} \quad a_4 Cp_4 (T_4 - T_6) = a_6 Cp_6 T_6 = a_1 Cp_1 T_1 + a_2 Cp_2 T_2$$
$$T_2 = T_3 = T_5$$

The equations above can be solved on a spreadsheet iteratively. The results of the calculation are shown in Table 12-18.

This type of calculation is very helpful to understanding performance of an industrial dryer. Once it is set up, different scenarios can be explored, such as changing the recycle rate. However, it is important to note that changing the conditions in the system can also affect the drying rate. For example, an increase of the recycle rate would increase the air velocity but also increase the humidity in the dryer. Using a drying kinetics model, such as the "characteristic curve" method (if that model is appropriate for the material), along with this model can help to optimize the system.

Through-circulation drying requires that the wet material be in a state of granular or pelleted subdivision so that hot air may be readily blown through it. Many materials meet this requirement without special preparation. Others require special and often elaborate pretreatment to render them suitable for through-circulation drying. The process of converting a wet solid to a form suitable for through-circulation of air is called *preforming*, and often the success or failure of this contacting method depends on the preforming step. Fibrous, flaky, and coarse granular materials are usually amenable to drying without preforming. They can be loaded directly onto the conveying screen by suitable spreading feeders of the oscillating-belt or vibrating type or by spiked drums or belts feeding from bins. When materials must be preformed, several methods are available, depending on the physical state of the wet solid.

1. Relatively dry materials such as centrifuge cakes can sometimes be granulated to give a suitably porous bed on the conveying screen.
2. Pasty materials can often be preformed by extrusion to form spaghetti-like pieces, about 6 mm in diameter and several centimeters long.
3. Wet pastes that cannot be granulated or extruded may be predried and preformed on a steam-heated finned drum. Preforming on a finned drum may be desirable also in that some predrying is accomplished.
4. Thixotropic filter cakes from rotary vacuum filters that cannot be preformed by any of the above methods can often be scored by knives on the filter, the scored cake discharging in pieces suitable for through-circulation drying.
5. Material that shrinks markedly during drying is often reloaded during the drying cycle to 2 to 6 times the original loading depth. This is usually done after a degree of shrinkage which, by opening the bed, has destroyed the effectiveness of contact between the air and solids.
6. In a few cases, powders have been pelleted or formed in briquettes to eliminate dustiness and permit drying by through-circulation. Table 12-19 gives a list of materials classified by preforming methods suitable for through-circulation drying.

Steam-heated air is the usual heat-transfer medium employed in these dryers, although combustion gases may also be used. Temperatures above 600 K are not usually feasible because of the problems of lubricating the conveyor, chain, and roller drives. Recirculation of air is in the range of 60 to 90 percent of the flow through the bed. Conveyors may be made of wire-mesh screen or perforated-steel plate. The minimum practical screen opening size is about 30-mesh (0.5 mm). Multiple bands in series may be used.

Vacuum band dryers utilize heating by conduction and are a continuous equivalent of vacuum tray (shelf) dryers, with the moving bands resting on heating plates. Drying is usually relatively slow, and it is common to find several bands stacked above one another, with material falling to the next band and flowing in opposite directions on each pass, to reduce dryer length and give some product turnover.

***Design Methods for Continuous Band Dryers*** A scoping calculation is a good starting point for designing a new system or for understanding an existing system. The required solids throughput $F$ and the inlet and outlet moisture content $X_I$ and $X_O$ are known, as is the ambient humidity $Y_I$. If the inlet gas temperature $T_{GI}$ is chosen, the outlet gas conditions (temperature $T_{GO}$ and humidity $Y_O$) can be found, either by calculation or (more simply and quickly) by using the constant-enthalpy lines on a psychrometric chart.

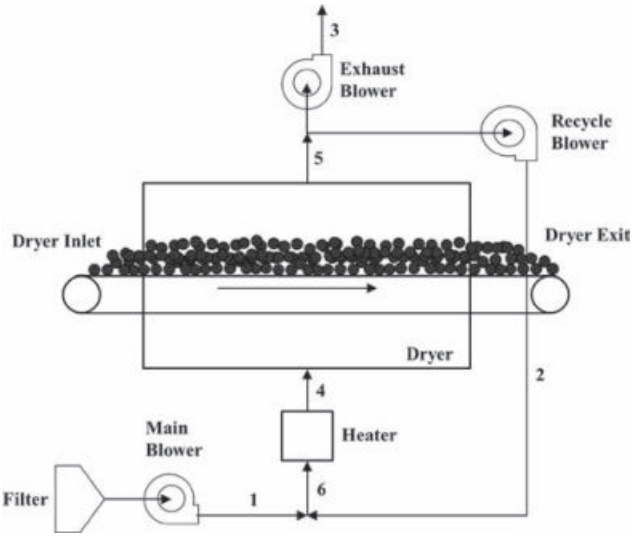

**FIG. 12-56** Drying of a course granular material with partially recycled air.

| Cotton linters | | | | | | |
| Rayon staple | | | | | | |

However, it may be necessary to allow for heat losses and sensible heating of solids, which typically reduce the useful enthalpy of the inlet gas by 10 to 20 percent. Also, if tightly bound moisture is being removed, the heat of wetting to break the bonds should be allowed for. The gas mass flow rate $G$ can now be calculated, as it is the only unknown in the mass balance on the solvent [Eq. (12-69)]. For through-circulation and dispersion dryers, the cross-sectional area $A$ is given by

$$A = \frac{G}{\rho_{GI} U_G} = \frac{F(X_I - X_O)}{\rho_{GI} U_G (Y_O - X_I)} \tag{12-69}$$

The linear dimensions of a rectangular bed can then be calculated. The result is usually accurate to within 10 percent, and it can be further improved by better estimates of velocity and heat losses.

The method gives no information about solids residence time or dryer length. A minimum drying time $t_{\min}$ can be calculated by evaluating the maximum (unhindered) drying rate $N_{cr}$, assuming gas-phase heat-transfer control and estimating a gas-to-solids heat-transfer coefficient. The simple Eq. (12-70) then applies:

$$t_{\min} = \frac{X_I - X_O}{N_{cr}} \tag{12-70}$$

Alternatively, it may be assumed that first-order falling-rate kinetics apply throughout the drying process, and one can scale the estimated drying time by using Eq. (12-70).

To correct from a calculated constant-rate (unhindered) drying time $t_{CR}$ to first-order falling-rate kinetics, the following equation is used, where $X_1$ is the initial, $X_2$ the final, and $X_E$ the equilibrium moisture content (all must be dry-basis):

$$\frac{t_{FR}}{t_{CR}} = \frac{X_1 - X_E}{X_1 - X_2} \ln\left(\frac{X_1 - X_E}{X_2 - X_E}\right) \tag{12-71}$$

However, these crude methods can give serious underestimates of the required drying time, and it is much better to measure the drying time experimentally and apply scaling methods. Example 12-16 applies this method to a batch rotary dryer.

A more detailed mathematical method of a through-circulation dryer has been developed by Thygeson [*Am. Inst. Chem. Eng. J.* **16**(5): 749 (1970)]. Rigorous modeling is possible with a two-dimensional incremental model, with steps both horizontally along the belt and vertically through the layer; nonuniformity of the layer across the belt could also be allowed for, if desired. Heat-transfer coefficients are typically in the range of 100 to 200 W/(m$^2$·K), and the relationship $h_c = 12(\rho_g U_g / d_p)^{0.5}$ may be used for a first estimate, where $\rho_g$ is gas density (kg/m$^3$); $U_g$, local gas velocity (m/s); and $d_p$, particle diameter (m). For 5-mm particles and air at 1 m/s, 80°C, and 1 kg/m$^3$ [mass flux 1 kg/(m$^2$·s)] this gives $h_c = 170$ W/(m$^2$·K).

In actual practice, design of a continuous through-circulation dryer is best based upon data taken in pilot-plant tests. Loading and distribution of solids on the screen are rarely as nearly uniform in commercial installations as in test dryers; 50 to 100 percent may be added to the test drying time for commercial design.

***Performance and Cost Data for Continuous Band and Tunnel Dryers*** Experimental performance data are given in Table 12-20 for numerous common materials. Performance data from several commercial through-circulation conveyor dryers are given in Table 12-21. Labor requirements vary depending on the time required for feed adjustments, inspection, etc. These dryers may consume as little as 1.1 kg of steam/kg of water evaporated, but 1.4 to 2 is a more common range. Thermal efficiency is a function of final moisture required and percent air recirculation.

Conveying-screen dryers are fabricated with conveyor widths from 0.3- to 4.4-m sections 1.6 to 2.5 m long. Each section consists of a sheet-metal enclosure, insulated sidewalls and roof, heating coils, a circulating fan, inlet air distributor baffles, a fines catch pan under the conveyor, and a conveyor screen (Fig. 12-54). Cabinet and auxiliary equipment fabrication is of aluminized steel or stainless-steel materials. Prices do not include temperature controllers, motor starters, preform equipment, or auxiliary feed and discharge conveyors.

Table 12-22 gives approximate purchase costs for equipment with type 304 stainless-steel hinged conveyor screens and includes steam-coil heaters, fans, motors, and a variable-speed conveyor drive. Cabinet and auxiliary equipment fabrication is of aluminized steel or stainless-steel materials. Prices do not include temperature controllers, motor starters, preform equipment, or auxiliary feed and discharge conveyors. These may add $75,000 to $160,000 to the dryer purchase cost (2005 costs).

**Batch Agitated and Rotating Dryers**

***Examples and Synonyms*** Pan dryers, spherical and conical dryers, side-screw, Nauta, turbosphere, batch paddle, ploughshare.

***Description*** An *agitated dryer* is defined as one on which the housing enclosing the process is stationary while solids movement is accomplished by an internal mechanical agitator. A rotary dryer is one in which the outer housing rotates. Many forms are in use, including batch and continuous versions. The batch forms are almost invariably heated by conduction with operation under vacuum. Vacuum is used in conjunction with drying or other chemical operations when low solids temperatures must be maintained because heat will cause damage to the product or change its nature; when air combines with the product as it is heated, causing oxidation or an explosive condition; when solvent recovery is required; and when materials must be dried to extremely low moisture levels. Vertical agitated pan, spherical, and conical dryers are mechanically agitated; tumbler or double-cone dryers have a rotating shell. All these types are typically used for the drying of solvent or water-wet, free-flowing powders in small batch sizes of 1000 L or less, as frequently found in the pharmaceutical, specialty chemical, and fine chemicals industries. Corrosion resistance and cleanability are often important, and common materials of construction include SS 304 and 316 as well as Hastelloy. The batch nature of operation is of value in the pharmaceutical industry to maintain batch identification. In addition to pharmaceutical materials, the conical mixer dryer is used to dry polymers, additives, inorganic salts, and many other specialty chemicals. As the size increases, the ratio of jacket heat-transfer surface area to volume falls, extending drying times. For larger batches, horizontal agitated pan dryers are more common, but there is substantial overlap of operating ranges. Drying times may be reduced for all types by heating the internal agitator, but this increases complexity and cost.

*Mechanical versus rotary agitation* Agitated dryers are applicable to processing solids that are relatively free-flowing and granular when discharged as product. Materials that are not free-flowing in their feed condition can be treated by recycle methods as described in the subsection Continuous Rotary Dryers. In general, agitated dryers have applications similar to those of rotating vessels. Their chief advantages compared with the latter are twofold: (1) Large-diameter rotary seals are not required at the solids and gas feed and exit points because the housing is stationary, and for this reason gas leakage problems are minimized. Rotary seals are required only at the points of entrance of the mechanical agitator shaft. (2) Use of a mechanical agitator for solids mixing introduces shear forces which are helpful for breaking up lumps and agglomerates. Balling and pelleting of sticky solids, an occasional occurrence in rotating vessels, can be prevented by special agitator design. The problems concerning dusting of fine particles in direct-heat units are identical to those discussed in subsection Continuous Rotary Dryers.

***Heated Agitators*** For all agitated dryers, in addition to the jacket heated area, heating the agitator with the same medium as the jacket (hot water,

steam, or thermal oil) will increase the heat-exchange area. This is usually accomplished via rotary joints. Obviously, heating the screw or agitator will mean shorter batch drying times, which yields higher productivity and better product quality owing to shorter exposure to the drying temperature, but capital and maintenance costs will be increased. In pan and conical dryers, the area is increased only modestly, by 15 to 30 percent; but in horizontal pan and paddle dryers, the opportunity is much greater and indeed the majority of the heat may be supplied through the agitator.

Also the mechanical power input of the agitator can be a significant additional heat source, and microwave assistance has also been used in filter dryers and conical dryers to shorten drying times (and is feasible in other types).

*Vacuum processing* All these types of dryer usually operate under vacuum, especially when drying heat-sensitive materials or when removing flammable organic solvents rather than water. The heating medium is hot water, steam, or thermal oil, with most applications in the temperature range of 50 to 150°C and pressures in the range of 3 to 30 kPa absolute. The vapors generated during the drying process are evacuated by a vacuum pump and passed through a condenser for recovery of the solvent. A dust filter is normally mounted over the vapor discharge line as it leaves the dryer, thus allowing any entrapped dust to be pulsed back into the process area. Standard cloth-type dust filters are available, along with sintered metal filters.

In vacuum processing and drying, a major objective is to create a large temperature-driving force between the jacket and the product. To accomplish this purpose at fairly low jacket temperatures, it is necessary to reduce the internal process pressure so that the liquid being removed will boil at a lower vapor pressure. It is not always economical, however, to reduce the internal pressure to extremely low levels because of the large vapor volumes thereby created. It is necessary to compromise on operating pressure, considering leakage, condensation problems, and the size of the vapor lines and pumping system. Very few vacuum dryers operate below 5 mmHg pressure on a commercial scale. Air in-leakage through gasket surfaces will be in the range of 0.2 kg/(h·lin m of gasketed surface) under these conditions. To keep vapor partial pressure and solids temperature low without pulling excessively high vacuum, a nitrogen bleed may be introduced, particularly in the later stages of drying. The vapor and solids surface temperatures then fall below the vapor boiling point, toward the wet-bulb temperature.

***Vertical Agitated Dryers*** This classification includes vertical pan dryers, filter dryers, and spherical and conical dryers.

*Vertical pan dryer* The basic vertical pan dryer consists of a short, squat vertical cylinder (Fig. 12-57 and Table 12-23) with an outer heating jacket and an internal rotating agitator, again with the axis vertical, which mixes the solid and sweeps the base of the pan. Heat is supplied by circulation of hot water, steam, or thermal fluid through the jacket; it may also be used for cooling at the end of the batch cycle, using cooling water or refrigerant. The agitator is usually a plain set of solid blades, but may be a ribbon-type screw or internally heated blades. Product is discharged from a door at the lower

side of the wall. Sticky materials may adhere to the agitator or be difficult to discharge.

*Filter dryer* The basic Nutsche filter dryer is like a vertical pan dryer, but with the bottom heated plate replaced by a filter plate (see also Sec. 18, Liquid-Solid Operations and Equipment). Hence, a slurry can be fed in and filtered, and the wet cake dried in situ. These units are especially popular in the pharmaceutical industry, as containment is good and a difficult wet-solids transfer operation is eliminated by carrying out both filtration and drying in the same vessel. Drying times tend to be longer than for vertical pan dryers, as the bottom plate is no longer heated. Some types (e.g., Mitchell Thermovac, Krauss-Maffei TNT) invert the unit between the filtration and drying stages to avoid this problem.

These are popular in the pharmaceutical and specialty chemicals industries as two operations are performed in the same piece of equipment without intermediate solids transfer, and containment is good.

*Spherical dryer* Sometimes called the *turbosphere,* this is another agitated dryer with a vertical axis mixing shaft, but rotation is typically faster than in the vertical pan unit, giving improved mixing and heat transfer. The dryer chamber is spherical, with solids discharge through a door or valve near the bottom.

*Conical mixer dryer* This is a vertically oriented conical vessel with an internally mounted rotating screw. Figure 12-58 shows a schematic of a typical conical mixer dryer. The screw rotates about its own axis (speeds up to 100 rpm) and around the interior of the vessel (speeds up to 0.4 rpm). Because it rotates around the full circumference of the vessel, the screw provides a self-cleaning effect for the heated vessel walls, as well as effective agitation; it may also be internally heated. Either top-drive (via an internal rotating arm) or bottom-drive (via a universal joint) may be used; the former is more common. The screw is cantilevered in the vessel and requires no additional support (even in vessel sizes up to 20-$m^3$ operating volume). Cleaning of the dryer is facilitated with *clean-in-place* (CIP) systems that can be used for cleaning, and/or the vessel can be completely flooded with water or solvents. The dryer makes maximum use of the product-heated areas—the filling volume of the vessel (up to the knuckle of the dished head) is the usable product loading. In some applications, microwaves have been used to provide additional energy input and shorten drying times.

***Horizontal Pan Dryer*** This dryer consists of a stationary cylindrical shell, mounted horizontally, in which a set of agitator blades mounted on a revolving central shaft stir the solids being treated. These dryers tend to be used for larger batches than vertical agitated or batch rotating dryers. Heat is supplied by circulation of hot water, steam, or other heat-transfer fluids through the jacket surrounding the shell and, in larger units, through the hollow central shaft. The agitator can take many different forms, including simple paddles, ploughshare-type blades, a single discontinuous spiral, or a double continuous spiral. The outer blades are set as closely as possible to the wall without touching, usually leaving a gap of 0.3 to 0.6 cm. Modern units occasionally employ spring-loaded shell scrapers mounted on the blades. The dryer is charged through a port at the top and emptied through one or more discharge nozzles at the bottom. Vacuum is applied and maintained by any of the conventional methods, i.e., steam jets, vacuum pumps, etc.

A similar type, the batch indirect rotary dryer, consists of a rotating horizontal cylindrical shell, suitably jacketed. Vacuum is applied to this unit through hollow trunnions with suitable packing glands. Rotary glands must be used also for admitting and removing the heating medium from the jacket. The inside of the shell may have lifting bars, welded longitudinally, to assist agitation of the solids. Continuous rotation is needed while emptying the solids, and a circular dust hood is frequently necessary to enclose the discharge-nozzle turning circle and prevent serious dust losses to the atmosphere during unloading. A typical horizontal pan vacuum dryer is illustrated in Fig. 12-59.

***Tumbler or Double-Cone Dryers*** These are rotating batch vacuum dryers, as shown in Fig. 12-60. Some types are an offset cylinder, but a double-cone shape is more common. They are very common in the pharmaceutical and fine chemicals industries. The gentle rotation can give less attrition than in some mechanically agitated dryers; on the other hand, formation of lumps and balls is more likely. The sloping walls of the cones permit more rapid emptying of solids when the dryer is in a stationary position, compared to a horizontal cylinder, which requires continuous rotation during emptying to convey product to the discharge nozzles. Several new designs of the double-cone type employ internal tubes or plate coils to provide additional heating surface.

On all rotating dryers, the vapor outlet tube is stationary; it enters the shell through a rotating gland and is fitted with an elbow and an upward extension so that the vapor inlet, usually protected by a felt dust filter, will be near the top of the shell at all times.

***Design, Scale-Up, and Performance*** Like all batch dryers, agitated and rotating dryers are primarily sized to physically contain the required batch volume. Note that the nominal capacity of most dryers is significantly lower than their total internal volume, because of the headspace needed for mechanical drives, inlet ports, suction lines, dust filters, etc. Care must be taken to determine whether a stated percentage fill is based on nominal capacity or geometric volume. Vacuum dryers are usually filled to 50 to 65 percent of their total shell volume.

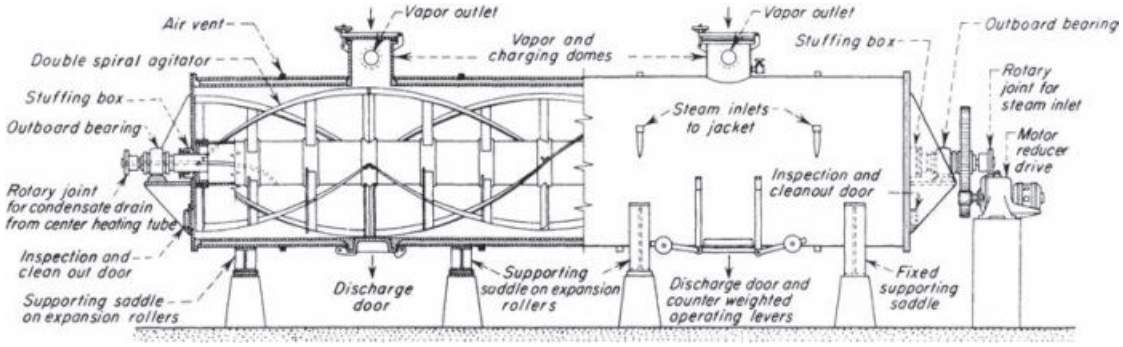

**FIG. 12-59** A typical horizontal pan vacuum dryer. (*Blaw-Knox Food & Chemical Equipment, Inc.*)

The standard scoping calculation methods for batch conduction drying apply. The rate of heat transfer from the heating medium through the dryer wall to the solids can be expressed by the usual formula

$$Q = hA\,\Delta T_m \tag{12-72}$$

where $Q$ = heat flux, J/s (Btu/h); $h$ = overall heat-transfer coefficient, J/(m$^2$·s·K) [Btu/(h·ft$^2$ jacket area·°F)]; $A$ = total jacket area, m$^2$ (ft$^2$); and $\Delta T_m$ = log-mean temperature driving force from heating medium to the solids, K (°F).

The overall heat-transfer rate is almost entirely dependent upon the film coefficient between the inner jacket wall and the solids, which depends on the dryer type and agitation rate and, to a large extent, on the solids characteristics. Overall heat-transfer coefficients may range from 30 to 200 J/(m$^2$·s·K), based upon total area if the dryer walls are kept reasonably clean. Heat-transfer coefficients as low as 5 or 10 J/(m$^2$·s·K) may be encountered if caking on the walls occurs.

For estimating purposes without tests, a reasonable coefficient for ordinary drying, and without taking the product to absolute dryness, may be assumed as $h$ = 50 J/(m$^2$·s·K) for mechanically agitated dryers (although higher figures have been quoted for conical and spherical dryers) and 35 J/(m$^2$·s·K) for rotating units. The true heat-transfer coefficient is usually higher, but this conservative assumption makes some allowance for the slowing down of drying during the falling-rate period. However, if at all possible, it is always preferable to do pilot-plant tests to establish the drying time of the actual material. Drying trials are conducted in small pilot dryers (50- to 100-L batch units) to determine material handling and drying retention times. Variables such as drying temperature, vacuum level, and screw speed are analyzed during the test trials. Scale-up to larger units is done based upon the area/volume ratio of the pilot unit versus the production dryer. In most applications, the overall drying time in the production models is in the range of 2 to 24 h.

Agitator or rotation speeds range from 3 to 8 rpm. Faster speeds yield a slight improvement in heat transfer but consume more power and in some cases, particularly in rotating units, can cause more "balling up" and other stickiness-related problems.

In all these dryers, the surface area tends to be proportional to the square of the diameter $D^2$, and the volume to diameter cubed $D^3$. Hence the area/volume ratio falls as the diameter increases, and drying times increase. It can be shown that the ratio of drying times in the production and pilot-plant dryers is proportional to the cube root of the ratio of batch volumes. However, if the agitator of the production unit is heated, the drying time increase can be reduced or reversed. Table 12-24 gives basic geometric relationships for agitated and rotating batch dryers, which can be used for approximate size estimation or (with great caution) for extrapolating drying times obtained from one dryer type to another. Note that these do not allow for nominal capacity or partial solids fill. For the paddle (horizontal pan) dryer with heated agitator, $R$ is the ratio of the heat transferred through the agitator to that through the walls, which is proportional to the factor $hA$ for each case.

In the absence of experimental data, the following method may be used for scoping calculations. For constant-rate drying, the drying time $t_{CR}$ can be calculated from

$$t_{CR} = \frac{m_s(X_{\text{initial}} - X_{\text{final}})\lambda_{ev}}{h_{ws}\Delta T_m A_s} \tag{12-73}$$

where $X_{\text{initial}}$ = initial dry-basis moisture content; $X_{\text{final}}$ = final dry-basis moisture content; $\lambda_{ev}$ = latent heat of vaporization; $A_s$ = surface area; $\Delta T_m$ = log-mean temperature difference.

To correct from a calculated constant-rate (unhindered) drying time $t_{CR}$ to first-order falling-rate kinetics, the following equation is used, where $X_1$ is the initial, $X_2$ the final, and $X_E$ the equilibrium moisture content (all must be dry-basis):

$$\frac{t_{FR}}{t_{CR}} = \frac{X_1 - X_E}{X_1 - X_2}\ln\left(\frac{X_1 - X_E}{X_2 - X_E}\right) \tag{12-74}$$

Note that $t_{FR} \geq t_{CR}$. Likewise, to convert to a two-stage drying process with constant-rate drying down to $X_{cr}$ and first-order falling-rate drying beyond, the equation is

$$\frac{t_{2S}}{t_{CR}} = \frac{X_1 - X_{cr}}{X_1 - X_2} + \frac{X_{cr} - X_E}{X_1 - X_2}\ln\left(\frac{X_{cr} - X_E}{X_2 - X_E}\right) \tag{12-75}$$

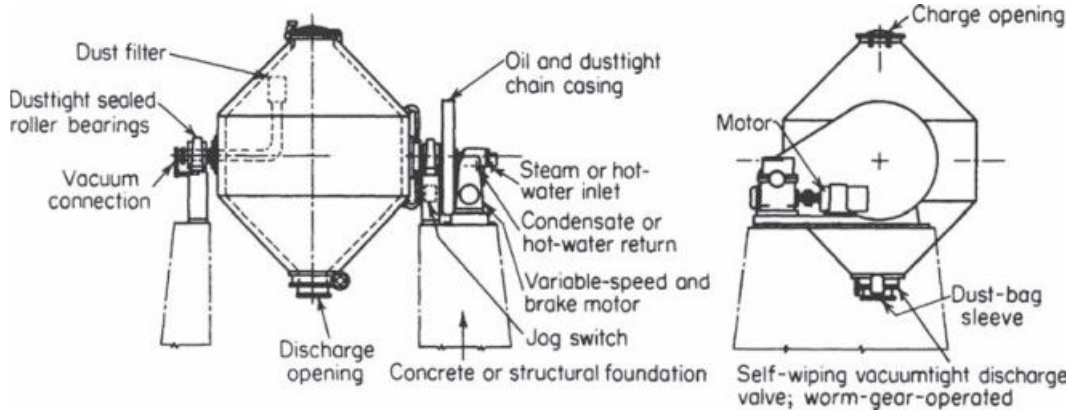

**FIG. 12-60** Rotating (double-cone) vacuum dryer. (*Stokes Vacuum, Inc.*)

**TABLE 12-24 Calculation of Key Dimensions for Various Batch Contact Dryers (Fig. 12-61 Shows the Geometries)**

| Dryer type | Volume as $f(D)$ | Typical $L/D$ | Diameter as $f(V)$ | Surface area as $f(D)$ | Ratio $A/V$ |
|---|---|---|---|---|---|
| Tumbler/double-cone | $V=\frac{\pi D^3}{12}\left(\frac{L}{D}\right)$ | 1.5 | $D=\left[\frac{12V}{\pi(L/D)}\right]^{1/3}$ | $A=\frac{\pi D^2}{2}\left[\left(\frac{L}{D}\right)^2+1\right]^{1/2}$ | $\frac{A}{V}=\frac{6}{D}\left[1+\left(\frac{L}{D}\right)^2\right]^{1/2}$ |
| Vertical pan | $V=\frac{\pi D^3}{4}\left(\frac{L}{D}\right)$ | 0.5 | $D=\left[\frac{4V}{\pi(L/D)}\right]^{1/3}$ | $A=\pi D^2\left(\frac{L}{D}+\frac{1}{4}\right)$ | $\frac{A}{V}=\frac{4}{D}\left(1+\frac{D}{4L}\right)$ |
| Spherical | $V=\frac{\pi D^3}{6}\left(\frac{L}{D}\right)$ | 1 | $D=\left[\frac{6V}{\pi(L/D)}\right]^{1/3}$ | $A=\pi D^2\left(\frac{L}{D}\right)$ | $\frac{A}{V}=\frac{6}{D}$ |
| Filter dryer | $V=\frac{\pi D^3}{4}\left(\frac{L}{D}\right)$ | 0.5 | $D=\left[\frac{4V}{\pi(L/D)}\right]^{1/3}$ | $A=\pi D^2\left(\frac{L}{D}\right)$ | $\frac{A}{V}=\frac{4}{D}$ |
| Conical agitated | $V=\frac{\pi D^3}{12}\left(\frac{L}{D}\right)$ | 1.5 | $D=\left[\frac{12V}{\pi(L/D)}\right]^{1/3}$ | $A=\frac{\pi D^2}{2}\left[\left(\frac{L}{D}\right)^2+\frac{1}{4}\right]^{1/2}$ | $\frac{A}{V}=\frac{6}{D}\left[1+\frac{1}{4}\left(\frac{D}{L}\right)^2\right]^{1/2}$ |
| Paddle (horizontal agitated) | $V=\frac{\pi D^3}{4}\left(\frac{L}{D}\right)$ | 5 | $D=\left[\frac{4V}{\pi(L/D)}\right]^{1/3}$ | $A=\pi D^2\left(\frac{L}{D}\right)$ | $\frac{A}{V}=\frac{4}{D}$ |
| Paddle, heated agitator | $V=\frac{\pi D^3}{4}\left(\frac{L}{D}\right)$ | 5 | $D=\left[\frac{4V}{\pi(L/D)}\right]^{1/3}$ | $A=\pi D^2\left(\frac{L}{D}\right)(1+R)$ | $\frac{A}{V}=\frac{4}{D}(1+R)$ |

***Example 12-16 Calculations for Batch Dryer*** For a 10-m$^3$ batch of material containing 5000 kg of dry solids and 30 percent moisture (dry basis), estimate the size of vacuum dryers required to contain the batch at 50 percent volumetric fill. Jacket temperature is 200°C, applied pressure is 100 mbar (0.1 bar), and the solvent is water (take latent heat as 2400 kJ/kg). Assuming the heat-transfer coefficient based on the total surface area to be 50 W/(m$^2\cdot$K) for all types, calculate the time to dry to 5 percent for (*a*) unhindered (constant-rate) drying throughout, (*b*) first-order falling-rate (hindered) drying throughout, (*c*) the case where experiment shows the actual drying time for a conical dryer to be 12.5 h and other cases are scaled accordingly. Take $R=5$ with the heated agitator. Assume the material is nonhygroscopic (equilibrium moisture content $X_E=0$).

*Solution* The dryer volume $V$ must be 20 m$^3$, and the diameter is calculated from column 4 of Table 12-24, assuming the default $L/D$ ratios. Table 12-25 gives the results. Water at 100 mbar boils at 46°C so take $\Delta T$ as 200 − 46 = 154°C. Then $Q$ is found from Eq. (12-72). For constant-rate drying throughout, drying time $t_{CR}$ = evaporation rate/heat input rate and was given by

$$t_{CR}=\frac{m_s(X_O-X_I)\lambda_{ev}}{h_{ws}\Delta T_{ws}A_s}=\frac{5000(0.3-0.05)(2400)}{0.05(154A_s)} \tag{12-76}$$

This gives $t_{CR}$ as 389,610/$A_s$ s or 108.23/$A_s$ h. Values for $A_s$ and calculated times for the various dryer types are given in Table 12-25.

For falling-rate drying throughout, time $t_{FR}$ is given by Eq. (12-77); the multiplying factor for drying time is 1.2 ln 6 = 2.15 for all dryer types.

$$\frac{t_{FR}}{t_{CR}}=\left(\frac{X_1-X_E}{X_1-X_2}\right)\ln\left(\frac{X_1-X_E}{X_2-X_E}\right)=\frac{0.3}{0.25}\ln\frac{0.3}{0.05} \tag{12-77}$$

If the material showed a critical moisture content, the calculation could be split into two sections for constant-rate and falling-rate drying. Likewise, the experimental drying time $t_{expt}$ for the conical dryer is 12.5 h which is a factor of 3.94 greater than the constant-rate drying time. A very rough estimate of drying times for the other dryer types has been made by applying the same scaling factor (3.94) to their constant-rate drying times. Two major sources of error are possible: (1) The drying kinetics could differ between dryers; and (2) if the estimated heat-transfer coefficient for either the base case or the new dryer type is in error, then the scaling factor will be wrong. All drying times have been shown in hours, as this is more convenient than seconds.

The paddle with heated agitator has the shortest drying time, and the filter dryer the longest (because the bottom plate is unheated). Other types are fairly comparable. The spherical dryer would usually have a higher heat-transfer coefficient and shorter drying time than shown.

An excellent model for a variety of agitated vacuum dryers has been developed and validated against experimental data. See Schlünder, E. and Mollekopf, N., "Vacuum Contact Drying of Free Flowing Mechanically Agitated Particulate Material," *Chemical Engineering and Processing: Process Intensification* **18**(2): 93–111 (March–April 1984).

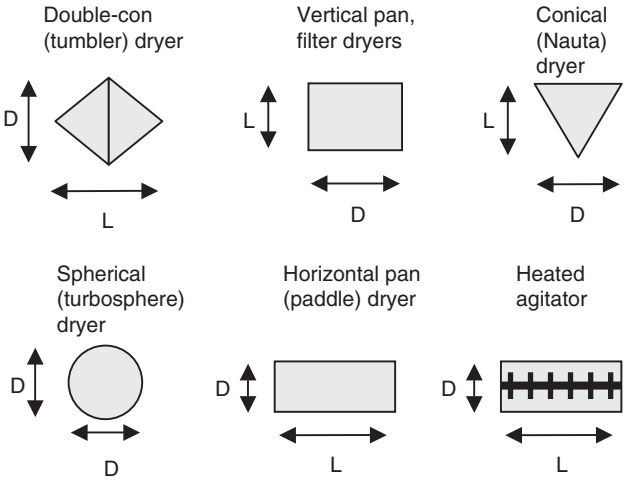

**FIG. 12-61** Basic geometries for batch dryer calculations.

***Performance Data for Batch Vacuum Rotary Dryers*** Typical performance data for horizontal pan vacuum dryers are given in Table 12-26. Size and cost data for rotary agitator units are given in Table 12-27. Data for double-cone rotating units are shown in Table 12-28.

**Continuous Agitated and Rotary Dryers**

***Examples and Synonyms*** Disk, Porcupine, Nara, Solidaire, Forberg, steam tube, paddle dryers, continuous rotary dryers, rotary kiln, steam-tube dryer, rotary calciner, Roto-Louvre dryer.

***Continuous Agitated Dryers: Description*** Continuous agitated dryers, often known as *paddle* or *horizontal agitated dryers*, consist of one or more horizontally mounted shells with internal mechanical agitators, which may take many different forms. They are a continuous equivalent of the horizontal pan dryer and are similar in construction, but usually of larger dimensions. They have many similarities to continuous indirect rotary dryers and are sometimes classified as rotary dryers, but this is a misnomer because the outer shell does not rotate, although in some types there is an inner shell which does. Frequently, the internal agitator is heated, and a wide variety of designs exist. Often two intermeshing agitators are used. There are important variants with high-speed agitator rotation and supplementary convective heating by hot air.

The basic differences are in the type of agitator, with the two key factors being the heat-transfer area and solids handling/stickiness characteristics. Unfortunately, the types giving the highest specific surface area (multiple tubes and coils) are often also the ones most susceptible to fouling and blockage and most difficult to clean. Figure 12-62 illustrates a number of different agitator types.

***Paddle Dryers*** Product trials are conducted in small pilot dryers (8- to 60-L batch or continuous units) to determine material handling and process retention times. Variables such as drying temperature, pressure level, and shaft speed are analyzed during the test trials. For initial design purposes, the heat-transfer coefficient for paddle dryers is typically in the range of 10 W/(m$^2\cdot$K) (light, free-flowing powders) up to 150 W/(m$^2\cdot$K) (dilute slurries). However, it is preferable to scale up from the test results, fitting the data to estimate the heat-transfer coefficient and scaling up on the basis of total area of heat-transfer surfaces, including heated agitators. Typical length/diameter ratios are between 5 and 8, similar to rotary dryers and greater than some batch horizontal pan dryers.

**TABLE 12-25 Comparative Dimensions and Drying Times for Various Batch Contact Dryers**

| Dryer type | $h$, kW/(m$^2$·K) | $L/D$ | $D$, m | $L$, m | $A$, m$^2$ | $t_{CR}$, h | $t_{FR}$, h | $t_{expt}$, h |

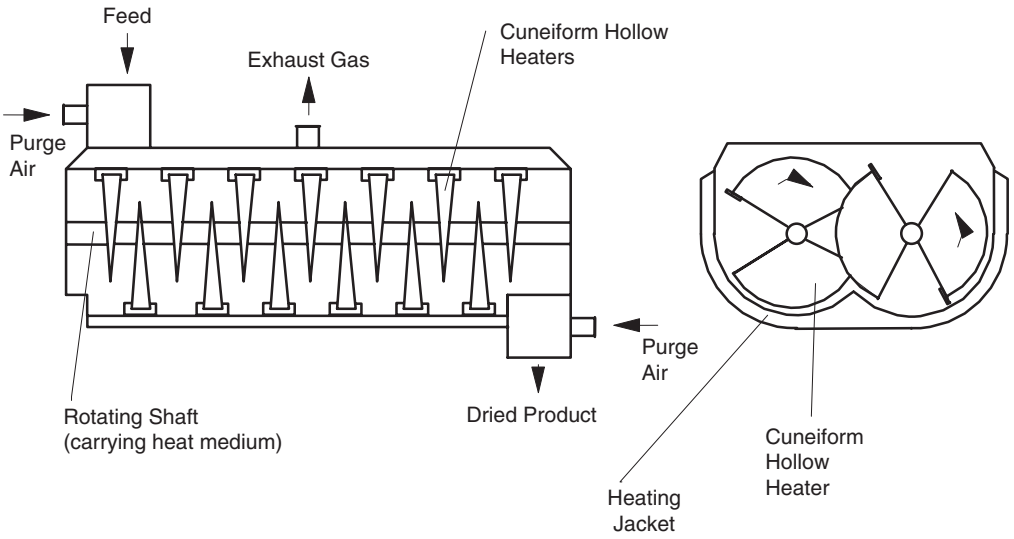

**FIG. 12-63** Nara twin-shaft paddle dryer.

The most common problem with paddle dryers (and with their closely related cousins, steam-tube and indirect rotary dryers) is the buildup of sticky deposits on the surface of the agitator or outer jacket. This leads, first, to reduced heat-transfer coefficients and slower drying and, second, to blockages and stalling of the rotor. Also thermal decomposition and loss of product quality can result. The problem is usually most acute at the feed end of the dryer, where the material is wettest and stickiest. A wide variety of different agitator designs have been devised to try to reduce stickiness problems and enhance cleanability while providing a high heat-transfer area. Many designs incorporate a high-torque drive combined with rugged shaft construction to prevent rotor stall during processing, and stationary mixing elements are installed in the process housing which continually clean the heat-exchange surfaces of the rotor to minimize any crust buildup and ensure an optimum heat-transfer coefficient at all times. Another alternative is to use two parallel intermeshing shafts, as in the Nara paddle dryer (Fig. 12-63). Suitably designed continuous paddle and batch horizontal pan dryers can handle a wide range of product consistencies (dilute slurries, pastes, friable powders) and can be used for processes such as reactions, mixing, drying, cooling, melting, sublimation, distilling, and vaporizing.

*Continuous Rotary Dryers: Description* A rotary dryer consists of a cylinder that rotates on suitable bearings and that is usually slightly inclined to the horizontal. The cylinder length may range from 4 to more than 10 times the diameter, which may vary from less than 0.3 to more than 3 m. Solids fed into one end of the drum are carried through it by gravity, with rolling, bouncing and sliding, and drag caused by the airflow either retarding or enhancing the movement, depending on whether the dryer is cocurrent or countercurrent. It is possible to classify rotary dryers into direct-fired, where heat is transferred to the solids by direct exchange between the gas and the solids, and indirect, where the heating medium is separated from physical contact with the solids by a metal wall or tube. Many rotary dryers contain flights or lifters, which are attached to the inside of the drum and which cascade the solids through the gas as the drum rotates.

For handling large quantities of granular solids, a cascading rotary dryer is often the equipment of choice. If the material is not naturally free-flowing, recycling of a portion of the final dry product may be used to precondition the feed, either in an external mixer or directly inside the drum. Hanging link chains and/or scrapper chains are also used for sticky feed materials.

Their operating characteristics when performing heat- and mass-transfer operations make them suitable for the accomplishment of drying, chemical reactions, solvent recovery, thermal decompositions, mixing, sintering, and agglomeration of solids. The specific types included are the following:

*Direct cascading rotary dryer (cooler).* This is usually a bare metal cylinder but with internal flights (shelves) which lift the material and drop it through the airflow. It is suitable for low- and medium-temperature operations, the operating temperature being limited primarily by the strength characteristics of the metal employed in fabrication.

*Direct rotary dryer (cooler).* As above but without internal flights.

*Direct rotary kiln.* This is a metal cylinder lined on the interior with insulating block and/or refractory brick. It is suitable for high-temperature operations.

*Indirect steam-tube dryer.* This is a bare metal cylinder provided with one or more rows of metal tubes installed longitudinally in the shell. It is suitable for operation up to available steam temperatures or in processes requiring water cooling of the tubes.

*Indirect rotary calciner.* This is a bare metal cylinder surrounded on the outside by a fired or electrically heated furnace. It is suitable for operation at medium temperatures up to the maximum that can be tolerated by the metal wall of the cylinder, usually 650 to 700 K for carbon steel and 800 to 1025 K for stainless steel.

*Direct Roto-Louvre dryer.* This is one of the more important special types, differing from the direct rotary unit in that true *through-circulation* of gas through the solids bed is provided. Like the direct rotary, it is suitable for low- and medium-temperature operation.

*Direct heat rotary dryer.* The direct heat units are generally the simplest and most economical in operation and construction, when the solids and gas can be permitted to be in contact. The required gas flow rate can be obtained from a heat and mass balance. The bed cross-sectional area is found from a scoping design calculation (a typical gas velocity is 3 m/s for cocurrent and 2 m/s for countercurrent units). Length is normally between 5 and 10 times the drum diameter (an $L/D$ value of 8 can be used for initial estimation) or can be calculated by using an incremental model (see Example 12-17).

A typical schematic diagram of a rotary dryer is shown in Fig. 12-64, while Fig. 12-65 shows typical lifting flight designs.

***Residence Time, Standard Configuration*** The residence time in a rotary dryer $\tau$ represents the average time that particles are present in the equipment, so it must match the required drying time.

The calculation of the residence time of material in the dryer is complex since the holdup depends on the design of the flights and material properties, such as the angle of repose. The flow of the material in the equipment to calculate the residence times has been the subject of a number of historical papers, including those by Sullivan et al. (U.S. Bureau of Mines Tech. Paper 384), Friedman and Marshall equation [*Chem. Eng. Progr.* **45**(8): 482 (1949)], Saeman and Mitchell [*Chem. Eng. Progr.* **50**(9): 467 (1954)], and Schofield and Glikin [*Trans. IChemE* **40:** 183 (1962)].

The most complete analysis of particle motion in rotary dryers is given by Matchett and Baker [*J. Sep. Proc. Technol.* **8:** 11 (1987)]. They considered both the airborne phase (particles falling through air) and the dense phase (particles in the flights or the rolling bed at the bottom). Typically, particles spend 90 to 95 percent of the time in the dense phase, but the majority of the drying takes place in the airborne phase. In the direction parallel to the dryer axis, most particle movement occurs through four mechanisms: by gravity and air drag in the airborne phase, and by bouncing, sliding, and rolling in the dense phase.

The combined particle velocity in the airborne phase is $U_{P1}$, which is the sum of the gravitational and air drag components for cocurrent dryers and the difference between them for countercurrent dryers. The dense-phase velocity, arising from bouncing, sliding, and rolling, is denoted $U_{P2}$.

Papadakis et al. [*Dry. Tech.* **12**(1&2): 259–277 (1994)] rearranged the Matchett and Baker model from its original "parallel" form into a more

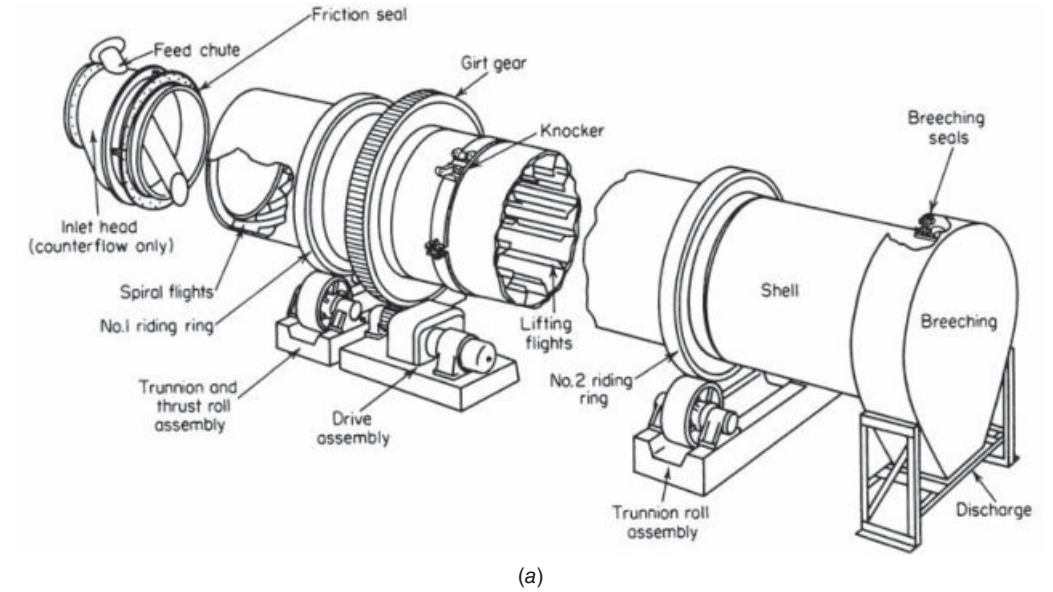

**FIG. 12-64** Component arrangement (*a*) and elevation (*b*) of countercurrent direct-heat rotary dryer. (*Air Preheater Company, Raymond & Bartlett Snow Products.*)

computationally convenient "series" form. The sum of the calculated residence times in the airborne and dense phases, $\tau_G$ and $\tau_S$, respectively, is the total solids residence time. The dryer length is simply the sum of the distances traveled in the two phases.

$$\tau = \tau_G + \tau_S \tag{12-78}$$

$$L = \tau_G U_{P1} + \tau_S U_{P2} \tag{12-79}$$

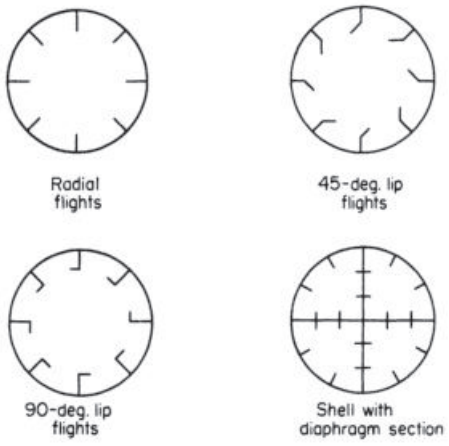

**FIG. 12-65** Typical lifting flight designs.

For airborne phase motion, the velocity is affected by gravity and air drag.

$$U_{P1} = U_{P1}^{O} + U_{P1}^{d} \tag{12-80}$$

The velocity $U_{P1}^{O}$ due to the gravitational component is most conveniently expressed as

$$U_{P1}^{O} = \sqrt{\frac{gD}{2}}\tan\alpha\, K_{\text{fall}}\sqrt{\frac{D_e}{D\cos\alpha}} = \sqrt{\frac{gD}{2}}\tan\alpha\, K_K \tag{12-81}$$

where $K_{\text{fall}}$ is a parameter that allows for particles falling from a number of positions, with different times of flight and lifting times, and is generally between 0.7 and 1; and the effective diameter (internal diameter between lips of flights) is $D_e$.

The contribution of air drag on the velocity of falling can be calculated using Eqs. (12-82) and (12-83). The value is positive for concurrent airflow and negative for countercurrent airflow. For Reynolds numbers up to 220, where $\text{Re} = \dfrac{U_{G,\text{super}} d_p \rho_g}{\mu_g}$,

$$U_{P1}^{d} = 7.45\times10^{-4}\,\text{Re}^{2.2}\frac{\mu U_{G\,\text{super}} t_a^*}{\rho_p d_p^2} \tag{12-82}$$

Above this Reynolds number, the following equation was recommended by Matchett and Baker (1987):

$$U_{P1}^{d} = 125\frac{\mu U_{G\,\text{super}} t_a^*}{\rho_p d_p^2} \tag{12-83}$$

The variable $t_a^*$ is the average time of flight of a particle in the airborne phase when the dryer is at the "design loaded," i.e., if the powder fills and does not overflow the flights; see Fig. 12-65. If the dryer has more powder than this (overloaded), then the flights will not be able to carry all of it up as far and so the time of flight will be lower.

The average time of flight of the particles can be estimated from

$$t_f = \left(\frac{2D}{g\cos\alpha}\right)^{1/2} K_{\text{fall}} \tag{12-84}$$

Here, since we are designing the dryer, $t_f = t_a^*$.

Bouncing, rolling, and sliding are not so easily analyzed theoretically. Matchett and Baker (cited above) suggested that the dense-phase velocity could be characterized in terms of a dimensionless dense-phase velocity number *a,* using Eq. (12-85). Values of *a* are in the range of 1 to 4.

$$U_{P2} = a \cdot N \cdot D \cdot \tan\alpha \tag{12-85}$$

Other workers suggested that, in underloaded and design-loaded dryers, bouncing was a significant transport mechanism, whereas for overloaded dryers, rolling was important. Bouncing mechanisms can depend on the airborne phase velocity $U_{P1}$, since this affects the angle at which the particles hit the bottom of the dryer and the distance they move forward. Rolling mechanisms would be expected to depend on the depth of the bottom bed, and hence on the difference between the actual holdup and the design-loaded holdup.

As an example of the typical numbers involved, Matchett and Baker [*J. Sep. Proc. Technol.* **9:** 5 (1988)] used their correlations to assess the data of Saeman and Mitchell for an industrial rotary dryer with $D$ = 1.83 m and $L$ = 10.67 m, with a slope of 4°, 0.067 m/m. For a typical run with $U_G$ = 0.98 m/s and $N$ = 0.08 r/s, they calculated that $U_{P1}^{\circ}$ = 0.140 m/s, $U_{P1}^{d}$ = –0.023 m/s, $U_{P_1}$ = 0.117 m/s, and $U_{P_2}$ = –0.02 m/s. The dryer modeled was countercurrent and therefore had a greater slope and lower gas velocity than those of a cocurrent unit; for the latter, $U_{P1}^{\circ}$ would be lower and $U_{P1}^{d}$ positive and larger. The ratio $\tau_S/\tau_G$ is approximately 12 in this case, so that the distance traveled in dense-phase motion would be about twice that in the airborne phase.

Kemp and Oakley [*Dry. Tech.* **20**(9): 1699 (2002)] showed that the ratio $\tau_G/\tau_S$ can be found by comparing the average time of flight from the top of the dryer to the bottom $t_f$ to the average time required for the particles to be lifted by the flights $t_d$. They derived the following equation:

$$\frac{\tau_S}{\tau_G} = \frac{t_d}{t_f} = \frac{K_{fl}}{N}\sqrt{\frac{g}{D}} \tag{12-86}$$

Here all the unknowns have been rolled into a single dimensionless parameter $K_{fl}$, given by

$$K_{fl} = \frac{\theta}{\pi\sqrt{2\sin\theta}}\sqrt{\frac{D}{D_e}} \tag{12-87}$$

Here $D_e$ is the effective diameter (internal diameter between lips of flights), and the solids are carried in the flights for an angle 2θ, on average, before falling. Kemp and Oakley concluded that $K_{fl}$ can be taken to be 0.4 to a first (and good) approximation. For overloaded dryers with a large rolling bed, $K_{fl}$ will increase. The form of Eq. (12-86) is very convenient for design purposes since it does not require $D_e$, which is unknown until a decision has been made on the type and geometry of the flights.

The model of Matchett and Baker has been shown by Kemp (Proc. IDS 2004, B, 790) to be similar in form to that proposed by Saeman and Mitchell:

$$\tau = \frac{1.1L}{ND\left[\tan\alpha\cdot(K_K/K_{fl}\sqrt{2}+a)+(1/K_{fl})\sqrt{\frac{1}{gD}\cdot U_{P1}^{d}}\right]} \tag{12-88}$$

In Eq. (12-88), $K_K/(K_{fl}\sqrt{2})$ will typically be on the order of unity, and reported values of *a* are in the range of 1 to 4. The airborne gravity component is usually smaller than the dense-phase motion but is not negligible.

***Heat- and Mass-Transfer Estimates*** Many rotary dryer studies have correlated heat- and mass-transfer data in terms of an overall volumetric heat-transfer coefficient $U_v a$ [W/(m$^3\cdot$K)], defined by

$$Q = U_v a \cdot V_{\text{dryer}} \cdot \Delta T_m \tag{12-89}$$

Here $Q$ is the overall rate of heat transfer between the gas and the solids (W), $V_{\text{dryer}}$ is the dryer volume (m$^3$), and $\Delta T_m$ is an average temperature driving force (K). When one is calculating the average temperature driving force, it is important to distinguish between the case of heat transfer with dry particles, where the change in the particle temperature is proportional to the change in the gas temperature, and the case of drying particles, where the particle temperature does not change so significantly. Where the particles are dry, the average temperature difference is the logarithmic mean of the temperature differences between the gas and the solids at the inlet and outlet of the dryer. The volumetric heat-transfer coefficient itself consists of a heat-transfer coefficient $U_v$, based on the effective area of contact between the gas and the solids, and the ratio *a* of this area to the dryer volume. Thus, this procedure eliminates the need to specify where most of the heat transfer occurs (e.g., to material in the air, on the flights, or in the rolling bed). Empirical correlations are of the form

$$U_v a = \frac{K' U_{G\,\text{super}}^{n}}{D} \tag{12-90}$$

where $K'$ depends on the solids properties, the flight geometry, the rotational speed, and the dryer holdup. In Eq. (12-90), *a* is the surface area per unit volume of the powder. Table 12-29 gives the values of *n* chosen by various authors, and Table 12-30 gives references and conditions for a few published studies. The most accepted value for the exponent *n* is 0.67; however, this is not universally true. This is not surprising considering the complicated particle flow mechanics in the equipment. Experimental data on the materials used are preferred.

**TABLE 12-29 Values of the Index *n* in Correlations for the Volumetric Heat-Transfer Coefficient (after Baker, 1983)**

| Author(s) | Exponent *n* |
|---|---|
| Saeman and Mitchell (1954) | 0 |
| Friedman and Marshall (1949) | 0.16 |
| Aiken and Polsak (1982) | 0.37 |
| Miller et al. (1942) | 0.46–0.60 |
| McCormick (1962) | 0.67 |
| Myklestad (1963) | 0.80 |

An alternative procedure is the use of a conventional film heat-transfer coefficient $h_f$ [W/(m$^2\cdot$K)]

$$Q = h_f \cdot A_s \cdot \Delta T \tag{12-91}$$

Here $Q$ is the local heat-transfer rate (W), $A_s$ is the total surface area of all the particles (m$^2$), and $\Delta T$ is the temperature difference between the gas and the solids (K). The method has the advantages that $h_f$ can be determined by relatively simple tests (or calculated from appropriate correlations in the literature), variations in operating conditions can be allowed for, and analogies between heat and mass transfer allow the film coefficients for these processes to be related. However, the area for heat transfer must be estimated under the complex conditions of gas-solids interaction present in particle cascades. Schofield and Glikin (1962) estimated this area to be the surface area of particles per unit mass $6/(\rho_P d_p)$, multiplied by the fraction of solids in the drum that are cascading through the gas at any moment, which was estimated as the fraction of time spent by particles cascading through the gas:

$$A_S = \frac{6}{\rho_P d_P}\frac{t_f}{t_f + t_d} \tag{12-92}$$

Schofield and Glikin estimated the heat-transfer coefficient by using the correlation given by McAdams (1954), which correlates data for gas-to-particle heat transfer in air to about 20 percent over a range of Reynolds numbers ($\text{Re}_p$, defined in the previous subsection) between 17 and 70,000:

$$\text{Nu}_P = 0.33 \cdot \text{Re}_p^{1/2} \tag{12-93}$$

**TABLE 12-30 Summary of the Predictions Using the Correlations for the Volumetric Heat-Transfer Coefficients of Various Authors (after Baker, 1983)**

| | $U_v a$, W/(m$^3\cdot$K) | |
|---|---|---|
| Author(s) | $U_{G\text{super}_1} = 1$ m/s | $U_{G\text{super}_1} = 3$ m/s |
| Miller et al. (1942) | | |
| Commercial data | 248 | 516 |
| Pilot-scale data | 82 | 184 |
| Friedman and Marshall (1949) | 67 | 138 |
| Saeman and Mitchell (1954) | 495–1155 | 1032–2410 |
| Myklestad (1963) | 423 | 1019 |

Here the particle Nusselt number is $Nu_p$, where $Nu_p = h_f d_p/k_G$, and $k_G$ is the thermal conductivity of the gas [W/(m·K)]. They stated that the heat-transfer rates predicted by this procedure were much larger than those measured on an industrial cooler, which is probably due to the particles on the inside of the cascades not experiencing the full gas velocity. Kamke and Wilson (1986) used a similar approach to model the drying of wood chips, but used the Ranz-Marshall (1952) equation to predict the heat-transfer coefficient:

$$\mathrm{Nu} = 2 + 0.6 \cdot \mathrm{Re}_p^{1/2} \cdot \mathrm{Pr}_G^{1/3} \tag{12-94}$$

where $Pr_G$ is the Prandtl number of the gas.

***Drying Time Estimates*** Sometimes, virtually all the drying takes place in the airborne phase. Under such circumstances, the airborne-phase residence time $\tau_G$ and the drying time are virtually the same, and the required drying time can be estimated from equivalent times in drying kinetics experiments, e.g., using a thin-layer test (Langrish, D.Phil. thesis, 1988).

***Example 12-17 Sizing of a Cascading Rotary Dryer*** The average gas velocity passing through a cocurrent, adiabatic, cascading rotary dryer is 4 m/s. The particles moving through the dryer have an average diameter of 5 mm (Sauter mean diameter), a solids density of 600 kg/m$^3$, and a shape factor of 0.75. The particles enter with a moisture content of 0.50 kg/kg (dry basis) and leave with a moisture content of 0.15 kg/kg (dry basis). The drying rate may be assumed to decrease linearly with average moisture content, with no unhindered (constant-rate) drying period. In addition, let us assume that the solids are nonhygroscopic (so that the equilibrium moisture content is zero; hygroscopic means that the equilibrium moisture content is nonzero).

The inlet humidity is 0.10 kg/kg (dry basis) due to the use of a direct-fired burner, and the ratio of the flow rates of dry solids to dry gas is unity ($F/G = 1$). The gas temperature at the inlet to the dryer is 800°C, and the gas may be assumed to behave as a pure water vapor/air mixture.

Suppose that this dryer has a slope $\alpha$ of 4° and a diameter $D$ of 1.5 m, operating at a rotational speed $N$ of 0.04 r/s.

What residence time is required to dry the solid material to the target moisture content? How long does the dryer need to be?

Data:

| | | |
|---|---|---|
| $U = 4$ m/s | $X_I = 0.50$ kg/kg | $F/G = 1$ |
| $d_{\text{particle}} = 0.005$ m | $X_O = 0.15$ kg/kg | $T_{GI} = 800$°C |
| $\rho_P = 600$ kg/m$^3$ | $X_{cr} = 0.50$ kg/kg | $Y_I = 0.10$ kg/kg |
| $\alpha_P = 0.75$ | $X_e = 0.0$ kg/kg | |

*Solution*

Application of concept of characteristic drying curve: A linear falling rate curve implies the following equation for the drying kinetics [see Solids Drying Fundamentals subsection, Eqs. (12-29) and (12-30)]:

$$f = \Phi \text{ assumption of linear drying kinetics}$$

where $f$ is the drying rate relative to the initial drying rate

$$f = \frac{N}{N_{\text{initial}}} \tag{12-37}$$

Since the material begins drying in the falling-rate period, the critical moisture content can be taken as the initial moisture content. The equilibrium moisture content is zero since the material is not hygroscopic.

$$\Phi = \frac{\overline{X} - X_{\text{eq}}}{X_{\text{cr}} - X_{\text{eq}}} = \frac{\overline{X}}{0.5} \tag{12-95}$$

*Application of mass balances (theory):* A mass balance around the inlet and any section of the dryer is shown in Fig. 12-66.

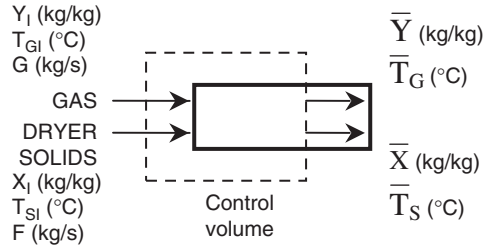

**FIG. 12-66** Mass balance around a typical section of a cocurrent dryer.

The essential idea is to calculate the average gas humidity $\overline{Y}$ at each average moisture content $\overline{X}$.

A differential mass balance on the air at any position in the bed is

$$F \cdot dX = -G \cdot dy \tag{12-96}$$

$$-\frac{dY}{dX} = \frac{F}{G} = \frac{\overline{Y} - Y_I}{X_I - \overline{X}} \tag{12-97}$$

where $Y$ = gas humidity, kg moisture/kg dry gas
$X$ = solids moisture content, kg moisture/kg dry solids
$W_G$ = flow rate of dry gas, kg dry gas/s
$W_S$ = flow rate of dry solids, kg dry solids/s

*Application of mass balances:* Plugging in the numbers gives the relationship between absolute humidity and moisture in the solids at any position.

$$\frac{\overline{Y} - 0.1}{0.5 - \overline{X}} = 1 = \frac{F}{G} \tag{12-98}$$

$$\overline{Y} = 0.6 - \overline{X} \tag{12-99}$$

$$Y_O = 0.6 - 0.15 = 0.45 \text{ kg/kg} \tag{12-100}$$

From the Mollier chart:

$$T_{wb} = 79°\text{C} \quad Y_s^* = 0.48 \text{ kg/kg}$$

For the whole dryer,

$$\overline{Y} = 0.275 \text{ kg/kg}$$

The mass balance information is important, but not the entire answer to the question. Now the residence time can be calculated from the kinetics.

*Application of concept of characteristic drying curve to estimating drying rates in practice (theory)*: The overall (required) change in moisture content is divided into a number of intervals of size $\Delta X$, and the problem is solved using a spreadsheet; note that $\Delta X$ is difference in the dry-basis moisture content, not distance. The sizes of the intervals need not be the same and should be finer where the fastest moisture content change occurs. For the sake of simplicity, this example will use intervals of uniform size. Then the application of the concept of a characteristic drying curve gives the following outcomes:

$$-\frac{d\,\overline{X}}{dt} = \text{drying rate} = \frac{f \cdot k \cdot \phi}{\rho_p} \frac{A_p}{V_p} (Y_s^* - \overline{Y}) \tag{12-101}$$

where $f$ = relative drying rate in interval (dimensionless)
$\overline{Y}$ = average humidity in interval, kg/kg
$\phi$ = humidity potential coefficient, close to unity
$\rho_p$ = density of dry solids, kg/m$^3$
$Y_s^*$ = humidity at saturation, from the adiabatic saturation contour on Mollier chart (Fig. 12-67)

$$\frac{A_p}{V_p} = \frac{\text{particle surface area}}{\text{particle volume}} = \frac{6}{\phi_p \cdot d_p} \tag{12-102}$$

where $d_{\text{particle}}$ = Sauter-mean particle diameter for mixture (volume-surface diameter), m
$\phi_p$ = particle shape factor, unity for spheres (dimensionless)
$k$ = mass-transfer coefficient, kg/(m$^2$·s), obtained from heat-transfer coefficient (often easier to obtain) using the Chilton-Colburn analogy

$$k \cdot \phi = \frac{\beta}{C_{PY}} h \tag{12-103}$$

where $\beta$ = psychrometric ratio, close to unity for air/water vapor system
$C_{PY}$ = humid heat capacity = $C_{PG} + YC_P = 1050 + 0.275 \times 2000 = 1600$ J/(kg·K)
$C_{PG}$ = specific heat capacity of dry gas (air) = 1050 J/(kg·K)
$C_{PV}$ = specific heat capacity of water vapor = 2000 J/(kg·K)

$$h = \text{heat-transfer coefficient, W/(m}^2 \cdot \text{K)} = \frac{\lambda_G}{d_{\text{particle}}} \cdot \mathrm{Nu}_p$$

$\lambda_G$ = thermal conductivity of gas = 0.02 W/(m·K)
$Nu_P$ = particle Nusselt number = $2 + 0.6\ \mathrm{Re}_P^{0.5}\ \mathrm{Pr}^{0.33}$
Pr = Prandtl number for air = 0.7

$$\mathrm{Re}_P = \text{particle Reynolds number} = \frac{U \cdot d_{\text{particle}}}{\nu}$$

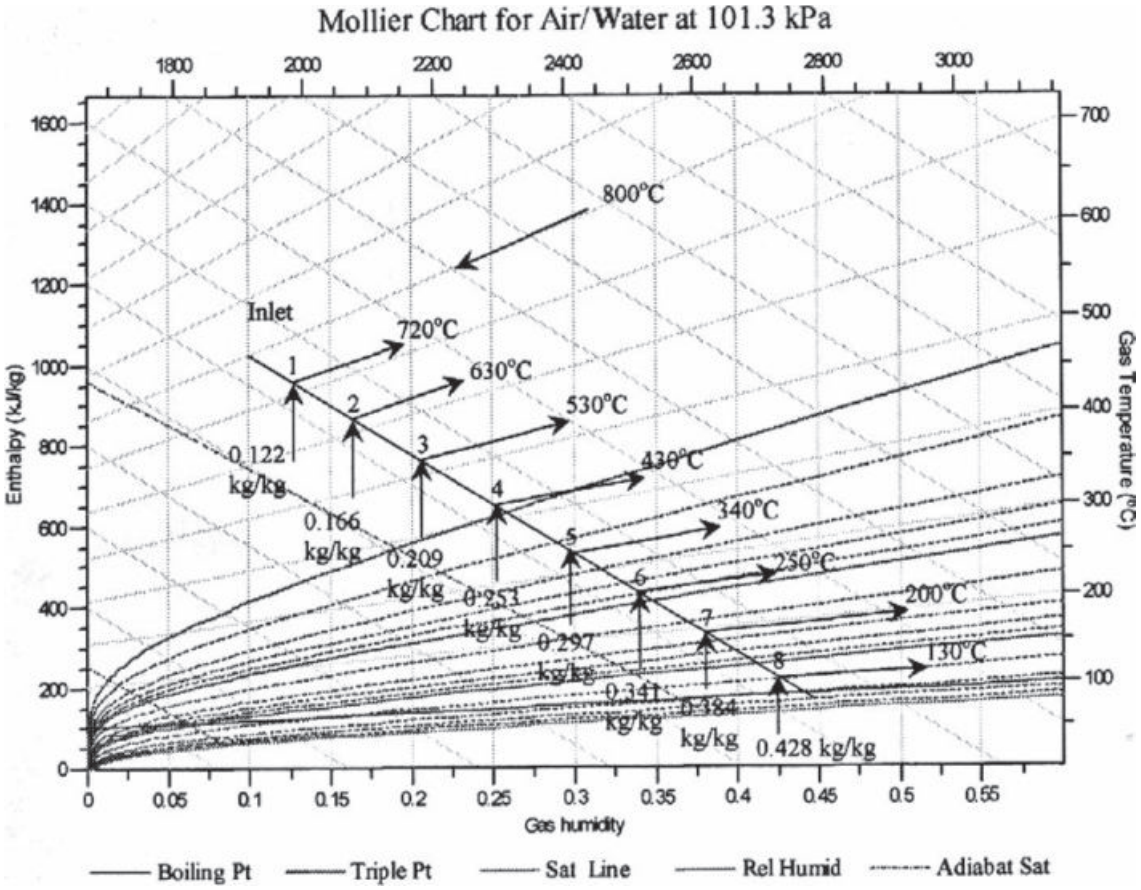

**FIG. 12-67** Enthalpy humidity chart used to generate the results in Table 12-31 plots humidity (abscissa) versus enthalpy (lines sloping diagonally from top left to bottom right).

$U$ = relative velocity between gas and particles; in cascading rotary dryers, this is almost constant throughout the dryer and close to the superficial gas velocity $U_{G\,\text{super}}$ (equals 4 m/s in this example)

$\nu$ = kinematic viscosity of gas at average $T_G$ in dryer = $15 \times 10^{-6}$ m$^2$/s

We might do a more accurate calculation by finding the gas properties at the conditions for each interval.

*Application of concept of characteristic drying curve to estimating drying rates in practice*

From the relationships above, $\text{Re}_p = \dfrac{U \cdot d_p}{\nu} = \dfrac{4 \cdot 0.005}{15 \times 10^{-6}} = 1333$; $\text{Nu}_p = 21.5$; $h = \dfrac{0.02}{0.005} \cdot 21.5 = 86 \dfrac{\text{W}}{\text{m}^2 \cdot \text{K}}$; $k = \dfrac{86}{1600} = 0.054 \dfrac{\text{kg}}{\text{m}^2 \cdot \text{s}}$; $\dfrac{A_p}{V_p} = \dfrac{6}{0.75 \cdot 0.005} = 1600\ \text{m}^{-1}$.

Plugging into Eq. (12-98) gives 0.

$$\frac{d\bar{X}}{dt} = f \frac{0.054 \cdot 1600}{600}(0.48 - \bar{Y}) = 0.14 \cdot f \cdot (0.48 - \bar{Y}) \tag{12-104}$$

As stated prior to this example, most of the drying in a cascading rotary dryer occurs while the particles are falling through the air. In this example, we will assume that is when all the drying occurs. We will also assume that while a particle is falling, the temperature can be calculated using a quasi-steady-state approximation. This means that we equate the heat transfer to the particle by convection to the evaporative cooling caused by drying, and we neglect the energy accumulation term.

$$h(T_G - T_S) = f \cdot N_w \cdot \Delta H_{\text{vap}} \tag{12-105}$$

where $N_w$ is the maximum (unhindered) drying rate. For completely unhindered drying, $f = 1$ and $T_S$ (the temperature of the solid) equals the wet-bulb temperature $T_W$. Plugging those into Eq. (12-105) and taking the ratio give

$$f = \frac{T_G - T_S}{T_G - T_W} \tag{12-106}$$

Now that the relationships are defined, we can perform the incremental calculation using a spreadsheet. This is shown in Table 12-31. We begin with column 2, where we set the increments of dry-basis moisture $X$ from the inlet to the exit of the dryer (which are known from the problem statement). The number of increments used is arbitrary; a higher number will give a more precise solution. Column 3 is the average of $X$ in each increment of column 1. Column 4 is the gas-phase composition $Y$, as calculated from Eq. (12-98).

Column 5 is the gas temperature, which is obtained from the Mollier diagram in Fig. 12-68. Mollier diagrams are explained in the Psychrometry subsection. The gas temperature cools due to the evaporation of water; the line on the diagram is an adiabatic saturation line. The first point to mark on the diagram, indicated by a star, is the inlet air condition (absolute humidity = 0.1 g/g and 800°C). The wet-bulb temperature of this air is 78°C, obtained by following the adiabatic saturation line to the saturation curve at the bottom and reading the temperature. If calculations are preferred to using the diagram, Eq. (12-6) may be used for the gas temperature and the procedure described in Table 12-5vi can be used to calculate the wet-bulb temperature.

The values of $f$ in column 6 are calculated from the average solids moisture content, Eq. (12-94); the temperature of the solids in column 7 is calculated from Eq. (12-103); and the drying rate is calculated from Eq. (12-103). The required drying time for the increment of $\Delta X$ in column 2 is calculated using the drying rate in column 10 (rightmost column). The drying times for all increments add to 50.82 s.

The value of 50.82 s is the time required for the particles when they are falling through the air. However, most of the residence time of the particles in the dryer is spent slowly rotating on the flights in a dense phase. The next steps in this analysis are to estimate the ratio of the time falling in the airborne phase to that of the time in dense phase and then the time in the dense phase per unit length of the dryer.

To estimate the time of the particles in the dense phase, we can use Eq. (12-87).

$$\frac{\tau_S}{\tau_G} = \frac{t_d}{t_f} = \frac{K_{fl}}{N}\sqrt{\frac{g}{D}} = \frac{0.4}{0.04\ \text{s}^{-1}}\sqrt{\frac{9.81\ \text{m/s}^2}{1.5\ \text{m}}} = 25.6 \tag{12-107}$$

$$\tau_S = 25.6 \cdot 50.8 = 1300\ \text{s}$$

The total required residence time is therefore $\tau_S + \tau_G = \tau = 1350.8$ s.

**TABLE 12-31 Variation in Process Conditions for the Example of a Cocurrent Cascading Rotary Dryer**

| out | 0.150 | **Total required gas-phase residence time (s) = 50.82 s (summation of last column)** | | | | | | | |

The length of dryer per second of residence time can be estimated by using Eq. (12-89).

First we need to calculate the particle velocity due to air drag while falling. Since $Re_p = 1300$, we use Eqs. (12-83) and (12-84).

$$U_{P1}^{d} = 125 \cdot \frac{\mu \cdot U_{G,\text{super}} t_a^*}{\rho_p d_p^2} = 125 \cdot \frac{1.8 \times 10^{-5} \dfrac{\text{kg}}{\text{m}\cdot\text{s}} \cdot \dfrac{4 \text{ m}}{\text{s}} \cdot 0.554 \text{ s}}{\left(600 \dfrac{\text{kg}}{\text{m}^3}\right)(0.005 \text{ m})^2} = 0.332 \text{ m/s}$$

$$t_a^* = t_f = \left(\frac{2D}{g\cos\alpha}\right)^{1/2} K_{\text{fall}} = \left(\frac{2 \cdot 1.5}{9.81 \cos 4°}\right)^{1/2} (1.0) = 0.554 \text{ s}$$

We can apply Eq. (12-88), using $K_K/(K_{fl}\sqrt{2}) \approx 1$, $K_{fl} \approx 0.4$, $K_{\text{fall}} \approx 1$, and take $a$ to equal 2.5 (within the range of 1 to 4).

$$\frac{\tau}{L} = \frac{1.1}{(0.04 \text{ s}^{-1})(1.5 \text{ m})} \times \left[\tan 4° \cdot (1 + 2.5) + \frac{1}{0.4\sqrt{9.81 \dfrac{\text{m}}{\text{s}^2} \cdot 1.5 \text{ m}}} \cdot 0.332 \text{ m/s}\right] = 30 \text{ s/m}$$

Since = 1300 s, $L$ = 1350.2/30 = 45 m. The dryer length/diameter ratio is therefore 45 m/1.5 m = 30, which is significantly larger than the recommended ratio of between 5:1 and 10:1. The remedy would then be to use a larger dryer diameter and repeat these calculations. The larger dryer diameter would decrease the gas velocity, slowing the particle velocity along the drum, increasing the residence time per unit length, and hence decreasing the required drum length, to give a more normal length/diameter ratio.

***Performance and Cost Data for Direct Heat Rotary Dryers*** Table 12-32 gives estimating-price data for direct rotary dryers employing steam-heated air. Higher-temperature operations requiring combustion chambers and fuel burners will cost more. The total installed cost of rotary dryers including instrumentation, auxiliaries, allocated building space, etc., will run from 150 to 300 percent of the purchase cost. Simple erection costs average 10 to 20 percent of the purchase cost.

Operating costs will include 5 to 10 percent of one worker's time, plus power and fuel required. Yearly maintenance costs will range from 5 to 10 percent of total installed costs. Total power for fans, dryer drive, and feed and product conveyors will be in the range of $0.5D^2$ to $1.0D^2$. Thermal efficiency of a high-temperature direct heat rotary dryer will range from 55 to 75 percent and, with steam-heated air, from 30 to 55 percent.

Table 12-32 gives some performance data for some cocurrent rotary dryers. A representative list of materials dried in direct heat rotary dryers is given in Table 12-33.

***Indirect Heat Rotary Steam-Tube Dryers*** Probably the most common type of indirect heat rotary dryer is the steam-tube dryer (Fig. 12-69). Steam-heated tubes running the full length of the cylinder are fastened symmetrically in one, two, or three concentric rows inside the cylinder and rotate with it. Tubes may be simple pipe with condensate draining by gravity into the discharge manifold or bayonet type. Bayonet-type tubes are also employed when units are used as water-tube coolers. When one is handling sticky materials, one row of tubes is preferred. These are occasionally shielded at the feed end of the dryer to prevent buildup of solids behind them. Lifting flights are usually inserted behind the tubes to promote solids agitation.

Wet feed enters the dryer through a chute or screw feeder. The product discharges through peripheral openings in the shell in ordinary dryers. These openings also serve to admit purge air to sweep moisture or other evolved gases from the shell. In practically all cases, gas flow is countercurrent to solids flow. To retain a deep bed of material within the dryer, normally a 10 to 20 percent fill level, the discharge openings are supplied with removable chutes extending radially into the dryer. These, on removal, permit complete emptying of the dryer.

Steam is admitted to the tubes through a revolving steam joint into the steam side of the manifold. Condensate is removed continuously, by gravity through the steam joint to a condensate receiver and by means of lifters in the condensate side of the manifold. By employing simple tubes, noncondensibles are continuously vented at the other ends of the tubes through

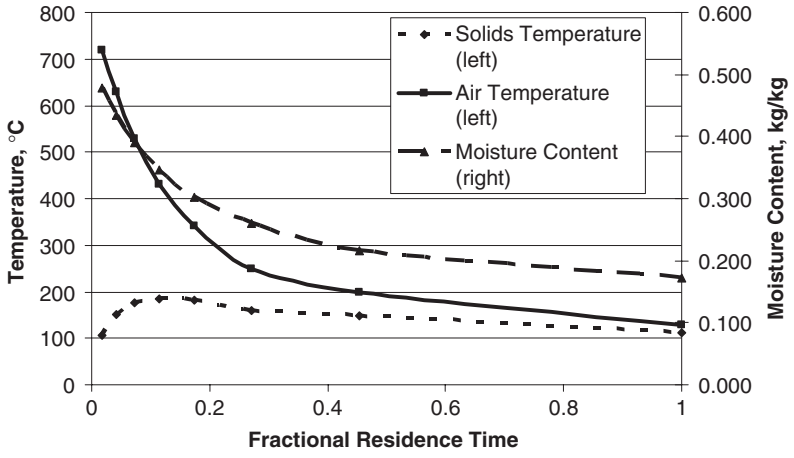

**FIG. 12-68** Typical variation of process conditions through a cocurrent cascading rotary dryer.

NOTE:
Material: heat-sensitive solid
Maximum solids temperature: 65°C
Feed conditions: 25 percent moisture, 27°C
Product conditions: 0.5 percent moisture, 65°C
Inlet-air temperature: 165°C
Exit-air temperature: 71°C
Assumed pressure drop in system: 200 mm
System includes finned air heaters, transition piece, dryer, drive, product collector, duct, and fan.
Prices are for carbon steel construction and include entire dryer system (November, 1994).
For 304 stainless-steel fabrication, multiply the prices given by 1.5.

Sarco-type vent valves mounted on an auxiliary manifold ring, also revolving with the cylinder.

Vapors ( from drying) are removed at the feed end of the dryer to the atmosphere through a natural-draft stack and settling chamber or wet scrubber. When employed in simple drying operations with $3.5 \times 10^5$ to $10 \times 10^5$ Pa steam, draft is controlled by a damper to admit only sufficient outside air to sweep moisture from the cylinder, discharging the air at 340 to 365 K and 80 to 90 percent saturation. In this way, shell gas velocities and dusting are minimized. When used for solvent recovery or other processes requiring a sealed system, sweep gas is recirculated through a scrubber-gas cooler and blower.

Steam-tube dryers are used for the continuous drying, heating, or cooling of granular or powdery solids which cannot be exposed to ordinary atmospheric or combustion gases. They are especially suitable for fine, dusty particles because of the low gas velocities required for purging of the cylinder. Tube sticking is avoided or reduced by employing recycle, shell knockers, etc., as previously described; tube scaling by sticky solids is one of the major hazards to efficient operation. The dryers are suitable for drying, solvent recovery, and chemical reactions. Steam-tube units have found effective employment in soda ash production, replacing more expensive indirect heat rotary calciners.

**TABLE 12-33 Representative Materials Dried in Direct-Heat Rotary Dryers***

| Material dried | Moisture content, % (wet basis) | | Heat efficiency % |
|---|---|---|---|
| | Initial | Final | |
| High-temperature: | | | |
| Sand | 10 | 0.5 | 61 |
| Stone | 6 | 0.5 | 65 |

*Design methods for indirect heat rotary steam-tube dryers* Heat-transfer coefficients in steam-tube dryers range from 30 to 85 W/(m$^2$·K). Coefficients will increase with increasing steam temperature because of increased heat transfer by radiation. In units carrying saturated steam at 420 to 450 K, the heat flux will range from 6300 W/m$^2$ for difficult-to-dry and organic solids to 1890 to 3790 W/m$^2$ for finely divided inorganic materials. The effect of steam pressure on heat-transfer rates up to $8.6 \times 10^5$ Pa is illustrated in Fig. 12-70.

*Performance and cost data for indirect heat rotary steam-tube dryers* Table 12-34 contains data for a number of standard sizes of steam-tube dryers. Prices tabulated are for ordinary carbon-steel construction. Installed costs will run from 150 to 300 percent of the purchase cost.

The thermal efficiency of steam-tube units will range from 70 to 90 percent, if a well-insulated cylinder is assumed. This does not allow for boiler efficiency, however, and is therefore not directly comparable with direct heat units such as the direct heat rotary dryer or indirect heat calciner.

Operating costs for these dryers include 5 to 10 percent of one person's time. Maintenance will average 5 to 10 percent of the total installed cost per year. Table 12-35 outlines typical performance data from three drying applications in steam-tube dryers.

***Indirect Rotary Calciners and Kilns*** These large-scale rotary processors are used for very high temperature operations. Operation is similar to that of rotary dryers. For additional information, refer to Perry's 7th Edition, pages 12-56 to 12-58.

***Indirect Heat Calciners*** Indirect heat rotary calciners, either batch or continuous, are employed for heat treating and drying at higher temperatures than can be obtained in steam-heated rotating equipment. They generally require a minimum flow of gas to purge the cylinder, to reduce dusting, and are suitable for gas-sealed operation with oxidizing, inert, or reducing atmospheres. Indirect calciners are widely utilized, and some examples of specific applications are as follows:

1. Activating charcoal
2. Reducing mineral high oxides to low oxides
3. Drying and devolatilizing contaminated soils and sludges
4. Calcination of alumina oxide–based catalysts
5. Drying and removal of sulfur from cobalt, copper, and nickel
6. Reduction of metal oxides in a hydrogen atmosphere
7. Oxidizing and "burning off" of organic impurities
8. Calcination of ferrites

This unit consists essentially of a cylindrical retort, rotating within a stationary insulation-lined furnace. The latter is arranged so that fuel combustion occurs within the annular ring between the retort and the furnace.

To prevent sliding of solids over the smooth interior of the shell, agitating flights running longitudinally along the inside wall are frequently provided. These normally do not shower the solids as in a direct heat vessel, but merely prevent sliding so that the bed will turn over and constantly expose new surface for heat and mass transfer. To prevent scaling of the shell interior by sticky solids, cylinder scraper and knocker arrangements are occasionally employed. For example, a scraper chain is fairly common practice in soda ash calciners, while knockers are frequently utilized on metallic oxide calciners.

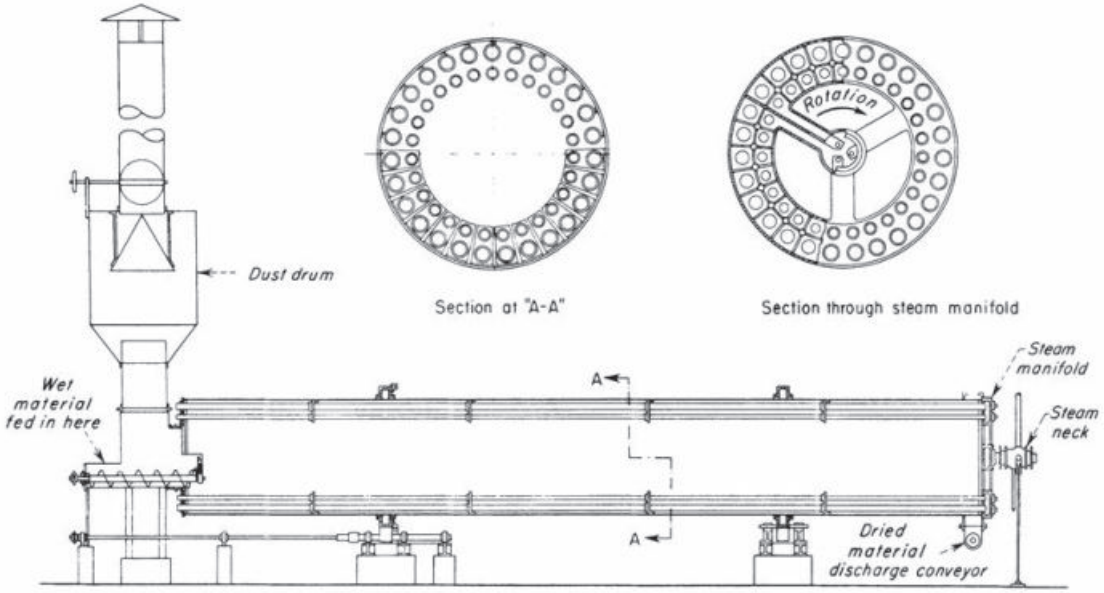

**FIG. 12-69** Steam-tube rotary dryer.

In general, the temperature range of operation for indirect heat calciners can vary over a wide range, from 475 K at the low end to approximately 1475 K at the high end. All types of carbon steel, stainless, and alloy construction are used, depending upon the temperature, process, and corrosion requirements.

*Design methods for calciners* In indirect heat calciners, heat transfer is primarily by radiation from the cylinder wall to the solids bed. The thermal efficiency ranges from 30 to 65 percent. By utilization of the furnace exhaust gases for preheated combustion air, steam production, or heat for other process steps, the thermal efficiency can be increased considerably. The limiting factors in heat transmission lie in the conductivity and radiation constants of the shell metal and solids bed. If the characteristics of these are known, equipment may be accurately sized by employing the Stefan-Boltzmann radiation equation. Apparent heat-transfer coefficients will range from 17 $W/(m^2 \cdot K)$ in low-temperature operations to 85 $W/(m^2 \cdot K)$ in high-temperature processes.

*Cost data for calciners* Power, operating, and maintenance costs are similar to those previously outlined for direct and indirect heat rotary dryers. Estimating purchase costs for preassembled and frame-mounted rotary calciners with carbon-steel and type 316 stainless-steel cylinders are given in Table 12-36 together with size, weight, and motor requirements. Sale price includes the cylinder, ordinary angle seals, furnace, drive, feed conveyor, burners, and controls. Installed cost may be estimated, not including building or foundation costs, at up to 50 percent of the purchase cost. A layout of a typical continuous calciner with an extended cooler section is illustrated in Fig. 12-71.

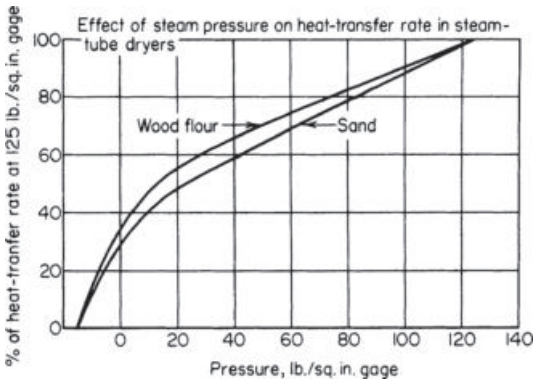

**FIG. 12-70** Effect of steam pressure on the heat-transfer rate in steam-tube dryers.

***Direct Heat Roto-Louvre Dryer*** One of the more important special types of rotating equipment is the Roto-Louvre dryer. As illustrated in Fig. 12-72, hot air (or cooling air) is blown through louvres in a double-wall rotating cylinder and up through the bed of solids. The latter moves continuously through the cylinder as it rotates. Constant turnover of the bed ensures uniform gas contacting for heat and mass transfer. The annular gas passage behind the louvres is partitioned so that contacting air enters the cylinder only beneath the solids bed. The number of louvres covered at any one time is roughly 30 percent. Because air circulates through the bed, fillage levels of 13 to 15 percent or greater are employed.

Roto-Louvre dryers range in size from 0.8 to 3.6 m in diameter and from 2.5 to 11 m long. The largest unit is reported capable of evaporating 5500 kg/h of water. Hot gases from 400 to 865 K may be employed. Because gas flow is through the bed of solids, high pressure drop, from 7 to 50 cm of water, may be encountered within the shell. For this reason, both a pressure inlet fan and an exhaust fan are provided in most applications to maintain the static pressure within the equipment as close as possible to atmospheric.

Roto-Louvre dryers are suitable for processing coarse granular solids which do not offer high resistance to airflow, do not require intimate gas contacting, and do not contain significant quantities of dust.

Heat transfer and mass transfer from the gas to the surface of the solids are extremely efficient; hence the equipment size required for a given duty is frequently less than that required when an ordinary direct heat rotary vessel with lifting flights is used. Purchase price savings are partially balanced, however, by the more complex construction of the Roto-Louvre unit. A Roto-Louvre dryer will have a capacity roughly 1.5 times that of a single-shell rotary dryer of the same size under equivalent operating conditions. Because of the cross-flow method of heat exchange, the average *temperature* is not a simple function of inlet and outlet temperatures. Three applications of Roto-Louvre dryers are outlined in Table 12-37. Installation, operating, power, and maintenance costs will be similar to those experienced with ordinary direct heat rotary dryers. *Thermal efficiency* will range from 30 to 70 percent.

### Fluidized-Bed and Spouted-Bed Dryers

***Examples and synonyms*** Fluid beds, fluidized beds, spouted beds, vibrating fluidized beds, vibro-fluidized bed.

***Description*** A fluidized bed is a deep layer of particles supported by both a distributor plate (containing numerous small holes) and the fluidizing gas. The bed has many properties of a liquid; the particles seek their own level, assume the shape of the vessel they are in, and exhibit buoyancy effects.

The basic principles of fluidized-bed technology are thoroughly described in Sec. 17, Gas-Solid Operations and Equipment. The technology has several advantages. These include no moving parts, rapid heat and mass transfer between gas and particles, rapid heat transfer between the gas/particle bed and immersed objects, intense mixing, and continuous or batch operation. These advantages allow fluidized beds to be used as both dryers and coolers.

As described in Sec. 17, the process parameter of the highest importance is the fluidizing gas velocity in the fluidized bed, also referred to as the superficial gas velocity. This velocity is of nominal character since the flow field will be disturbed and distorted by the presence of the solid phase and the turbulent fluctuations created by the gas/solid interaction.

Proper design and operation of a fluidized-bed dryer requires consideration of fluidization and drying characteristics of a material, the fluidization velocity, the particle size distribution, the design of the gas distributor plate, the operating conditions, and the mode of operation.

*Fluidization characteristics* have been investigated by Geldart, resulting in the well-known Geldart diagram (Fig. 12-73). The Geldart diagram shows that particulate material can be handled successfully in a fluidized bed only if it is not too fine or too coarse with a mean particle size between 20 μm and 10 mm. Fluidized beds are best suited for flowable particles that are regular in shape and not too sticky. Needle- or leaflike shaped particles should be considered as nonfluidizable.

The total drying time needed to reach the final moisture and the heat sensitivity of the material is an important parameter for design of an industrial plant. Small batch fluidized-bed tests can measure a drying curve as shown in Fig. 12-74. Figure 12-74*a* shows two drying curves for the same material. The curves differ based on the bed loading. The drying curves clearly show that the moisture is rapidly evaporating while the material is maintained at a low temperature. This particular material does not have a constant-rate period, evidenced by the decline in drying rate and rise of temperature with time. This is indicative of the drying of the surface of the particles; as they dry, the driving force for evaporation decreases. A moisture sorption isotherm, described in the Solids Drying Fundamentals subsection, is how this decrease can be quantified. The falling rate, by itself, does not mean that the rate is limited by internal mass transfer within each particle.

Additional drying curves can be measured to determine whether the drying rate of a material is internally or externally limited. Internally limited materials are slow to dry with moisture that is tightly bound and unable to move to the evaporating surface of the individual particles quickly enough; changes in superficial velocity and bed depth do not influence drying. Externally limited materials are influenced by the external drying conditions at which they are dried including both drying temperature and superficial gas velocity.

The drying curve data presented in Fig. 12-74*a* were normalized as shown in Fig. 12-74*b*. This suggests externally limited drying behavior. In this particular material, the rate is falling due to the dryness of the particles but not due to slow moisture transport through each particle. Rate-limiting steps in drying processes are described further in the Solids-Drying Fundamentals subsection; specifically, see Fig. 12-25.

See Table 12-38 to learn how to increase the throughput by using the air velocity or bed depth, depending on whether the drying rate is controlled externally or internally.

For production, increasing gas velocity is beneficial for externally limited materials, giving reduced drying time and either a higher throughput or a smaller bed area, but gives no real benefit for internally limited materials; likewise, increasing bed depth is beneficial for internally limited materials, giving either a higher throughput or enabling use of a smaller bed area with the same drying time but not for externally limited materials. However, using unnecessarily high gas velocity or an unnecessarily deep bed can increase the pressure drop, operating costs, elutriation, attrition, and backmixing.

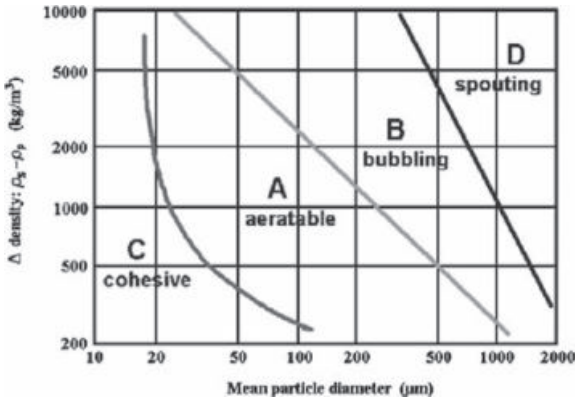

**FIG. 12-73** Geldart diagram.

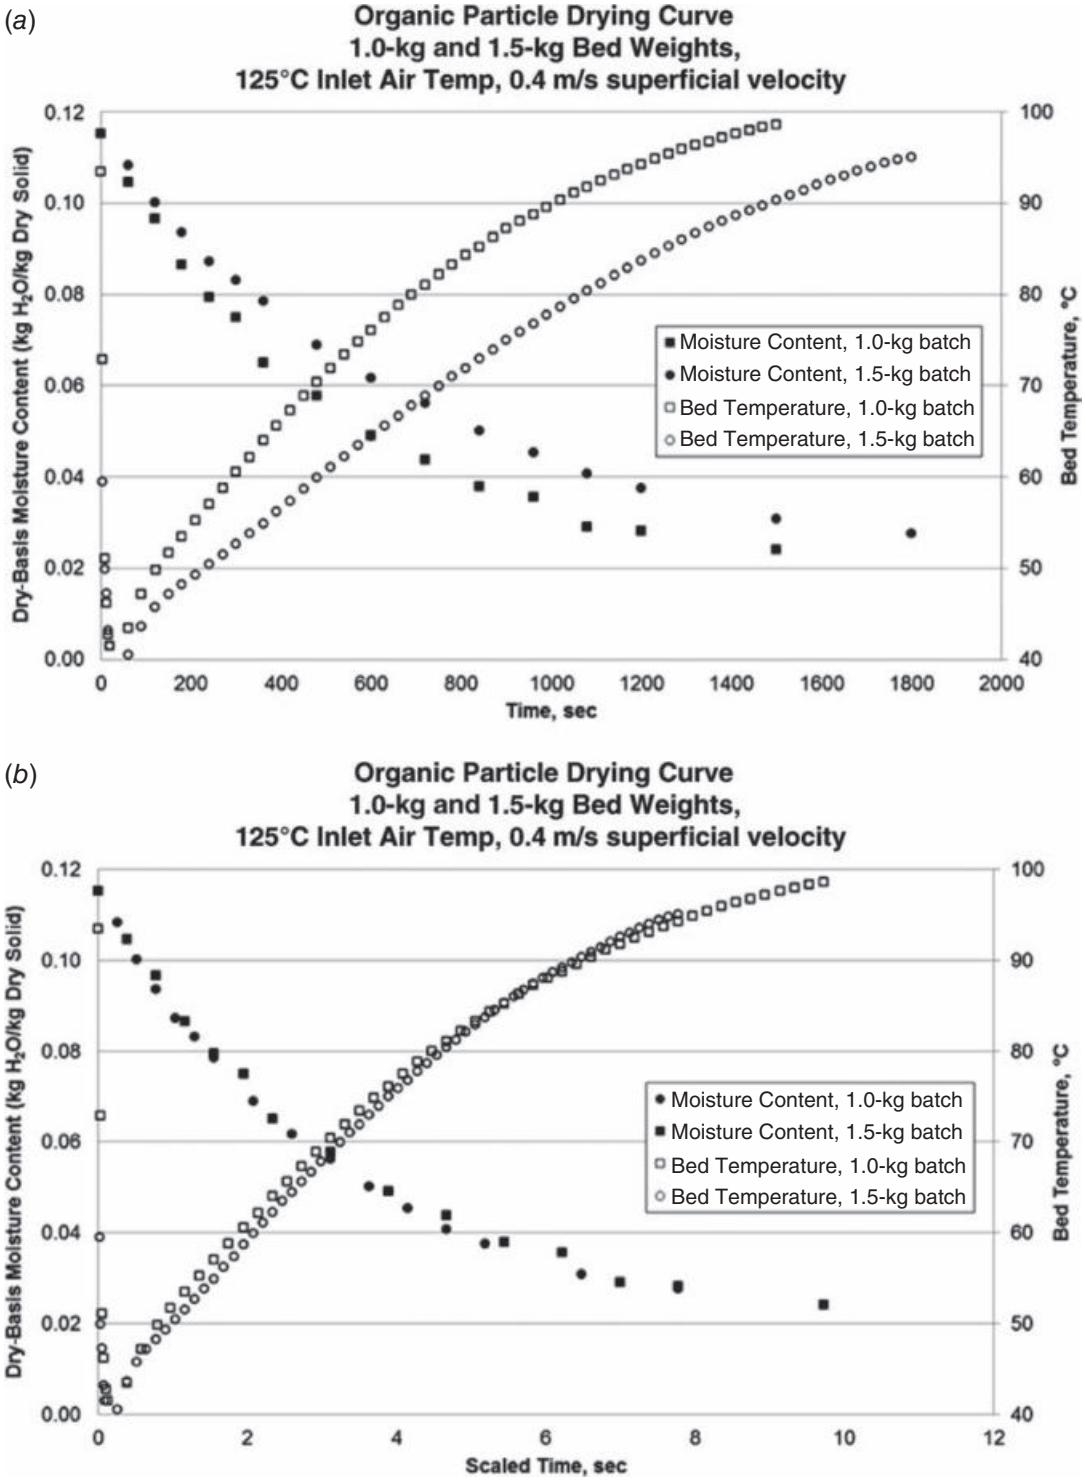

**FIG. 12-74** Drying curve of organic material.

The fluidization velocity is of major importance, as indicated in the introduction. Each material will have individual requirements for the gas velocity and pressure drop to provide good fluidization. An investigation of the relationship between fluidization velocity and bed pressure drop for a given material is called a *fluidization curve*. An example is shown in Fig. 12-75. The results are illustrative and intended to give a clear picture of the relationship. The minimum fluidization velocity can be estimated from the Wen and Yu correlation [*AIChE J.* **12**(3): 610–612 (1966)] given in Sec. 19.

At a superficial velocity below the value required for minimum fluidization, the pressure drop over the bed will increase proportionally with the velocity. Above a critical velocity, the pressure drop corresponds to the weight of the fluidized mass of material. This is referred to as the *minimum fluidization*; the bed is said to be in an incipiently fluidized state. A further increase in the superficial velocity will result in little or no increase in the pressure drop. The particle layer now behaves as a liquid, and the bed volume expands considerably. At even higher gas velocities the motion will be

**TABLE 12-38 Comparison of Internally and Externally Limited Drying**

| | | |
|---|---|---|
| **Internally limited drying** | | |
| **Batch** | Air velocity | 2X air velocity ≈ no change in drying time |
| | Bed depth | 2X bed depth ≈ no change in drying time |
| **Continuous** | Air velocity | 2X air velocity ≈ no change in production rate |
| | Bed depth | 2X bed depth ≈ production rate increases |
| **Externally limited drying** | | |
| **Batch** | Air velocity | 2X air velocity ≈ 1/2 drying time |
| | Bed depth | 2X bed depth ≈ 2X drying time |
| **Continuous** | Air velocity | 2X air velocity ≈ 2X production rate |
| | Bed depth | 2X bed depth ≈ no change in production rate |

stronger, and the excess gas flow will tend to appear as bubbles. In this state the particle layer will undergo vigorous mixing, while still appearing as a dense layer of fluidlike material or a boiling liquid. A further increase in the superficial velocity will result in the solid phase being entrained by the gas flow and will appear as lean phase pneumatic transport. Accordingly, the pressure drop falls to zero. Figure 17-4 provides examples of these fluidization regimes.

However, as a general recommendation, a value between the critical value and the value where the pressure drop falls off will be right. A first choice could be a factor of 2 to 5 times the minimum fluidization velocity. The fluidizing velocity value that will serve a drying task best cannot be derived exactly from the diagram and must be verified through experimentation.

There are additional consequences to using a high air velocity in fluidized beds such as particle elutriation and attrition. Given a particle size distribution in the bed, the finer particles will have a lower terminal velocity and will be selectively carried out of the bed, i.e., elutriated. See Geldart et al., "Entrainment of FCC from Fluidized Beds—a New Correlation for Elutriation Rate Constant $K^*_{i\infty}$," *Powder Technol.* **95:** 240–247 (1998), for more information on this transformation.

The design of the gas distributor plate is important for several reasons. First, the plate serves as a manifold, distributing fluidization and drying gas evenly and preventing dead spots in the bed. This requires an even pattern of orifices in the plate and a sufficient pressure drop over the plate. As a general rule, the pressure drop across the gas distributor should equal at least one-half of the pressure drop across the powder bed with the following range (of pressure drops across the plate) of 500 to 2500 Pa. The estimation of the pressure drop in design situations may be difficult except for the case of the traditional perforated sheet with cylindrical holes perpendicular to the plane of the plate, as shown in Fig. 12-76. For this type of plate, see McAllister et al., "Perforated-Plate Performance," *Chem. Eng. Sci.* **9:** 25–35 (1958). A calculation using this formula will show that a plate giving a required pressure drop of 1500 Pa and a typical fluidizing velocity of 0.35 m/s will need an open area of roughly 1 percent. Provided by a plate of 1-mm thickness and 1-mm-diameter holes, this requires approximately 12,732 holes per square meter.

However, this type of plate is being replaced in most fluid-bed applications because of its inherent disadvantages, which are caused by the manufacture of the plate, i.e., punching holes of a smaller diameter than the thickness of the plate itself. The result is that the plates are weak and are prone to sifting finer particles. The perpendicular flow pattern also means that the plate does not provide a transport capacity for lumps of powder along the plane of the plate.

**FIG. 12-76** Traditional perforated plate for fluid-bed application.

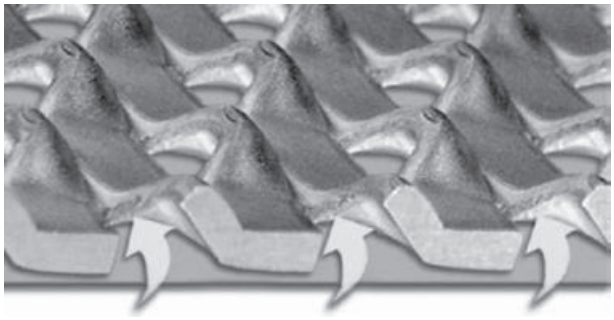

**FIG. 12-77** Conidur plate for fluid-bed application. (*Hein, Lehmann Trenn- und Fördertechnik GmbH.*)

**FIG. 12-78** Gill Plate for fluid-bed application. (*GEA*)

This transport capacity is provided by so-called gill-type plates of which there are two distinct categories. One category is the type where plates are punched in a very fine regular pattern, not only to provide holes or orifices but also to deform the plate so that each orifice acquires a shape suited for acceleration of the gas flow in magnitude and direction. An example of this type is shown in Fig. 12-77, representing the Conidur type of plate.

The particular feature of Conidur sheets is the specific hole shape which creates a directional airflow to help in discharging the product and influences the retention time in the fluid bed. The special method of manufacturing Conidur sheets enables finishing of fine perforations in sheets with an initial thickness many times over the hole width. Perforations of only 100 μm in an initial sheet thickness of 0.7 mm are possible. With holes this small 1 $m^2$ of plate may comprise several hundred thousand individual orifices.

The capacity of contributing to the transport of powder in the plane of the plate due to the horizontal component of the gas velocity is also the present for the second category of plates of the gill type. Figure 12-78 shows an example.

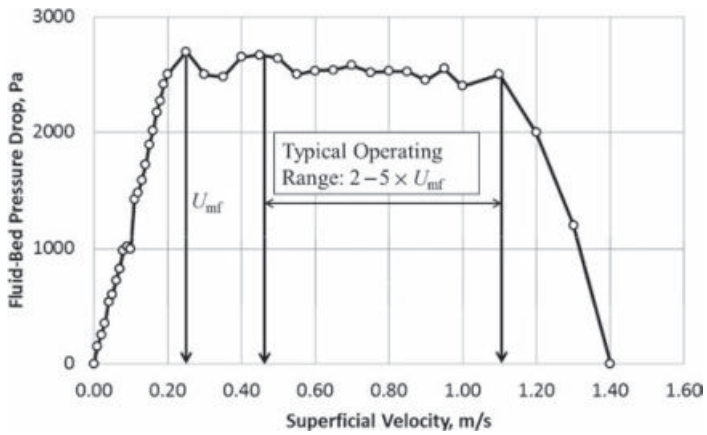

**FIG. 12-75** Fluid-bed pressure drop versus fluidizing velocity. (*revised, GEA*)

**FIG. 12-79** Non-sifting Gill Plate. (*Patented by GEA*)

In this type of plate, the holes or orifices are large, and the number of gills per square meter is just a few thousand. The gas flow through each of the gills has a strong component parallel to the plate, providing powder transport capacity as well as a cleaning effect. The gills are punched individually or in groups and can be oriented individually to provide a possibility of articulating the horizontal transport effect.

In certain applications in the food and pharmaceutical industries, the nonsifting property of a fluid-bed plate is particularly appreciated. This property of a gill-type plate can be enhanced as illustrated in Fig. 12-79, where the hole after punching is additionally deformed so that the gill overlaps the orifice.

The final type of fluid-bed plate mentioned here is the so bubble plate type. Illustrated in Fig. 12-80, in principle it is a gill-type plate. The orifice is cut out of the plate, and the bubble is subsequently pressed so that the orifice is oriented in a predominantly horizontal direction. A fluid-bed plate will typically have only 1600 holes per $m^2$. By this technology a combination of three key features is established. The plate is nonsifting, it has directional transport capacity that can be articulated through individual orientation of bubbles, and it is totally free of cracks that may compromise sanitary aspects of the installation.

The operating conditions of a fluid bed are, to a high degree, dictated by the properties of the material to be dried. For most products, the temperature is of primary importance, since the fluidized state results in very high heat-transfer rates so that heat sensitivity may restrict temperature and thereby prolong process time.

To achieve the most favorable combination of conditions to carry out a fluid-bed drying process, it is necessary to consider the different modes of fluid-bed drying available.

**Industrial Fluid-Bed Drying** The first major distinction between fluid-bed types is the choice of mode: batch or continuous.

Batch fluid beds may appear in several forms. The process chamber has a perforated plate or screen in the bottom and a drying gas outlet at the top, usually fitted with an internal filter. The drying gas enters the fluid bed through a plenum chamber below the perforated plate and leaves through the filter arrangement. The batch of material is enclosed in the process chamber for the duration of the process.

Figure 12-81 shows a sketch of a typical batch fluid-bed dryer as used in the food and pharmaceutical industries. The process chamber is conical in order to create a freeboard velocity in the upper part of the chamber that is lower than the fluidizing velocity just above the plate. The enclosed product batch is prevented from escaping the process chamber and will therefore allow a freer choice of fluidizing velocity than is the case in a continuous fluid bed, as described later.

Continuous fluid beds may be even more varied than batch fluid beds. The main distinction between continuous fluid beds will be according to the solids flow pattern in the dryer. The continuous fluid bed will have an inlet point for moist granular materials to be dried and an outlet for the dried material. If the moist material is immediately fluidizable, it can be introduced directly onto the plate and led through the bed in a plug-flow pattern that will enhance control of product residence time and temperature control. If the moist granular material is too sticky or cohesive due to surface moisture and requires a certain degree of drying before fluidization, it can be handled by a backmix fluid bed, to be described later.

Continuous plug-flow beds are designed to lead the solids flow along a distinct path through the bed. Baffles will be arranged to prevent or limit solids mixing in the horizontal direction. Thereby the residence time distribution of the solids becomes narrow. The bed may be of cylindrical or rectangular shape.

The temperature and moisture contents of the solids will vary along the path of solids through the bed and thereby enable the solids to come close to equilibrium with the drying gas. A typical plug-flow fluid bed is shown in Fig. 12-82.

Continuous plug-flow beds of stationary as well as vibrating type may benefit strongly from use of the gill-type fluid-bed plates with the capacity for controlling the movement of powder along the plate and around bends and corners created by baffles. Proper use of these means may make it possible to optimize the combination of fluidization velocity, bed layer height, and powder residence time.

**FIG. 12-80** Bubble Plate. (*Patented by GEA.*)

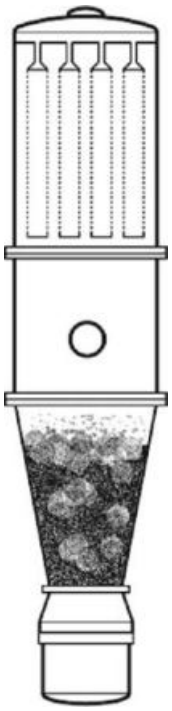

**FIG. 12-81** Batch-type fluid bed. (*Aeromatic-Fielder.*)

Continuous backmix beds are used in particular when the moist granular material needs a certain degree of drying before it can fluidize. By distributing the material over the surface of an operating fluid bed arranged for total solids mixing, also called *backmix flow*, it will be absorbed by the dryer material in the bed, and lumping as well as sticking to the chamber surfaces will be avoided. The distribution of the feed can be arranged in different ways, among which a rotary thrower is an obvious choice. A typical backmix fluid bed is shown in Fig. 12-83. Backmix fluid beds can be of box-shaped design or cylindrical.

The whole mass of material in the backmix fluid bed will be totally mixed, and all powder particles in the bed will experience the same air temperature regardless of their position on the drying curve illustrated in Fig. 12-74*a*. The residence time distribution becomes very wide, and part of the material may get a very long residence time while another part may get a very short time.

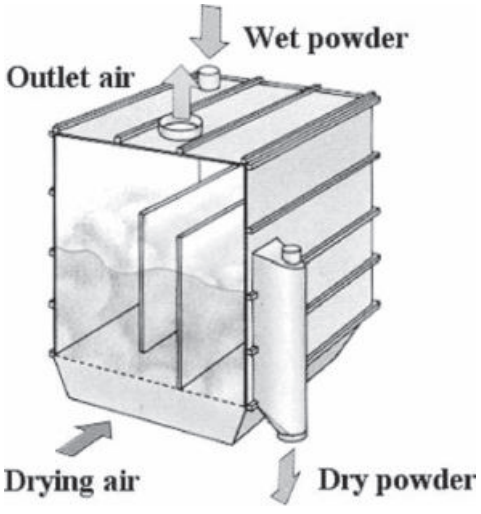

**FIG. 12-82** Continuous plug-flow fluid bed. (*GEA*)

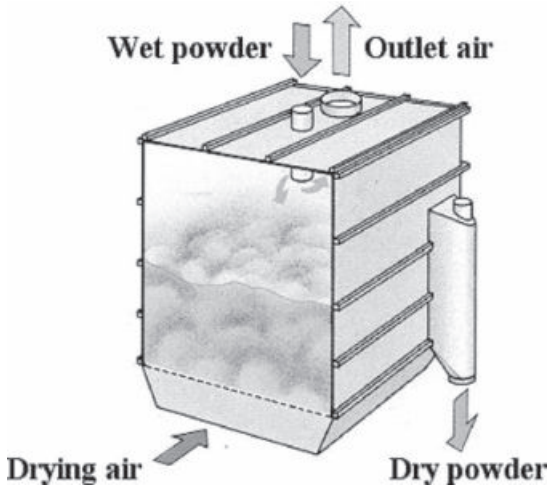

**FIG. 12-83** Continuous backmix fluid bed. (*GEA*)

Continuous-contact fluid beds are common in the chemical industry as the solution to the problem arising from materials requiring low fluidizing air temperature due to heat sensitivity and high energy input to complete the drying operation.

The main feature of the contact fluid bed is the presence of heating panels, which are plate or tube structures submerged in the fluidized-bed layer and heated internally by an energy source such as steam, water, or oil. The fluidized state of the bed provides very high heat-transfer rates between the fluidizing gas, the fluidized material, and any objects submerged in the bed. The result is that a very significant portion of the required energy input can be provided by the heating panels without risk of overheating the material. The fluidized state of the bed ensures that the material in the bed will flow with little restriction around the heating panels.

**Design and Scale-Up of Fluid Beds** When fluid-bed technology can be applied to drying of granular products, significant advantages compared to other drying processes can be observed. Design variables such as fluidizing velocity, critical moisture content for fluidization, and residence time required for drying to the specified residual moisture must, however, be established by experimental or pilot test before design steps can be taken. Reliable and highly integrated fluid-bed systems of either batch or continuous type can be designed, but only by using a combination of such pilot tests and industrial experience.

For scale-up based on an experimentally recorded batch drying curve, including performance mode calculations and altering operating conditions, Kemp and Oakley (2002) showed that the drying time for a given range of moisture content $\Delta X$ scales according to the following relationships:

$$\text{Externally limited (fast drying material):} \quad Z = \frac{\Delta\tau_2}{\Delta\tau_1} = \frac{(m_B/A)_2 G_1 (T_{GI} - T_{wb})_1}{(m_B/A)_1 G_2 (T_{GI} - T_{wb})_2} \tag{12-108}$$

$$\text{Internally limited (slow drying material):} \quad Z = \frac{\Delta\tau_2}{\Delta\tau_1} = \frac{(T_{GI} - T_{wb})_1}{(T_{GI} - T_{wb})_2} \tag{12-109}$$

Here 1 denotes experimental or original conditions and 2 denotes full-scale or new conditions; $Z$ is the normalization factor; $G$ is gas mass flux; $m_B/A$ is bed mass per unit area, proportional to bed depth $z$. This method can be used to scale a batch drying curve section by section. Almost always, one of these two simplified limiting cases applies, known as externally limited and internally limited normalization.

For a typical pilot-plant experiment, the fluidization velocity and temperature driving forces are similar to those of the full-size bed, but the bed diameter or depth can be much less. Hence, for externally limited normalization, the $m_B/A$ term dominates; $Z$ can be much greater than 1.

***Example 12-18 Scaling a Batch Fluidized-Bed Dryer*** An experimental batch drying curve has been measured at 100°C, and the drying time was 30 min. The bed diameter was 0.15 m with a bed mass of 1.0 kg. Assume that temperature driving forces are proportional to $T - T_{wb}$, with $T_{wb} = 30$°C and that the air mass flux = 0.55 kg/(m$^2 \cdot$ s). Assuming a scaling normalization factor of 2.5, calculate the bed area for a new dryer that can produce 1000 kg. The new bed will operate at 150°C with $T_{wb} = 38$°C and an air mass flux $G_2 = 0.75$ kg/(m$^2 \cdot$ s).

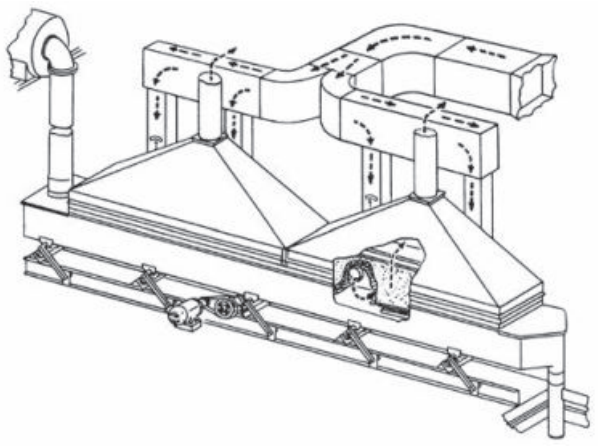

**FIG. 12-84** Vibrating conveyor dryer. (*Carrier Vibrating Equipment, Inc.*)

$$A = \frac{(1000\text{ kg})(0.55\text{ kg/m}^2\cdot\text{s})(150^\circ - 38^\circ)}{(1\text{ kg}/0.017\text{ m}^2)(0.75\text{ kg/m}^2\cdot\text{s})(100^\circ - 30^\circ)(2.5)} = 9.03\text{ m}^2$$

More complicated mathematical models exist for design and scaling of fluid-bed dryers, namely, those described by Tsotsas et al., "Experimental Investigation and Modelling of Continuous Fluidized Bed Drying under Steady-State and Dynamic Conditions," *Chem. Eng. Sci.* **57:** 5021–5038 (2002).

**Vibrating Fluidized-Bed Dryers** Information on vibrating conveyors and their mechanical construction is given in Sec. 21, Solids Processing and Particle Technology. The vibrating conveyor dryer is a modified form of fluidized-bed equipment, in which fluidization is maintained by a combination of pneumatic and mechanical forces. The heating gas is introduced into a plenum beneath the conveying deck through ducts and flexible hose connections and passes up through a screen, perforated, or slotted conveying deck, through the fluidized bed of solids, and into an exhaust hood (Fig. 12-84). If ambient air is employed for cooling, the sides of the plenum may be open and a simple exhaust system used; however, because the gas distribution plate may be designed for several inches of water pressure drop to ensure a uniform velocity distribution through the bed of solids, a combination pressure-blower exhaust-fan system is desirable to balance the pressure above the deck with the outside atmosphere and prevent gas in-leakage or blowing at the solids feed and exit points.

Units are fabricated in widths from 0.3 to 1.5 m. Lengths are variable from 3 to 50 m; however, most commercial units will not exceed a length of 10 to 16 m per section. Power required for the vibrating drive will be approximately 0.4 kW/m$^2$ of deck.

Capacity is primarily limited by the air velocity that can be used without excessive dust entrainment. Table 12-39 shows limiting air velocities suitable for various solids particles. Usually, the equipment is satisfactory for particles larger than 150 μm.

When a stationary vessel is employed for fluidization, all solids being treated must be fluidized; nonfluidizable fractions fall to the bottom of the bed and may eventually block the gas distributor. The addition of mechanical vibration to a fluidized system offers the following advantages:

1. Equipment can handle nonfluidizable solids fractions.
2. Prescreening or sizing of the feed is less critical than in a stationary fluidized bed.
3. Air channeling at the incipient fluidization velocity is reduced.

**TABLE 12-39 Estimating Maximum Superficial Air Velocities Through Vibrating-Conveyor Screens***

| | Velocity, m/s | |
|---|---|---|
| Mesh size | 2.0 specific gravity | 1.0 specific gravity |
| 200 | 0.22 | 0.13 |
| 100 | 0.69 | 0.38 |
| 50 | 1.4 | 0.89 |
| 30 | 2.6 | 1.8 |
| 20 | 3.2 | 2.5 |
| 10 | 6.9 | 4.6 |
| 5 | 11.4 | 7.9 |

*Carrier Vibrating Equipment, Inc.

4. Fluidization may be accomplished with lower pressures and gas velocities.
5. Vibrating conveyor dryers are suitable for free-flowing solids containing mainly surface moisture.

Retention is limited by conveying speeds which range from 0.02 to 0.12 m/s. Bed depth rarely exceeds 7 cm, although units are fabricated to carry 30- to 46-cm-deep beds; these also employ plate and pipe coils suspended in the bed to provide additional heat-transfer area. Vibrating dryers are not suitable for fibrous materials which mat or for sticky solids which may ball or adhere to the deck.

For estimating purposes for direct heat drying applications, it can be assumed that the average exit gas temperature leaving the solids bed will approach the final solids discharge temperature on an ordinary unit carrying a 5- to 15-cm-deep bed. Calculation of the heat load and selection of an inlet air temperature and superficial velocity (Table 12-39) will then permit approximate sizing, provided an approximation of the minimum required retention time can be made.

Vibrating conveyors employing direct contacting of solids with hot, humid air have also been used for the agglomeration of fine powders, chiefly for the preparation of agglomerated water-dispersible food products. Control of inlet air temperature and dew point permits the uniform addition of small quantities of liquids to solids by condensation on the cool incoming-particle surfaces. The wetting section of the conveyor is followed immediately by a warm-air drying section and particle screening.

*Spouted Beds* The spouted-bed technique was developed primarily for solids too coarse to be handled in fluidized beds, typically classified as type D on the Geldart diagram.

Although their applications overlap, the methods of gas-solids mixing are completely different. A schematic view of a spouted bed is given in Fig. 12-85. Mixing and gas-solids contacting are achieved first in a fluid "spout," flowing upward through the center of a loosely packed bed of solids. Particles are entrained by the fluid and conveyed to the top of the bed. They then flow downward in the surrounding annulus as in an ordinary gravity bed, countercurrently to gas flow. The mechanisms of gas flow and solids flow in spouted beds were first described by Mathur and Gishler [*Am. Inst. Chem. Eng. J.* **1**(2): 157–164 (1955)]. Drying studies have been carried out by Cowan [*Eng. J.* **41:** 5, 60–64 (1958)], and a theoretical equation for predicting the minimum fluid velocity necessary to initiate spouting was developed by Madonna and Lama [*Am. Inst. Chem. Eng. J.* **4**(4): 497 (1958)]. Investigations to determine maximum spoutable depths and to develop theoretical relationships based on vessel geometry and operating variables have been carried out by Lefroy [*Trans. Inst. Chem. Eng.* **47**(5): T120–128 (1969)] and Reddy [*Can. J. Chem. Eng.* **46**(5): 329–334 (1968)]. Information on the scale-up of spouted beds is provided by Passos, Mujumdar, and Massarani [*Drying Technol.* **12**(1–2): 351–391 (1994)].

Gas flow in a spouted bed is partially through the spout and partially through the annulus. About 30 percent of the gas entering the system immediately diffuses into the downward-flowing annulus. Near the top of the bed, the quantity in the annulus approaches 66 percent of the total gas flow; the gas flow through the annulus at any point in the bed equals that which would flow through a loosely packed solids bed under the same conditions of pressure drop. Solids flow in the annulus is both downward and slightly inward. As the fluid spout rises in the bed, it entrains more and more particles, losing velocity and gas into the annulus. The volume of solids displaced by the spout is roughly 6 percent of the total bed.

On the basis of experimental studies, Mathur and Gishler derived an empirical correlation to describe the minimum fluid flow necessary for spouting, in 3- to 12-in-diameter columns:

$$u = \frac{D_p}{D_c}\left(\frac{D_o}{D_c}\right)^{1/3}\left[\frac{2gL(\rho_s - \rho_f)}{\rho_f}\right]^{0.5} \qquad (12\text{-}110)$$

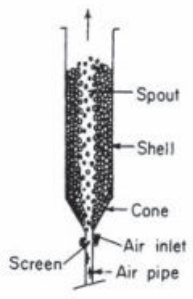

**FIG. 12-85** Schematic diagram of spouted bed. Schematic diagram of spouted bed. [Mathur and Gishler, *Am. Inst. Chem. Eng. J.* **1:** 2, 15 (1955).]

where $u$ = superficial fluid velocity through the bed; $D_p$ = particle diameter; $D_c$ = column (or bed) diameter; $D_o$ = fluid inlet orifice diameter; $L$ = bed height; $\rho_s$ = absolute solids density; $\rho_f$ = fluid density; and $g$ = gravity acceleration. The inlet orifice diameter, air rate, bed diameter, and bed depth were all found to be critical and interdependent:

1. In a given-diameter bed, deeper beds can be spouted as the gas inlet orifice size is decreased.
2. Increasing bed diameter increases spoutable depth.
3. As indicated by Eq. (12-110), the superficial fluid velocity required for spouting increases with bed depth and orifice diameter and decreases as the bed diameter is increased.

### Pneumatic Conveying Dryers

***Synonyms and Examples*** Flash dryer, spin flash dryer, ring dryer.

***Description*** Pneumatic conveyor dryers comprise a long tube or duct carrying a gas at high velocity, a fan to propel the gas, a suitable feeder for addition and dispersion of particulate solids in the gas stream, and a cyclone collector or other separation equipment for final recovery of solids from the gas.

Pneumatic conveying dryers simultaneously dry and convey particles by using high-velocity hot air. The quantity and velocity of the gas phase are sufficient to lift and convey the solids against the forces of gravity and friction. These systems are sometimes incorrectly called *flash dryers* when in fact the moisture is not actually "flashed" off. (True flash dryers are sometimes used for soap drying to describe moisture removal when pressure is quickly reduced.) Pneumatic systems may be distinguished by two characteristics:

1. Retention of a given solids particle in the system is on average very short, usually no more than a few seconds. This means that any process conducted in a pneumatic system cannot be internally controlled (diffusion-controlled). The solids particles must be so small that heat transfer and mass transfer from the interiors are essentially instantaneous.
2. On an energy content basis, the system is balanced at all times; i.e., there is sufficient energy in the gas (or solids) present in the system at any time to complete the work on all the solids (or gas) present at the same time. This is significant in that there is no lag in response to control changes or in starting up and shutting down the system; no partially processed residual solids or gas need be retained between runs.

It is for these reasons that pneumatic equipment is especially suitable for processing heat-sensitive, easily oxidized, explosive, or flammable materials which cannot be exposed to process conditions for extended periods.

The solids feeder may be of any type: Screw feeders, venturi sections, high-speed grinders, and dispersion mills are employed. For pneumatic conveyors, selection of the correct feeder to obtain thorough initial dispersion of solids in the gas is of major importance. For example, by employing an air-swept hammer mill in a drying operation, 65 to 95 percent of the total heat may be transferred within the mill itself if all the drying gas is passed through it. Fans may be of the induced-draft or the forced-draft type. The former is usually preferred because the system can then be operated under a slight negative pressure. Dust and hot gas will not be blown out through leaks in the equipment. Cyclone separators are preferred for low investment. If maximum recovery of dust or noxious fumes is required, the cyclone may be followed by a wet scrubber or bag collector.

Pneumatic conveyors are suitable for materials which are granular and free-flowing when dispersed in the gas stream, so they do not stick on the conveyor walls or agglomerate. Sticky materials such as filter cakes may be dispersed and partially dried by an air-swept disintegrator in many cases. Otherwise, dry product may be recycled and mixed with fresh feed, and then the two dispersed are together in a disintegrator. Coarse material containing internal moisture may be subjected to fine grinding in a hammer mill.

The main requirement in all applications is that the operation be instantaneously completed; internal diffusion of moisture must not be limiting in drying operations, and particle sizes must be small enough that the thermal conductivity of the solids does not control during heating and cooling operations. Pneumatic conveyors are rarely suitable for abrasive solids. Pneumatic conveying can result in significant particle size reduction, particularly when crystalline or other friable materials are being handled. This may or may not be desirable but must be recognized if the system is selected. The action is similar to that of a fluid-energy grinder.

Pneumatic conveyors may be single-stage or multistage. The former is employed for evaporation of small quantities of surface moisture. Multistage installations are used for difficult drying processes, e.g., drying heat-sensitive products containing large quantities of moisture and drying materials initially containing internal as well as surface moisture.

Typical single- and two-stage drying systems are illustrated in Figs. 12-86, 12-87, and 12-88. Figure 12-86 illustrates the flow diagram of a single-stage dryer with a paddle mixer, a screw conveyor followed by a rotary disperser for introduction of the feed into the airstream at the throat of a venturi section. The drying takes place in the drying column after which the dry product is collected in a cyclone. A diverter introduces the option of recycling part of the product into the mixer in order to handle somewhat sticky products. The environmental requirements are met with a wet scrubber in the exhaust stream.

Figure 12-87 illustrates a two-stage dryer where the initial feed material is dried in a flash dryer by using the spent drying air from the second stage. This semidried product is then introduced into the second-stage flash dryer for contact with the hottest air. This concept is in use in the pulp and paper industry. Its use is limited to materials that are dry enough on the surface after the first stage to avoid plugging of the first-stage cyclone. The main advantage of the two-stage concept is the heat economy which is improved considerably over that of the single-stage concept.

Figure 12-88 is an elevation view of an actual single-stage dryer. It employs an integral coarse-fraction classifier to separate undried particles for recycle.

Several typical products dried in pneumatic conveyors are described in Table 12-40.

*Design methods for pneumatic conveyor dryers* Depending upon the temperature sensitivity of the product, inlet air temperatures between 125 and 750°C are employed. With a heat-sensitive solid, a high initial moisture content should permit use of a high inlet air temperature. Evaporation of surface moisture takes place at essentially the wet-bulb air temperature. Until this has been completed, by which time the air will have cooled significantly, the surface-moisture film prevents the solids temperature from exceeding the wet-bulb temperature of the air. Pneumatic conveyors are used for solids having initial moisture contents ranging from 3 to 90 percent, wet basis. The air quantity required and solids-to-gas loading are fixed by

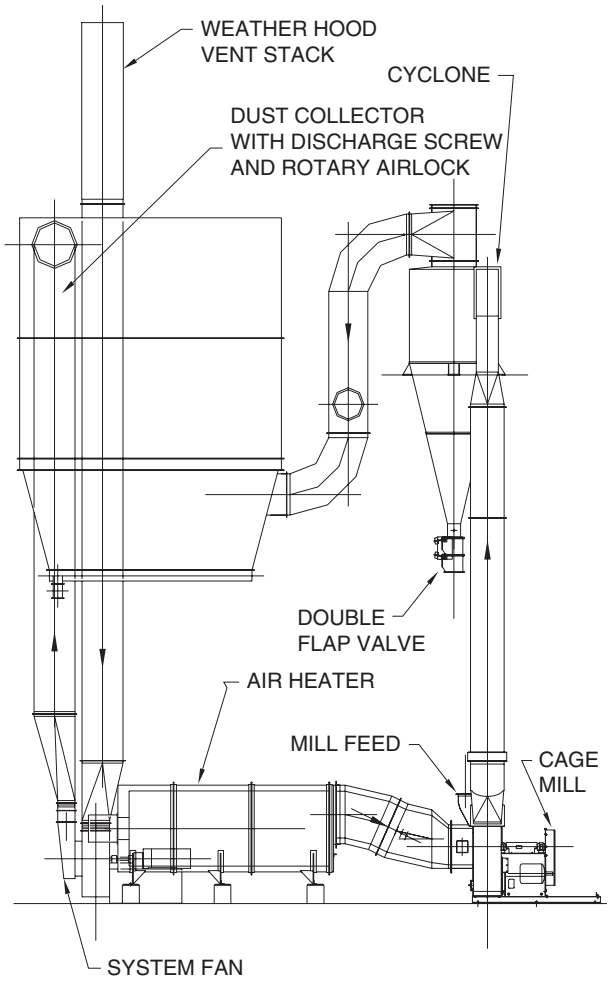

**FIG. 12-86** Flow diagram of single-stage flash dryer. (*Air Preheater Company, Raymond & Bartlett Snow Products.*)

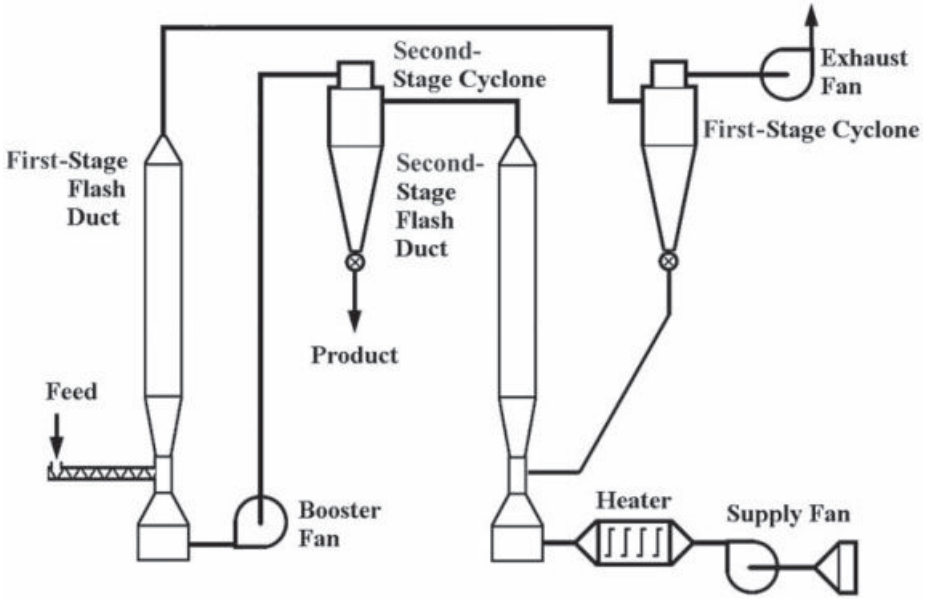

**FIG. 12-87** Flow diagram of countercurrent two-stage flash dryer. (*GEA*)

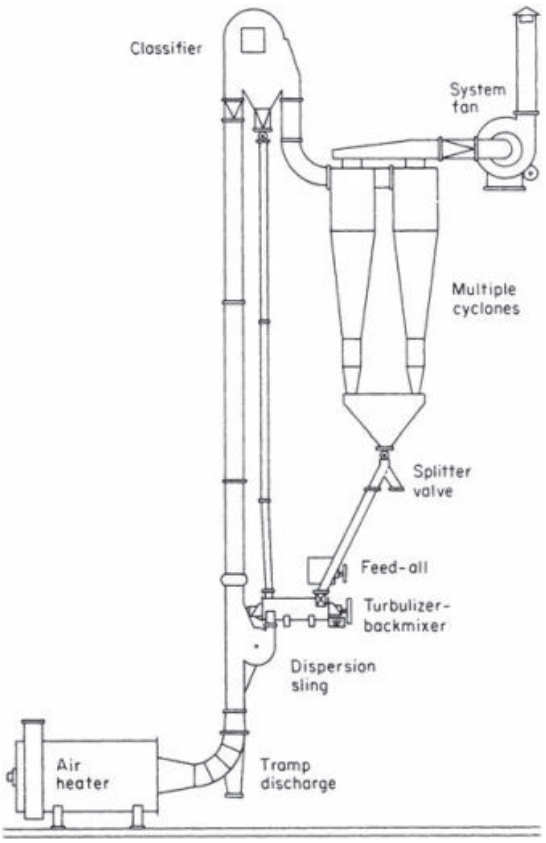

**FIG. 12-88** Flow diagram of Strong Scott flash dryer with integral coarse-fraction classifier. (*Bepex Corp.*)

the moisture load, the inlet air temperature, and frequently the exit air humidity. See Example 12-19 for a calculation of the mass and energy balance of a pneumatic conveying dryer. The gas velocity in the conveying duct must be sufficient to convey the largest particle. This may be calculated accurately by methods given in Sec. 17, Gas-Solids Operations and Equipment. For estimating purposes, a velocity of 25 m/s, calculated at the exit air temperature, is frequently employed. The exit solids temperature will approach the exit gas dry-bulb temperature.

Observation of operating conveyors indicates that the solids are rarely uniformly dispersed in the gas phase. With infrequent exceptions, the particles move in a streaklike pattern, following a streamline along the duct wall where the flow velocity is at a minimum. Complete or even partial diffusion in the gas phase is rarely experienced even with low-specific-gravity particles. Air velocities may approach 20 to 30 m/s. It is doubtful, however, that even finer and lighter materials reach more than 80 percent of this speed, while heavier and larger fractions may travel at much slower rates [Fischer, *Mech. Eng.* **81**(11): 67–69 (1959)]. Very little information and few operating data have been published on pneumatic conveyor dryers which would permit a true theoretical basis for design.

Therefore, firm design always requires pilot tests. It is believed, however, that the significant velocity effect in a pneumatic conveyor is the difference in velocities between gas and solids, which is strongly linked to heat- and mass-transfer coefficients and is the reason why a major part of the total drying actually occurs in the feed input section.

See Mills, D., *Pneumatic Conveying Design Guide*, 3d ed., Elsevier, Amsterdam, Netherlands, 2015 for comprehensive information on pneumatic conveying systems.

For estimating purposes, the conveyor cross-section is fixed by the assumed air velocity and quantity. The standard scoping design method is used, obtaining the required gas flow rate from a heat and mass balance, and the duct cross-sectional area and diameter from the gas velocity (if unknown, a typical value is 20 m/s). An incremental model may be used to predict drying conditions along the duct. However, several parameters are hard to obtain, and conditions change rapidly near the feed point. Hence, for reliable estimates of drying time and duct length, pilot-plant tests should always be used. A conveyor length larger than 50 duct diameters is rarely required. The length of the full-scale dryer should always be somewhat larger than required in pilot-plant tests, because wall effects are higher in small-diameter ducts. This gives greater relative velocity (and thus higher heat transfer) and lower particle velocity in the pilot-plant dryer, both effects giving a shorter length than the full-scale dryer for a given amount of drying. If desired, the length difference on scale-up can be predicted by using the incremental model and the pilot-plant data to back-calculate the uncertain parameters; see Kemp, *Drying Technol.* **12**(1&2): 279–297 (1994) and Kemp and Oakley (2002).

An alternative method of estimating dryer size very roughly is to estimate a volumetric heat-transfer coefficient [typical values are around 2000 J/($m^3 \cdot s \cdot K$)] and thus calculate dryer volume.

Pressure drop in the system may be computed by methods described in Sec. 6, Fluid and Particle Dynamics. To prevent excessive leakage into or out of the system, which may have a total pressure drop of 2000 to 4000 Pa, rotary air locks or screw feeders are employed at the solids inlet and discharge.

***Ring Dryers*** The ring dryer is a development of flash, or pneumatic conveyor, drying technology, designed to increase the versatility of application of this technology and overcome many of its limitations.

One of the great advantages of flash drying is the very short retention time, typically no more than a few seconds. However, in a conventional flash dryer, residence time is fixed, and this limits its application to materials in which the drying mechanism is not diffusion-controlled and where a range of moisture within the final product is acceptable. The ring dryer offers two advantages over the flash dryer. First, residence time is controlled by the use of an adjustable internal classifier that allows fine particles, which dry quickly, to leave while larger particles, which dry slowly, have an extended residence time within the system. Second, the combination of the classifier with an internal mill can allow simultaneous grinding and drying with control of product particle size and moisture. Available with a range of different feed systems to handle a variety of applications, the ring dryer provides wide versatility.

The essential difference between a conventional flash dryer and the ring dryer is the manifold centrifugal classifier. The manifold provides classification of the product about to leave the dryer by using differential centrifugal force.

**TABLE 12-40 Typical Products Dried in Pneumatic Conveyor Dryers (Barr-Rosin)**

| Material | Initial moisture, wet basis, % | Final moisture, wet basis, % | Plant configuration |
|---|---|---|---|
| Expandable polystyrene beads | 3 | 0.1 | Single-stage flash |
| Coal fines | 23 | 1.0 | Single-stage flash |
| Polycarbonate resin | 25 | 10 | Single-stage flash |
| Potato starch | 42 | 20 | Single-stage flash |
| Aspirin | 22 | 0.1 | Single-stage flash |
| Melamine | 20 | 0.05 | Single-stage flash |
| Com gluten meal | 60 | 10 | Feed-type ring dryer |
| Maize fiber | 60 | 18 | Feed-type ring dryer |
| Distillers dried grains (DDGs) | 65 | 10 | Feed-type ring dryer |
| Vital wheat gluten | 70 | 7 | Full-ring dryer |
| Casein | 50 | 10 | Full-ring dryer |
| Tricalcium phosphate | 30 | 0.5 | Full-ring dryer |
| Zeolite | 45 | 20 | Full-ring dryer |
| Orange peels | 82 | 10 | Full-ring dryer |
| Modified com starch | 40 | 10 | P-type ring dryer |
| Methylcellulose | 45 | 25 | P-type ring dryer |

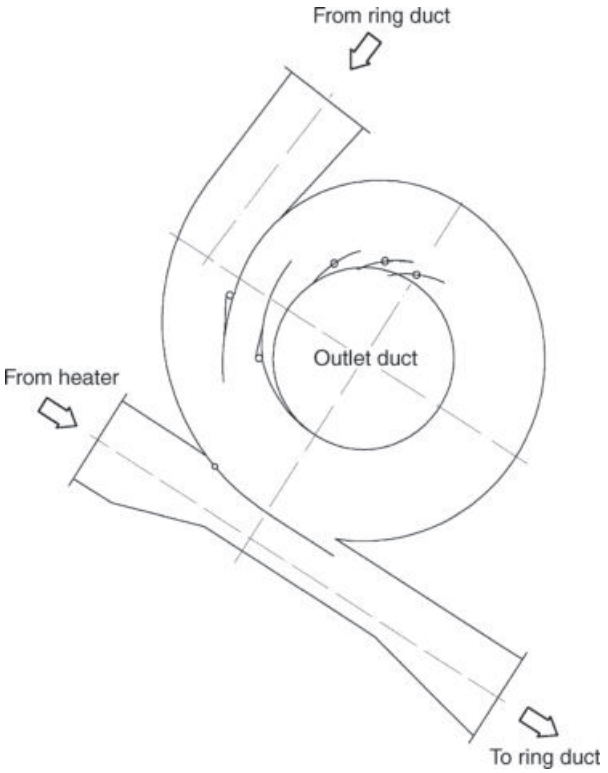

**FIG. 12-89** Full manifold classifier for ring dryer. (*Barr-Rosin.*)

The manifold, as shown in Fig. 12-89, uses the centrifugal effect of an airstream passing around the curve to concentrate the product into a moving layer, with the dense material on the outside and the light material on the inside.

This enables the adjustable splitter blades within the manifold classifier to segregate the denser, wetter material and return it for a further circuit of drying. Fine, dried material is allowed to leave the dryer with the exhaust air and to pass to the product collection system. This selective extension of residence time ensures a more evenly dried material than is possible from a conventional flash dryer. Many materials that have traditionally been regarded as difficult to dry can be processed to the required moisture content in a ring dryer. The recycle requirements of products in different applications can vary substantially depending upon the scale of operation, ease of drying, and finished-product specification. The location of reintroduction of undried material back into the drying medium has a significant impact upon the dryer performance and final-product characteristics.

The full ring dryer is the most versatile configuration of the ring dryer. See Fig. 12-90. It incorporates a multistage classifier which allows much higher recycle rates than the single-stage manifold. This configuration usually incorporates a disintegrator which provides adjustable amounts of product grinding depending upon the speed and manifold setting. For sensitive or fine materials, the disintegrator can be omitted. Alternative feed locations are available to suit the material sensitivity and the final-product requirements. The full ring configuration gives a very high degree of control of both residence time and particle size, and it is used for a wide variety of applications from small production rates of pharmaceutical and fine chemicals to large production rates of food products, bulk chemicals, and minerals.

Other ring dryer configurations are available, including ones that have a cyclone within the loop to enable readdition of larger particles to remix or redispersion with the feed.

An important element in optimizing the performance of a flash or ring dryer is the degree of dispersion at the feed point. Maximizing the product surface area in this region of highest evaporative driving force is a key objective in the design of this type of dryer. Ring dryers are fed using equipment similar to that of conventional flash dryers. Ring dryers with vertical configuration are normally fed by a flooded screw and a disperser which propels the wet feed into a high-velocity venturi, in which the bulk of the evaporation takes place. The full ring dryer normally employs an air-swept disperser or mill within the drying circuit to provide screenless grinding when required. Together with the manifold classifier this ensures a product with a uniform particle size. For liquid, slurry, or pasty feed materials, backmixing of the feed with a portion of the dry product will be carried out to produce a conditioned friable material. This further increases the versatility of the ring dryer, allowing it to handle sludge and slurry feeds with ease.

The air velocity required and air/solids ratio are determined by the evaporative load, the air inlet temperature, and the exhaust air humidity. Too high an exhaust air humidity would prevent complete drying, so then a higher air inlet temperature and air/solids ratio would be required. The air velocity within the dryer must be sufficient to convey the largest particle, or agglomerate. The air/solids ratio must be high enough to convey both the product and backmix, together with internal recycle from the manifold. For estimating purposes, a velocity of 25 m/s, calculated at dryer exhaust conditions, is appropriate for both pneumatic conveyor and ring dryers.

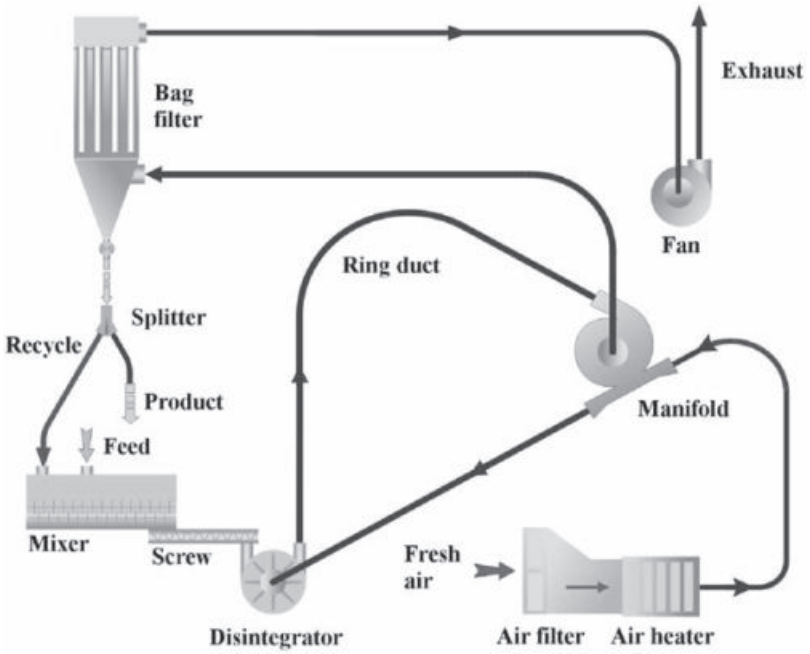

**FIG. 12-90** Flow diagram of full manifold-type ring dryer. (*Barr-Rosin.*)

***Example 12-19 Mass and Energy Balance for a Pneumatic Conveying Dryer*** Calculate the exit temperature and relative humidity of a pneumatic conveying system with an inlet air temperature, mass flow rate, and absolute humidity of 700°C, 9 kg/s, and 0.01 g/g, respectively. The feed material has a flow rate of 6.12 kg/s and wet-basis moisture content of 35 percent. Use the following physical properties: $C_{p,\text{air}} = 1.0\ \text{J/(g·K)}$, $C_{p,\text{dry solids}} = \text{J/(g·K)}$, $C_{p,\text{liquid water}} = 4.18\ \text{J/(g·K)}$, $C_{p,\text{water vapor}} = 2.0\ \text{J/(g·K)}$, and heat of vaporization of water (at 100°C) = 2257 J/g.

*Solution* First, assume all the water in the feed evaporates. If all the water in the feed evaporates, then the mass flow of water vapor exiting the dryer will equal the water vapor entering the dryer (0.01 · 9 kg/s) plus the water evaporated (0.35 · 6.12 kg/s), which equals 2.24 kg/s. The dry air feed rate is (1 – 0.01) · 9 kg/s, so the absolute humidity in the exhaust is 2.24/[(1 – 0.01) · 9] = 0.239 kg water vapor/kg dry air.

The energy balance can be calculated on a spreadsheet, by setting the sum of the enthalpy terms to zero and solving iteratively for $T_{\text{out}}$. The last three terms calculate the change of enthalpy of water entering as a liquid (within the solid) in the feed at one temperature and exiting as a vapor at a different temperature. Enthalpy is a state function, so we can choose any convenient calculation path. Since we have the heat of vaporization at 100°C, it is convenient to sum the energy terms for the heating of the liquid water to the evaporation temperature of 100°C, vaporize it at that temperature, then account for the enthalpy difference between water vaper at 100°C and the exit temperature. The solution for $T_{\text{out}}$ is 87°C in this case.

$$\begin{aligned} &G_{\text{dry air}}\, C_{p,\text{ air}}\,(T_{\text{air in}} - T_{\text{out}}) + G_{\text{water vapor out}}\, C_{p,\text{ water vapor}}\,(T_{\text{air in}} - T_{\text{out}}) \\ &\quad + F_{\text{solids in}}\, C_{p,\text{ solids}}\,(T_{\text{solids in}} - T_{\text{out}}) \\ &\quad + F_{\text{liquid water out}}\, C_{p,\text{ liquid water}}\,(T_{\text{solids in}} - T_{\text{evap}}) - G_{\text{evaporated}} \cdot \Delta H_{\text{vap}} \\ &\quad + G_{\text{evaporated}}\, C_{p,\text{ water vapor}}\,(T_{\text{evap}} - T_{\text{out}}) = 0 \end{aligned}$$

$$\begin{aligned} &(9.44)(1.0 - 0.01)(700 - 87) + (9.44)(0.01)(2.0)(700 - 87) \\ &\quad + (3.98)(1.46)(21 - 87) + (2.14)(4.18)(21 - 100) - (2.14)(2257) \\ &\quad + (2.14)(2.0)(100 - 87) = 0 \end{aligned}$$

Air at a temperature of 87°C and an absolute humidity of 0.239 kg/kg has a relative humidity of 45 percent. The *relative humidity* is the ratio of the partial pressure to the vapor pressure of pure water at the exhaust temperature. Table 12-1 can be used to calculate the partial pressure of water and Eq. (12-5) to calculate the vapor pressure of pure water.

An exhaust relative humidity of 45 percent may be too high for the product. To make this judgment, a moisture sorption isotherm is needed. If this product were to have an isotherm such as the one shown in Fig. 12-20, then the moisture of the product would be at least 8 percent exiting the dryer. To target a specific moisture content of the exiting material, the isotherm can be used to select a maximum exit relative humidity and the calculation above can be repeated. An isotherm equation could be included in the calculation algorithm, the assumption of complete evaporation can also be changed, and an estimate of heat losses to the environment can be included if more-exact calculations are needed.

***Agitated Flash Dryers*** Agitated flash dryers produce fine powders from feeds with high solids contents, in the form of filter cakes, pastes, or thick, viscous liquids. Many continuous dryers are unable to dry highly viscous feeds. Spray dryers require a pumpable feed. Conventional flash dryers often require backmixing of dry product to the feed in order to fluidize. Other drying methods for viscous pastes and filter cakes are well known, such as contact, drum, band, and tray dryers. They all require long processing time, large floor space, high maintenance, and aftertreatment such as milling.

The agitated flash dryer offers a number of process advantages, such as ability to dry pastes, sludges, and filter cakes to a homogeneous, fine powder in a single-unit operation; continuous operation; compact layout; effective heat- and mass-transfer short drying times; negligible heat loss and high thermal efficiency; and easy access and cleanability.

The agitated flash dryer (Fig. 12-91) consists of four major components: feed system, drying chamber, heater, and exhaust air system. Wet feed enters the feed tank, which has a slow-rotating impeller to break up large particles. The level in the feed tank is maintained by a level controller. The feed is metered at a constant rate into the drying chamber via a screw conveyor mounted under the feed tank. If the feed is shear-thinning and can be pumped, the screw feeder can be replaced by a positive displacement pump.

The drying chamber is the heart of the system consisting of three important components: air disperser, rotating disintegrator, and drying section. Hot, drying air enters the air disperser tangentially and is introduced into the drying chamber as a swirling airflow. The swirling airflow is established by a guide-vane arrangement. The rotating disintegrator is mounted at the base of the drying chamber. The feed, exposed to the hot, swirling airflow and the agitation of the rotating disintegrator, is broken up and dried. The fine, dry particles exit with the exhaust air and are collected in the bag filter. The speed of the rotating disintegrator controls the particle size. The outlet air temperature controls the product moisture content.

The drying air is heated either directly or indirectly, depending upon the feed material, powder properties, and available fuel source. The heat

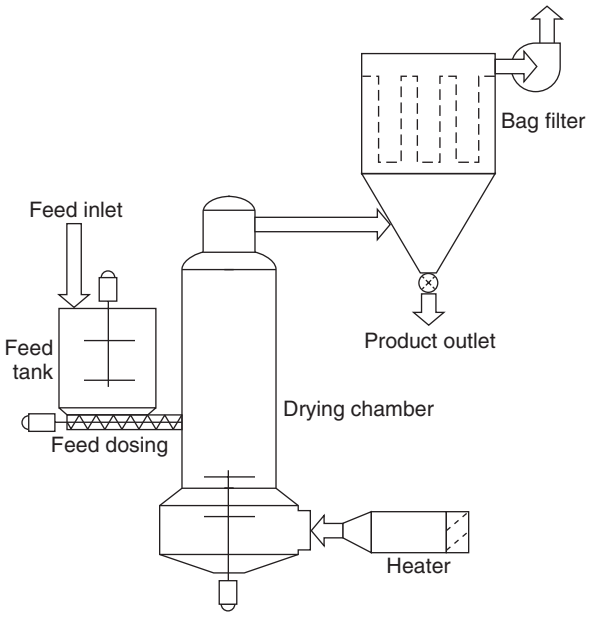

**FIG. 12-91** Agitated flash dryer with open cycle. (*GEA*)

sensitivity of the product determines the drying air temperature. The highest possible value is used to optimize thermal efficiency. A bag filter is usually recommended for collecting the fine particles produced. The exhaust fan maintains a slight vacuum in the dryer, to prevent powder leakage into the surroundings. The appropriate process system is selected according to the feed and powder characteristics, available heating source, energy utilization, and operational health and safety requirements.

Open systems use atmospheric air for drying. In cases where products pose a potential for dust explosion, plants are provided with pressure relief or suppression systems. For recycle systems, the drying system medium is recycled, and the evaporated solvent is recovered as condensate. There are two alternative designs. In the self-inertizing mode, oxygen content is held below 5 percent by combustion control at the heater. This is recommended for products with serious dust explosion hazards. In the inert mode, nitrogen is the drying gas. This is used when an organic solvent is evaporated or product oxidation during drying must be prevented.

*Design methods* The size of the agitated flash dryer is based on the evaporation rate required. The operating temperatures are product-specific. Once established, they determine the airflow requirements. The drying chamber is designed based on air velocity (approximately 3 to 4 m/s) and residence time (product-specific).

**Spray Dryers** Spray drying is a process for the transformation of a pumpable liquid feed into dried particulates in a single operation. The process comprises atomization of the feed followed by intense contact with hot air. The dry particulate product is formed while the spray droplets are still suspended in the hot drying air. The process is concluded by the separation and recovery of the product from the drying air.

*Industrial Applications* Thousands of products are spray-dried. The most common products may include agrochemicals, catalysts, ceramics, chemicals, detergents, dyestuffs and pigments, foodstuffs, pharmaceuticals, and waste products. A few examples are shown in Table 12-41.

For each of these product groups and any other product, successful drying depends on the proper selection of a plant concept and operational parameters, in particular inlet and outlet temperatures and the atomization method. The air temperatures are traditionally established through experiments and test work. The inlet temperatures reflect the heat sensitivity of the different products, and the outlet temperatures the willingness of the products to release moisture. The percentage of moisture in the feed is an indication of feed viscosity and other properties that influence the pumpability atomization behavior.

A spray-drying plant comprises six process stages, as shown in Table 12-42.

*Preatomization* Spray drying may require a number of operations prior to the drying process. These operations are meant to ensure optimal atomization processes for the given feedstock. Elements for preatomization include but are not limited to low- and/or high-pressure pumping, high-shear mixing and/or in-line milling, viscosity modifications, and preheating. These processes can be achieved by any number of unit operations or equipment.

**TABLE 12-41 Some Products That Have Been Successfully Spray-Dried**

| Product | Air temperature, K | | Water in feed, % | Air/evap. ratio, kg/kg | Air/prod. ratio, kg/kg |
|---|---|---|---|---|---|
| | In | Out | | | |
| Yeast | 500 | 335 | 86 | 15.4 | 96.2 |
| Zinc sulfate | 600 | 380 | 55 | 12.4 | 15.2 |
| Lignin | 475 | 365 | 63 | 24.3 | 41.4 |
| Aluminum hydroxide | 590 | 325 | 93 | 9.7 | 128.4 |
| Silica gel | 590 | 350 | 95 | 10.9 | 206.5 |
| Magnesium carbonate | 590 | 320 | 92 | 9.5 | 108.7 |
| Tannin extract | 440 | 340 | 46 | 26.4 | 22.5 |
| Coffee extract | 420 | 355 | 70 | 40.6 | 94.8 |
| Detergent | 505 | 395 | 50 | 25.4 | 25.4 |
| Manganese sulfate | 590 | 415 | 50 | 16.3 | 16.3 |
| Aluminum sulfate | 415 | 350 | 70 | 40.5 | 94.4 |
| Urea resin | 535 | 355 | 60 | 14.8 | 22.1 |
| Sodium sulfide | 500 | 340 | 50 | 16.5 | 16.5 |
| Pigment | 515 | 335 | 73 | 14.4 | 39 |

*Atomization Stage* Atomization creates very a large surface area which enables rapid evaporation from the droplets in the spray. For example, atomization of 1 L of water into a uniform spray of 100-μm droplets results in approximately $1.9 \times 10^9$ individual particles with a combined surface area of 60 $m^2$.

Atomization is the primary means to create the final particle attributes; the droplet size distribution from the nozzle directly affects the particle size distribution of the dry powder. Atomization fundamentals are discussed further in Sec. 14 of this text and in the Lefebvre and Lipp references at the end of this section. In this section, we focus on the most important elements of atomization for spray-drying applications.

*Choice of atomizer system* The choice of atomizer system for a specific spray-drying operation depends upon

1. The particle size distribution required in the final dried product
2. The physical and chemical properties of the feed liquid (e.g., rheology)
3. The shape of the drying chamber

In this subsection, we introduce and compare the three most common atomization methods for spray drying: rotary atomization, hydraulic nozzles (also called pressure nozzles), and two-fluid nozzles (also called pneumatic nozzles). Table 12-43 shows a comparison of these three methods.

Other specialized atomizers such as ultrasonic nozzles may be used; their use is severely limited based on high operating costs, low individual production rates, and inability to handle viscous feedstocks.

**TABLE 12-42 Stages of Spray Drying**

| Process stages for spray drying | Methods |
|---|---|
| 1. Preatomization | Pumping<br>In-line milling<br>Viscosity modification<br>Preheating |

| 3. Spray/hot air interaction | Cocurrent flow<br>Countercurrent flow<br>Mixed flow |
| 4. Evaporation | Drying<br>Particle morphology |
| 5. Post-treatment | Fluid-bed dryer<br>Sieve<br>Cooling<br>Agglomeration |
| 6. Recovery | Drying chamber<br>Dry collector<br>Wet collector |

*Rotary Atomizer* The liquid feed is supplied to the atomizer by gravity or hydraulic pressure. A liquid distributor system leads the feed to the inner part of a rotating wheel. Since the wheel is mounted on a spindle supported by bearings in the atomizer structure, the liquid distributor is usually formed as an annular gap or a ring of holes of various shapes or orifices concentric with the spindle and wheel. The liquid is forced to follow the wheel either by friction or by contact with internal vanes in the wheel. Due to the high centrifugal forces acting on the liquid, it moves rapidly toward the rim of the wheel, where it is ejected as a film or a series of jets or ligaments (see Fig. 12-92).

By interaction with the surrounding air, the liquid breaks up to form a spray of droplets of varying size. The spray pattern is virtually horizontal with a spray angle said to be 180°. The mean droplet size of the spray depends strongly on the atomizer wheel speed and to a much lesser degree on the feed rate and the feed physical properties such as viscosity. More details about spray characteristics such as droplet size distribution are given below.

As indicated earlier, the atomizer wheel speed is the important parameter influencing the spray droplet size and thus the particle size of the final product. Also important for the atomization process is the selection of a wheel capable of handling a specific liquid feed with characteristic properties such as abrasiveness, high viscosity/nonnewtonian behavior. A highly abrasive feedstock can quickly erode a wheel if proper materials are not used.

The most common design of atomizer wheel has radial vanes. This wheel type is widely used in the chemical industry and is virtually blockage-free and simple to operate, even at very high speed. For high-capacity applications, the number and height of the vanes may be increased to maintain limited liquid-film thickness conditions on each vane.

Wheels with radial vanes have one important drawback, i.e., their capacity for pumping large amounts of air through the wheel. This so-called air pumping effect causes unwanted product aeration, resulting in powders of low bulk density for some sensitive spray-dried products.

Unwanted air pumping effect and product aeration can be reduced through careful wheel design involving change of the shape of the vanes that may appear forward-curved, as seen in Fig. 12-93*a*. This wheel type is used widely in the dairy industry to produce powders of high bulk density. The powder bulk density may increase as much as 15 percent when a curved vane wheel is replacing a radial vane wheel of standard design.

Another way of reducing the air pumping effect is to reduce the space between the vanes so that the liquid feed takes up a larger fraction of the available cross-sectional area. This feature is used with the so-called bushing wheels shown in Fig. 12-93*b*. This wheel combines two important design aspects. The air pumping effect is reduced by reducing the flow area to a number of circular orifices, each 5 to 10 mm in diameter.

Table 12-44 gives the main operational parameters for three typical atomizers covering the wide range of capacity and size.

The Niro F1000 atomizer is one of the largest rotary atomizers offered to industry today. It has a capacity up to 200 ton/h in one single atomizer. As indicated above, the atomizer wheel speed is the important parameter influencing the spray droplet size. The wheel speed $U$ also determines the power consumption $P_s$ of the atomizer; see Table 12-44 for calculations and estimates for various atomizers. The capacity limit of an atomizer is normally its maximum power rating.

Since the atomizer wheel peripheral speed is proportional to the rotational speed, the maximum feed rate that can be handled by a rotary atomizer declines with the square of the rotational speed. The maximum feed rates indicated in Table 12-44 are therefore not available at the higher end of the speed ranges.

The rotary atomizer has one distinct advantage over other means of atomization. The degree or fineness of atomization achieved at a given speed is only slightly affected by changes in the feed rate. In other words, the rotary atomizer has a large turndown capability.

*Hydraulic pressure nozzle* In hydraulic pressure nozzles, the liquid is fed to the nozzle under pressure. In the nozzle orifice, the pressure energy is converted to kinetic energy. The internal parts of the nozzle are normally designed to apply a certain amount of swirl to the feed flow so that it issues from the orifice as a high-speed film in the form of a cone with a desired vertex angle (see Fig. 12-94). This film disintegrates readily into droplets due to instabilities. The vertex or spray angle is normally on the order of 50° to 80°, a much narrower spray pattern than is seen with rotary atomizers. This means that spray drying chamber designs for pressure nozzle atomization differ substantially from designs used with rotary atomizers. The droplet size distribution produced by a pressure nozzle atomizer varies inversely with the pressure and to some degree with the feed rate and viscosity. The capacity of a pressure nozzle varies with the square root of the pressure. To obtain a certain droplet size, the pressure nozzle must operate very close to the design pressure and feed rate. This implies that the pressure nozzle has very little turndown capability.

**TABLE 12-43 Comparison of Rotary, Hydraulic, and Two-Fluid Atomizers**

| Atomizer | Rotary | Hydraulic (Pressure) | Two-fluid |
|---|---|---|---|
| Advantages | High feed rates<br>Can tolerate abrasive materials<br>Negligible blocking<br>Low-pressure feed system<br>Simple size adjustment<br>Narrow size distribution<br>Minimal agglomeration<br>Large turndown | Simple construction<br>Low cost<br>Low energy consumption<br>Spray characteristic can be changed by nozzle design<br>Dryer chambers generally smaller than those for rotary | Can atomize highly viscous materials<br>Control of size, pattern, and capacity during operation<br>Low-pressure feed system<br>Dryer chambers generally smaller than those for rotary<br>Can produce sprays of high homogeneity and small size |
| Disadvantages | Higher energy consumption than pressure nozzles<br>Cannot tolerate highly viscous fluids<br>Requires a large chamber diameter | Control of size, pattern, and capacity during operation not possible<br>Swirl nozzles not suitable for suspensions due to phase separation<br>Tendency to clog<br>Wear can greatly affect nozzle performance<br>Requires high-pressure pumps<br>Low turndown | Higher cost than pressure nozzles<br>Must be operated within design parameters for both liquid and air feeds |
| Cost considerations | Cost is in the capital investment of the atomizer wheel and motor | Cost is in the high-pressure pumping of the feed | Cost is in the requirements for large air compressors |
| Key considerations | Can be limited as the wheel periphery speed required for fine atomization puts the wheel under extreme tensile stress<br>Due to high capacity of the atomizers, typically only one is required in most dryers | Suited for coarse atomization as pressures above 300 bar are not practical<br>Since capacity of an individual nozzle is limited, dryer may require multiple nozzles | Droplet size tends to vary inversely with the ratio of gas to liquid<br>The capacity is not linked to performance, so some turndown is possible<br>Since capacity of an individual nozzle is limited, dryer may require multiple nozzles |
| Power consumption | 5–11 kWh/ton | up to 3 kWh/ton | up to 25 kWh/ton |
| Typical droplet size | 40–100 μm | 50–250 μm | 5–500 μm |
| Typical spray angle | 180° | 50°–80° | 10°–60° |

Hydraulic pressure nozzles cannot combine the capability for fine atomization with high feed capacity in one single unit. Many spray dryer applications, where pressure nozzles are applied, require multinozzle systems with the consequence that start-up, operational control, and shutdown procedures become more complicated.

*Two-fluid nozzle atomization* In two-fluid nozzle atomizers, the liquid feed is fed to the nozzle under marginal or no pressure conditions. An additional flow of gas, normally air, is fed to the nozzle under pressure. Near the nozzle orifice, internally or externally, the two fluids (feed and pressurized gas) are mixed and the pressure energy is converted to kinetic energy, as shown in Fig. 12-95. The flow of feed disintegrates into droplets during the interaction with the high-speed gas flow which may have sonic velocity.

The spray angle obtained with two-fluid nozzles is normally on the order of 10° to 60°. The spray pattern may be narrow and is related to the spread of a free jet of gas. Spray-drying chamber designs for two-fluid nozzle atomization are very specialized according to the application.

The droplet size produced by a two-fluid nozzle atomizer varies inversely with the ratio of gas to liquid and with the pressure of the atomization gas. The capacity of a two-fluid nozzle is not linked to its atomization performance. Therefore, two-fluid nozzles can be attributed with some turndown capability.

Two-fluid nozzles share with pressure nozzles the lack of high feed capacity combined with fine atomization in one single unit. Many spray dryer applications with two-fluid nozzle atomization have a very high number of individual nozzles. The main advantage of two-fluid nozzles is the capability to achieve very fine atomization.

Table 12-45 shows several relationships between liquid properties and spray qualities.

In general, spray drying operation parameters are experience and pilot-scale testing. Droplet size is critical for all spray-drying operations. When droplet size data are unavailable for a spray, the scientific literature contains numerous empirical relationships that can be used to make predictions of the droplet sizes in a spray. If any difference between the atomization means mentioned here were to be pointed out, it would be the tendency for two-fluid nozzles to have the wider particle size distribution and narrower pressure nozzles with rotary atomizers in between.

*Spray/Hot Air Contact* Atomization is first and most important process stage in spray drying. The final result of the process does, however, depend to a very large degree on the second stage, the spray/hot air contact. This stage influences the quality of the product. In general terms, three possible forms can be defined. These are depicted in Fig. 12-96 as cocurrent, countercurrent, and mixed flow.

Different drying chamber forms and different methods of hot air introduction accompany the different flow pattern forms and are selected according to

- Required particle size in product specification
- Required particle form
- Temperature or heat sensitivity of the dried particle

Figure 12-96*a* shows a cocurrent cone-based tall form chamber with roof gas disperser. This chamber design is used primarily with pressure nozzle atomization to produce powders of large particle sizes with a minimum of agglomeration. The chamber can be equipped with an oversize cone section to maximize powder discharge from the chamber bottom. This type of dryer is often used for dyestuffs, baby foods, detergents, and instant coffee powder.

Figure 12-96*b* shows a standard cocurrent cone-based chamber with roof gas disperser. The chamber can have either single- or two-point discharge and can be equipped with rotary or nozzle atomization. Fine or moderately coarse powders can be produced. This type of dryer finds application in dairy, food, chemical, pharmaceutical, agrochemical, and polymer industries. A version of Fig. 12-96*b* with a flat-based cocurrent chamber can be used with limited building height.

Figure 12-96*c* shows a countercurrent flow chamber with pressure nozzle atomization. This design is in limited use because it cannot produce heat-sensitive products. Detergent powder is the main application; see Huntington, D. L., *Drying Technol.* **22**(6): 1261–1287 (2004), for a large-scale example.

Figure 12-96*d* shows a high-temperature chamber with the hot gas distributor arranged internally on the centerline of the chamber. The atomizer is rotary. Inlet temperature in the range of 600 to 1000°C can be utilized in the drying of non-heat-sensitive products in the chemical and mining industries. Kaolin and mineral flotation concentrates are typical examples.

Figure 12-96*e* shows a mixed-flow chamber with pressure nozzle atomization arranged in *fountain* mode. This design is ideal for producing a coarse product in a limited-size low-cost drying chamber. This type of dryer is used extensively for ceramic products. Powder removal requires a sweeping suction device. One of few advantages is ease of access for manual cleaning. These are widely used in production of flavoring materials.

The layouts in Fig. 12-96 can be augmented with an integrated fluid-bed chamber in the spray dryer. The final stage of the drying process is accomplished in a fluid bed located in the lower cone of the chamber. This type of operation allows lower outlet temperatures to be used, leading to fewer temperature effects on the powder and higher energy efficiency. Similarly, the layouts can be modified with an integrated belt chamber where product is sprayed onto a moving belt, which also acts as the air exhaust filter. It is highly suitable for slowly crystallizing and high-fat products. Previous operational difficulties derived from hygienic problems on the belt have been overcome, and the integrated belt dryer is now moving the limits of products that can be dried by spray drying.

In general terms, selection of chamber design and flow pattern form follows these guidelines:

- Use cocurrent spray drying for heat-sensitive products of fine as well as coarse particle size, where the final product temperature must be kept lower than the dryer outlet temperature.

(*a*) (*b*)

**FIG. 12-93** Rotary atomizers: (*a*) forward-curved vane; (*b*) vaned and bushing-type rotary wheels. (*GEA*)

- Use countercurrent spray drying for products which are not heat-sensitive, but may require some degree of heat treatment to obtain a special characteristic, i.e., porosity or bulk density. In this case the final powder temperature may be higher than the dryer outlet temperature.
- Use mixed-flow spray drying when a coarse product is required and the product can withstand short time exposure to heat without adverse effects on dried product quality.
- Dryers with rotary atomizers have a wider diameter to accommodate the spray pattern without wall buildup.

*Evaporation Stage* Evaporation takes place from a moisture film that establishes on the droplet surface. The droplet surface temperature is kept low and close to the adiabatic saturation temperature of the drying air. As the temperature of the drying air drops off and the solids content of the droplet/particle increases, the evaporation rate is reduced. The drying chamber design must provide a sufficient residence time in suspended condition for the particle to enable completion of the moisture removal.

During the evaporation stage, the atomized spray droplet size distribution may undergo changes as droplets shrink, expand, collapse, fracture, or agglomerate. The quality of a spray-dried product is often strongly dependent on its morphological characteristics. Attributes include particle size, density, ability to dissolve, fragility, retention of trace volatile components (aroma), etc.

Typical morphological changes that may occur are outlined in Fig. 21-175 of Perry's 8th ed. and in Fig. 12-97 [Walton and Mumford, "The Morphology of Spray-Dried Particles—The Effects of Process Variables upon the Morphology of Spray-dried Particles," *Trans IChemE* **77**(Part A): 442–460 (1999)]. See also numerous articles from C. J. King.

These morphological transformations can be difficult to predict a priori and require experimentation to determine final particle properties. A number of experimental studies have been conducted on single droplets to better understand the mechanisms [Hecht, J. P., and King, C. J., *Ind. Eng. Chem. Res.* **39:** 1766–1774 (2000)].

*Post-treatment* Manipulating powder properties including moisture content, particle size, density, morphology, and dispersibility can be done with a variety of unit operations. These include fluid-bed dryers and agglomerators, coaters, sieves, granulator, presses, etc. The treatment will depend on the final uses of the product dried. Post-treatment may take place prior to or after dry product recovery.

*Product Recovery* Product recovery is the last stage of the spray-drying process. Two distinct systems are used:

- In two-point discharge, primary discharge of a coarse powder fraction is achieved by gravity from the base of the drying chamber. The fine fraction is recovered by secondary equipment downstream of the chamber air exit.
- In single-point discharge, total recovery of dry product is accomplished in the dryer separation equipment.

Collection of powder from an airstream is a large subject area of its own. In spray drying, dry collection of powder in a nondestructive way is achieved by use of cyclones, filters with textile bags or metallic cartridges, and electrostatic precipitators or a combination thereof.

With the current emphasis on environmental protection, many spray dryers are equipped with additional means to collect even the finest fraction. This collection is often destructive to the powder. Equipment in use includes wet scrubbers, bag or other kinds of filters, and in a few cases incinerators.

**Industrial Designs and Systems** Thousands of different products are processed in spray dryers representing a wide range of feed and product properties as well as drying conditions. The flexibility of the spray-drying concept, which is the main reason for this wide application, is described by the following systems.

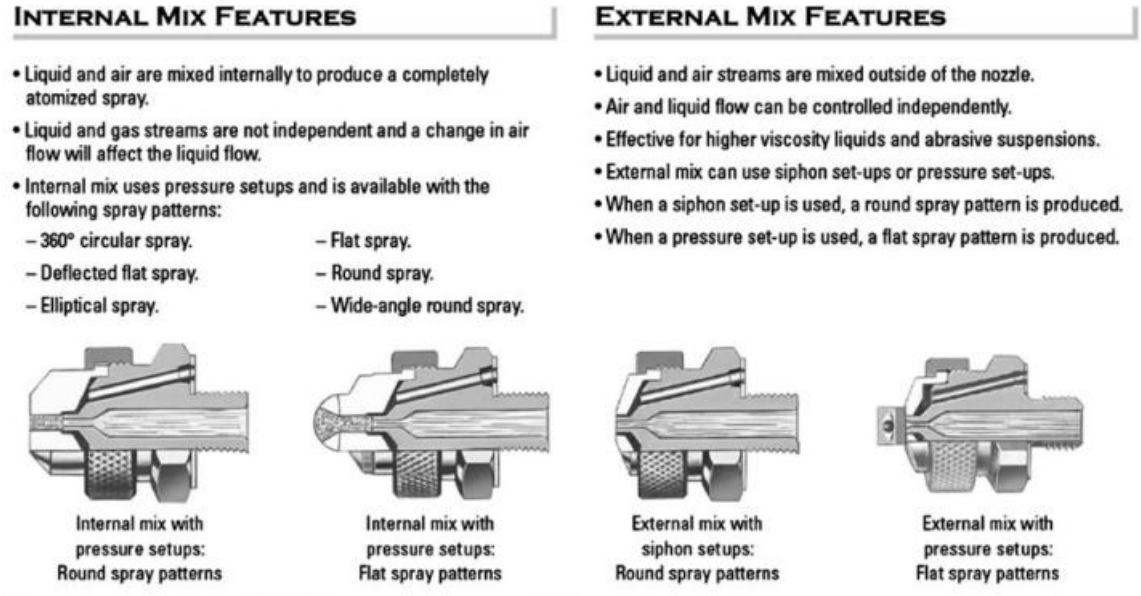

**FIG. 12-95** Schematic view of two-fluid atomizers. (*Spraying Systems Co.*)

**Plant Layouts** All the above-mentioned chamber layouts can be used in open-cycle, partial-recycle, or closed-cycle layouts. The selection is based on the needs of operation, feed, drying gas, solvent and powder specification, and environmental considerations.

An open-cycle layout is by far the most common in industrial spray drying. The open layout involves intake of drying air from the atmosphere and discharge of exhaust air to the atmosphere. Drying air can be supplemented by a waste heat source to reduce overall fuel consumption. The heater may be direct, i.e., natural gas burner, or indirect by steam-heated heat exchanger or other heat recovery systems. An example of an open-cycle layout is shown in Fig. 12-98.

A closed-cycle layout is used for drying inflammable or toxic solvent feedstocks or gases. The closed-cycle layout ensures complete solvent recovery and prevents explosion and fire risks. The reason for the use of a solvent system is often to avoid oxidation/degradation of the dried product. Consequently closed-cycle plants are gastight installations operating with an inert drying medium, usually nitrogen. These plants operate at a slight gauge pressure to prevent inward leakage of air.

Partial recycle is used in a plant type applied for products of moderate sensitivity toward oxygen. The atmospheric drying air is heated in a direct fuel-burning heater. Part of the exhaust air, depleted of its oxygen content by the combustion, is dried by using a condenser and recycled to the heater. This type of plant is also designated self-inertizing.

As a consequence, the amount of drying air or gas required for drying one unit of feed or product varies considerably. A quick scoping estimate of the size of an industrial spray dryer can be made on this basis. The required evaporation rate or product rate can be multiplied by the relevant ratio to give the mass flow rate of the drying gas. The next step would be to calculate the size of a spray-drying chamber to allow the drying gas at outlet conditions for a given residence time.

**TABLE 12-45 Properties of Fluids and How They Influence Atomization (Spraying Systems)**

| | Increase with specific gravity | Increase in viscosity | Increase in fluid temperature | Increase in surface tension |
|---|---|---|---|---|
| Pattern quality | Negligible | Deteriorates | Improves | Negligible |
| Capacity | Decreases | — | — | No effect |
| Spray angle | Negligible | Decreases | Increases | Decreases |
| Drop size | Negligible | Increases | Decreases | Increases |
| Drop velocity | Decreases | Decreases | Increases | Negligible |
| Impact | Negligible | Decreases | Increases | Negligible |
| Wear | Negligible | Decreases | — | No effect |

***Example 12-20 Scoping Exercise for Size of Spray Dryer*** Estimate the size of a zinc sulfate spray dryer with cylindrical chamber with diameter $D$, height $H$ equal to $D$, and a 60° conical bottom. The dryer has an evaporative capacity of 2.0 ton/h and requires a drying gas flow rate of 8.45 kg/s with a residence time of 25 s. The outlet gas density is 0.89 kg/m$^3$.

The dryer has a nominal geometric volume $V_{\text{chamber}}$ (cylinder on top of cone) of

$$V_{\text{chamber}} = \frac{\pi}{4} D^2 \times \left( H + \frac{1}{3} \cdot \frac{\sqrt{3}}{2} D \right) = 1.01 \times D^3$$

Based on the drying gas flow rate, outlet gas density, and residence time, the required chamber volume is

$$V_{\text{chamber}} = (8.45 \text{ kg/s})/(0.89 \text{ kg/m}^3) \times 25 \text{ s} = 237 \text{ m}^3$$

The chamber size now becomes

$$D = \sqrt[3]{\frac{237}{1.01}} = 6.2 \text{ m}$$

The selection of the plant concept involves the dryer modes illustrated in Fig. 12-96. For different products a range of plant concepts are available to secure successful drying at the lowest cost. These concepts are illustrated in Fig. 12-99.

Figure 12-99 shows a traditional spray dryer layout with a cone-based chamber and roof gas disperser. The chamber has two-point discharge and rotary atomization. The powder leaving the chamber bottom as well as the fines collected by the cyclone is conveyed pneumatically to a conveying cyclone from which the product discharges. A bag filter serves as the common air pollution control system.

Figure 12-99 also shows closed-cycle spray dryer layout used to dry certain products with a nonaqueous solvent in an inert gas flow. The background for this may be product sensitivity to water and oxygen or severe explosion risk. Typical products can be tungsten carbide or pharmaceuticals.

Figure 12-99 also shows an integrated fluid-bed chamber layout of the type used to produce agglomerated product. The drying process is accomplished in several stages, the first being a spray dryer with atomization. The second stage is an integrated static fluid bed located in the lower cone of the chamber. The final stages are completed in external fluid beds of the vibrating type. This type of operation allows lower outlet temperatures to be used, leading to fewer temperature effects on the powder and higher energy efficiency. The chamber has a mixed-flow concept with air entering and exiting at the top of the chamber. This chamber is ideal for heat-sensitive, sticky products. It can be used with pressure nozzle as well as rotary atomization. An important feature is the return of fine particles to the chamber to enhance the agglomeration effect. Many products have been made feasible for spray drying by the development of this concept, which was initially

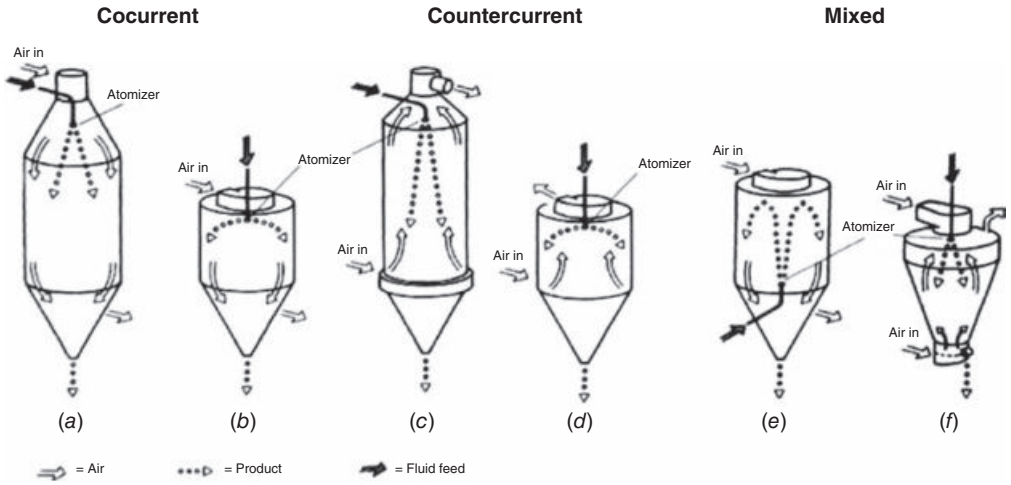

**FIG. 12-96** Different forms of spray/hot air contact. (*revised, GEA*)

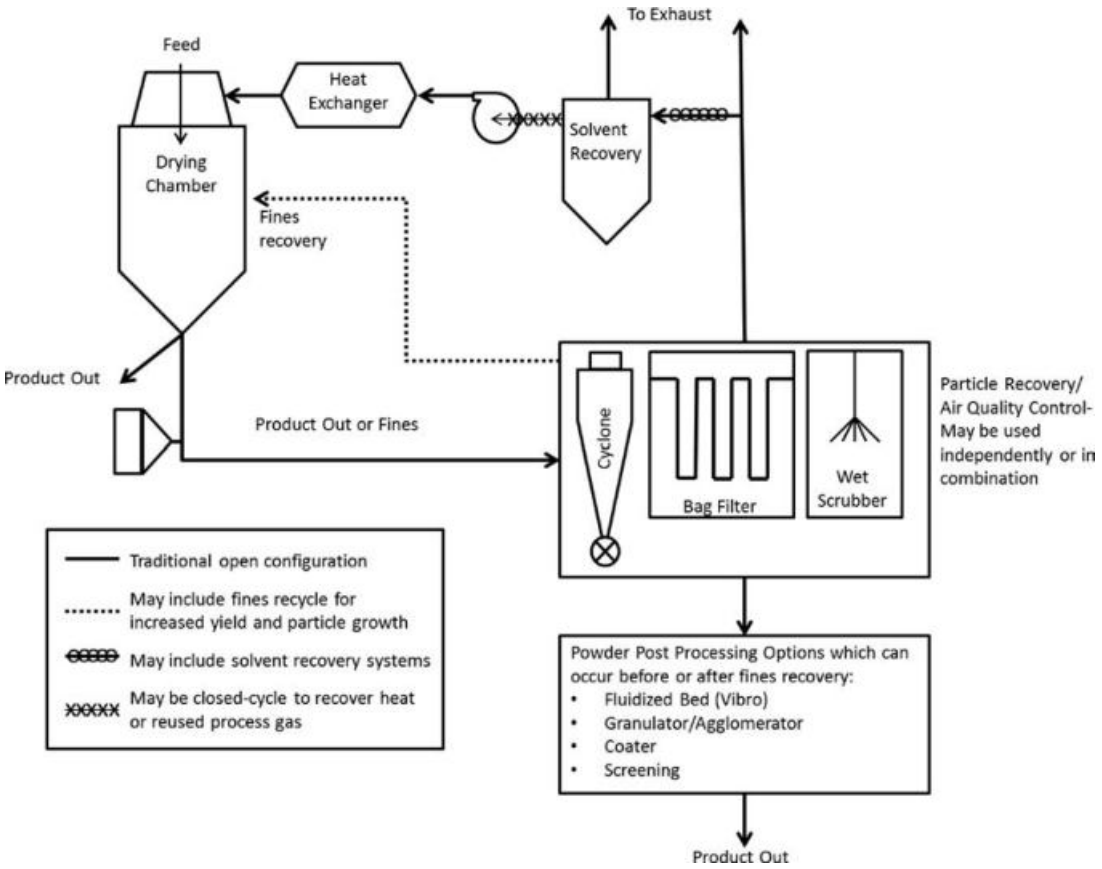

**FIG. 12-99** Spray dryer layout with multiple possible configurations.

aimed at the food and dairy industry. Recent applications have, however, included dyestuffs, agrochemicals, polymers, and detergents.

**Spray Dryer Modeling** Modeling of spray dryers is a unique challenge due to the vast differences in the length scales [dryer (1.0 to 10 μ in diameter) compared to droplets (100 μm in diameter)], billions of particles, one or more sprays, and multiple, complex micro-scale transformations. Making measurements inside a spray dryer to develop and validate models is notoriously difficult. *Computational fluid dynamics* (CFD) can be used to examine the complex airflow patterns within many dryers and also to track particle trajectories. Other modeling techniques have examined the drying kinetics of various droplet types. Invariably, efforts to date have simplified either the air patterns in the dryer or the drop-drying dynamics. A recent notable effort to combine these scales is the EDECAD Project [Verdurmen et al., "Agglomeration in Spray Drying Installations (The EDECAD Project): Stickiness Measurements and Simulation Results," *Drying Technol.* **24:** 721–726 (2006)].

Drynetics is a commercially available method to incorporate experimental single-drop drying into CFD software. Experiments can be conducted on individual droplets of a feed to determine their drying properties. The results are then transferred to the CFD software with the help of appropriate mathematical models, making it possible to simulate the drying process accurately. This modeling workflow is seen in Fig. 12-100.

Drying kinetics as well as morphology formation during drying of a single particle can be found experimentally by using an apparatus such as the *drying kinetics analyzer* (DKA) which is based on the principle of ultrasonic levitation. In an ultrasonic levitator a small particle may be held constant against gravity due to the forces of an ultrasonic field between the so-called transmitter and the so-called reflector. While the levitated particle is drying, it may be monitored with a camera to record the morphology development and by an infrared device to record the development in particle temperature. A levitator can be encapsulated in a drying chamber so that the drying gas temperature and humidity may be set arbitrarily. If the drying gas is injected through small holes in the reflector below the particle, as in the DKA, the relative velocity between the gas and droplets in a spray dryer may be simulated. Further, equipment such as the DKA may also be used to analyze the solidification of a melted particle (Coolnetics) which is relevant, e.g., for congealing processes. Here a melt or a solid particle can be inserted into the ultrasonic field. If a solid particle is inserted, it may subsequently be melted, e.g., using laser light or by infrared radiation.

***Example 12-21 Mass and Energy Balance on a Spray Dryer*** A pilot-scale spray dryer has a nominal evaporative rate of 1.0 kg water/h. The dryer is typically operated with an inlet air temperature of 200°C. The dryer is operated with an inlet airflow of 26.4 kg/h. The feedstock has a moisture content of 70 percent (wet basis) and is fed in to the dryer at 25°C. The powder exits the dryer at 6 percent moisture and the same temperature as the exiting air. The ambient air conditions are 22°C and 55 percent relative humidity.

1. Calculate the relative humidity in the exhaust airstream.
2. Calculate the exit air and product temperature.
3. Estimate the increase in production if the moisture content of the feedstock is decreased from 70 to 65 percent.

*Solution* The mass balance is given by the following equations:

$$F_{\text{bone dry solids in}} = F_{\text{bone dry solids out}}$$

$$F_{\text{liquid water in}} = F_{\text{liquid water out}} + F_{\text{evaporated}}$$

$$G_{\text{dry air in}} = G_{\text{dry air out}}$$

$$G_{\text{water vapor in}} + F_{\text{evaporated}} = G_{\text{water vapor out}}$$

The wet-basis moisture content of the incoming feedstock and outgoing powder are given by

$$w_{\text{in}} = \frac{F_{\text{liquid water in}}}{F_{\text{liquid water in}} + F_{\text{bone dry solids in}}}$$

$$w_{\text{out}} = \frac{F_{\text{liquid water out}}}{F_{\text{liquid water out}} + F_{\text{bone dry solids out}}}$$

The relationship between the total airflow and the absolute humidity is given by

$$G_{\text{dry air}} = G_{\text{air}} \frac{1}{1+Y} = 10 \text{ kg/h} \frac{1}{1+0.009} = 9.91 \text{ kg/h}$$

The absolute humidity of each air stream is given by

$$Y_{\text{in}} = \frac{G_{\text{water vapor in}}}{G_{\text{dry air in}}}$$

$$Y_{\text{out}} = \frac{G_{\text{water vapor out}}}{G_{\text{dry air out}}}$$

The mass flow rate of bone-dry solids into the dryer can be calculated from the evaporation rate and the incoming and exit moisture contents:

$$F_{\text{evap}} = F_{\text{liquid water in}} - F_{\text{liquid water out}}$$

$$F_{\text{evap}} = \frac{w_{\text{in}}}{1-w_{\text{in}}} F_{\text{bone dry solids in}} - \frac{w_{\text{out}}}{1-w_{\text{out}}} F_{\text{bone dry solids out}}$$

This can be simplified as follows:

$$F_{\text{solids}} = \frac{F_{\text{evaporated}}}{\frac{w_{\text{in}}}{1-w_{\text{in}}} - \frac{w_{\text{out}}}{1-w_{\text{out}}}} = \frac{1.0 \text{ kg/h}}{\frac{0.7}{0.3} - \frac{0.06}{0.94}} = 0.44 \text{ kg/h}$$

$$F_{\text{liquid water in}} = \frac{w_{\text{in}}}{1-w_{\text{in}}} F_{\text{solids}} = \frac{0.7}{0.3} 0.44 \text{ kg/h} = 1.03 \text{ kg/h}$$

$$F_{\text{liquid water out}} = \frac{w_{\text{out}}}{1-w_{\text{out}}} F_{\text{solids}} = \frac{0.06}{0.94} 0.44 \text{ kg/h} = 0.03 \text{ kg/h}$$

Since the dryer heats ambient air, the absolute humidity can be determined from the psychrometric chart. The mass flow rate of dry air and water vapor can be calculated from the overall airflow rate and the absolute humidity of the incoming air:

$$G_{\text{water vapor in}} = G_{\text{air}} \frac{1}{1+Y_{\text{in}}} Y_{\text{in}} = 26.16 \text{ kg/h} \cdot 0.009 = 0.24 \text{ kg/h}$$

$$G_{\text{water vapor out}} = G_{\text{water vapor in}} + F_{\text{evap}} = 0.24 \text{ kg/h} + 1.0 \text{ kg/h} = 1.24 \text{ kg/h}$$

$$Y_{\text{out}} = \frac{G_{\text{water vapor out}}}{G_{\text{dry air out}}} = \frac{1.24 \text{ kg/h}}{26.16 \text{ kg/h}} = 0.047$$

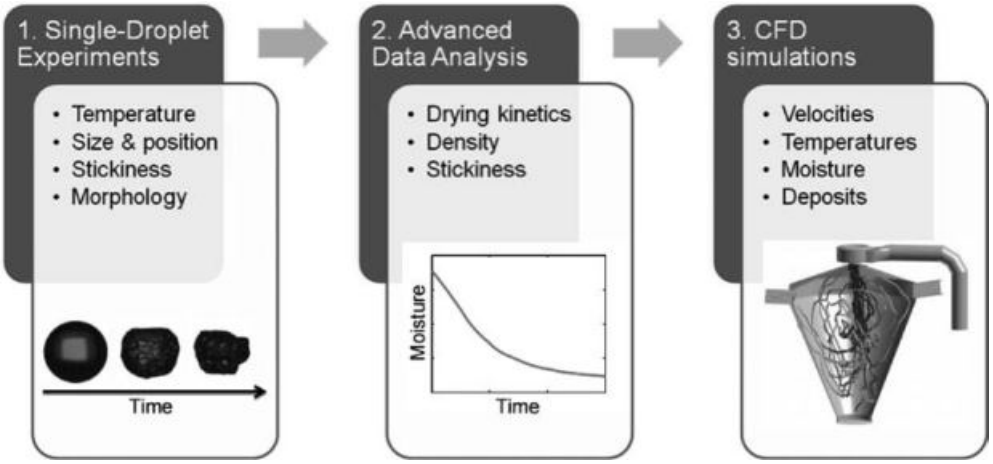

**FIG. 12-100** Modeling work flow for spray-drying modeling, Drynetics. (*GEA*)

Next an energy balance must be used to estimate the outgoing air and product temperature:

$$H_{\text{dry air in}} + H_{\text{water vapor in}} + H_{\text{bone dry solids in}} + H_{\text{liquid water in}} = H_{\text{dry air out}} + H_{\text{water vapor out}} + H_{\text{bone dry solids out}} + H_{\text{liquid water out}} + \text{heat losses to surroundings}$$

Heat losses to the surrounding environment can be difficult to calculate and can be neglected for a first approximation. This assumption is more valid for larger systems than smaller systems and is neglected in this example.

The equation above was rearranged in terms of enthalpy differences:

$$\Delta H_{\text{dry air}} + \Delta H_{\text{water vapor}} + \Delta H_{\text{solids}} + \Delta H_{\text{liquid water}} + \Delta H_{\text{evap}} = 0$$

Since enthalpy is a state function, the path for determination must be stated. There are several paths that would yield equivalent results. For this example, it is assumed that the evaporation is occurring at the inlet temperature and that the water vapor is being heated from the inlet temperature to the outlet temperature. The terms of the equation can be evaluated by using

$$\begin{aligned}
\Delta H_{\text{dry air}} &= G_{\text{dry air}} C_{p,\text{ air}} (T_{\text{air in}} - T_{\text{air out}}) \\
\Delta H_{\text{water vapor}} &= G_{\text{water vapor out}} C_{p,\text{ water vapor}} (T_{\text{air in}} - T_{\text{air out}}) \\
\Delta H_{\text{solids}} &= F_{\text{solids}} C_{p,\text{ solids}} (T_{\text{solids in}} - T_{\text{solids out}}) \\
\Delta H_{\text{liquid water}} &= F_{\text{liquid water out}} C_{p,\text{ liquid water}} (T_{\text{solids in}} - T_{\text{solids out}}) \\
\Delta H_{\text{evap}} &= -G_{\text{evaporated}} \cdot \Delta H_{\text{vap}} + G_{\text{evap}} C_{p,\text{ water vapor}} (T_{\text{evap}} - T_{\text{out}})
\end{aligned}$$

Since the powder and air exit the dryer at the same temperature, $T_{\text{air out}} = T_{\text{solids out}} = T_{\text{out}}$, the relationships above can be rewritten as

$$\begin{aligned}
&G_{\text{dry air}} C_{p,\text{ air}} (T_{\text{air in}} - T_{\text{out}}) + G_{\text{water vapor out}} C_{p,\text{ water vapor}} (T_{\text{air in}} - T_{\text{out}}) \\
&+ F_{\text{solids in}} C_{p,\text{ solids}} (T_{\text{solids in}} - T_{\text{out}}) \\
&+ F_{\text{liquid water out}} C_{p,\text{ liquid water}} (T_{\text{solids in}} - T_{\text{out}}) - G_{\text{evap}} \cdot \Delta H_{\text{vap}} \\
&+ G_{\text{evap}} C_{p,\text{ water vapor}} (T_{\text{evap}} - T_{\text{out}}) = 0
\end{aligned}$$

From the steam tables $\Delta H_{\text{vap}}$ at 25°C = 2442 kJ/kg, $h_l$ = 105 kJ/kg, and at 200°C (superheated, low pressure) $h_g$ = 2880 kJ/kg.

$$\begin{aligned}
&(26.16 \text{ kg/h})(1 \text{ kJ/kg} \cdot °\text{C})(200°\text{C} - T_{\text{out}}) + (1.24 \text{ kg/h})(2 \text{ kJ/kg} \cdot °\text{C})(200°\text{C} - T_{\text{out}}) \\
&+ (0.44 \text{ kg/h}) \left[ 2.5 \frac{\text{kJ}}{\text{kg} \cdot °\text{C}} \right] (25°\text{C} - T_{\text{out}}) \\
&+ (1.03 \text{ kg/h})(4.18 \text{ kJ/kg} \cdot °\text{C})(25°\text{C} - T_{\text{out}}) - 1.0 \text{ kg/h} \cdot \frac{2775 \text{ kJ}}{\text{kg}} \\
&+ (1.0 \text{ kg/h})(2.5 \text{ kJ/kg} \cdot °\text{C})(100°\text{C} - T_{\text{out}}) = 0 \\
&T_{\text{out}} = 99.9°\text{C}
\end{aligned}$$

With the absolute humidity defined and the outlet temperature calculated, the exit relative humidity was determined from the psychrometric chart as 7.1 percent.

Assuming the drying kinetics and the nominal evaporation rate remain the same with a decrease in the inlet moisture content (there may be a slight adjustment to the energy balance):

$$F_{\text{out}} = \left(1 + \frac{w_{\text{out}}}{1 - w_{\text{out}}}\right) \frac{F_{\text{evap}}}{\dfrac{w_{\text{in}}}{1 - w_{\text{in}}} - \dfrac{w_{\text{out}}}{1 - w_{\text{out}}}} = \left(1 + \frac{0.06}{0.94}\right) \frac{1.0 \text{ kg/h}}{\dfrac{0.7}{0.3} - \dfrac{0.06}{0.94}} = 0.47 \text{ kg/h}$$

$$F_{\text{out}} = \left(1 + \frac{w_{\text{out}}}{1 - w_{\text{out}}}\right) \frac{F_{\text{evap}}}{\dfrac{w_{\text{in}}}{1 - w_{\text{in}}} - \dfrac{w_{\text{out}}}{1 - w_{\text{out}}}} = \left(1 + \frac{0.06}{0.94}\right) \frac{1.0 \text{ kg/h}}{\dfrac{0.65}{0.35} - \dfrac{0.06}{0.94}} = 0.59 \text{ kg/h}$$

This suggests the throughput can increase by 27 percent assuming the inlet moisture content can be decreased by 5 percent.

### Drum and Thin-Film Dryers

***Synonyms and Examples*** Drum dryer, film drum dryer, thin-film dryer (note: this term is used by the paper industry for heated cylinder dryers—these are covered in Sheet Drying).

***Description Drum (Film-Drum) Dryers*** A film of liquid or paste is spread onto the outer surface of a rotating, internally heated drum. Heat transfer occurs by conduction. At the end of the revolution the dry product is removed by a doctor's knife. The material can be in the form of powder, flakes, or chips and typically is 100 to 300 μm thick. Drum dryers cannot handle feedstocks that do not adhere to metal, products that dry to a glazed film, or thermoplastics. The drum is heated normally by condensing steam or in vacuum drum dryers by hot water. Figure 12-101 shows three of the many possible forms. The dip feed system is the simplest and most common arrangement, but is not suitable for viscous or pasty materials. The nip feed system is usually employed on double-drum dryers, especially for viscous materials, but it cannot handle lumpy or abrasive solids. With nip feed systems, the fluid is exposed to the hot surface of the drum, possibly causing the liquid to boil. This may change the fluid rheology due to sudden evaporation and liquid heating or degrade the fluid. Lumpy or abrasive solids are usually applied by roller, and this is also effective for sticky and pasty materials. Spray and splash devices are used for feeding heat-sensitive, low-viscosity materials. Vacuum drum dryers are simply conventional units encased in a vacuum chamber with a suitable air lock for product discharge. Air impingement is also used as a secondary heat source on drum and can dryers, as shown in Fig. 12-102. Impingement or other additional air can be used to purge saturated vapor away from the drums to aid in drying.

In drum drying, the moist material covers a hot surface which supplies the heat required for the drying process.

Let us consider a moist material lying on a hot flat plate of infinite extent. Figure 12-103 illustrates the temperature profile for the fall in temperature from $T_H$ in the heating fluid to $T_G$ in the surrounding air. It is assumed that the temperatures remain steady, unhindered drying takes place, and there is no air gap between the material being dried and the heating surface.

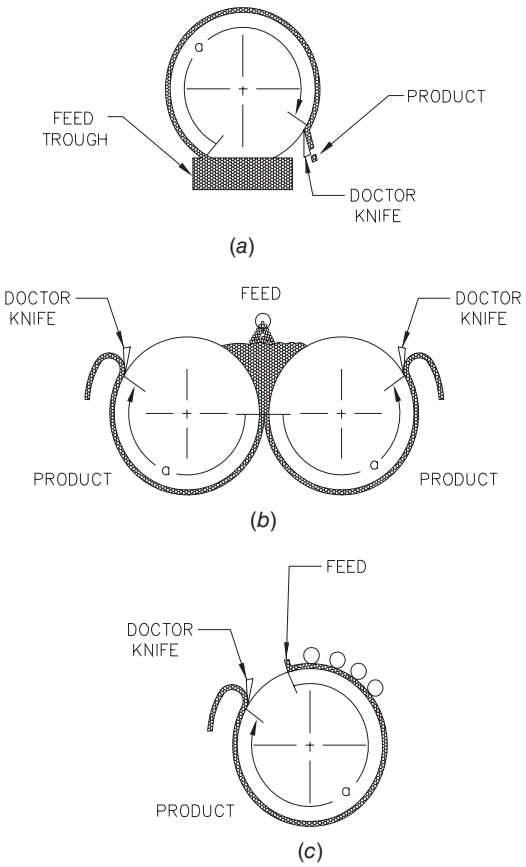

**FIG. 12-101** Main types of drum dryers. (*a*) Dip; (*b*) nip; (*c*) roller.

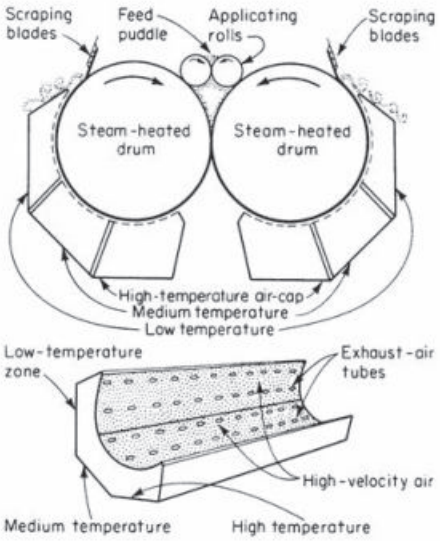

**FIG. 12-102** Example of the use of air impingement in drying as a secondary heat source on a double-drum dryer. (*Sloan, C.E., et. al, Chem. Eng.,* **197**, *June 19, 1967*)

The heat conducted through the wall and material is dissipated by evaporation of moisture and convection from the moist surface to the surrounding air. A heat balance yields

$$U(T_H - T_S) = N_W \Delta H_{VS} + h_C(T_S - T_G) \tag{12-111}$$

where $U$ is the overall heat-transfer coefficient. This coefficient is found from the reciprocal law of summing resistances in series:

$$\frac{1}{U} = \frac{1}{h_H} + \frac{b_B}{\lambda_B} + \frac{b_s}{\lambda_s} \tag{12-112}$$

in which $h_H$ is the heat-transfer coefficient for convection inside the heating fluid. If condensing steam is used, this coefficient is very large normally and the corresponding resistance $1/h_H$ is negligible. Rearrangement of Eq. (12-111) yields an expression for the maximum drying rate

$$N_W = \frac{U(T_H - T_S) - h_C(T_S - T_G)}{\Delta H_{VS}} \tag{12-113}$$

Equation (12-113), as it stands, would give an overestimate of the maximum drying rate for the case of contact drying over heated rolls, when there are significant heat losses from the ends of the drum and only part of the drum's surface can be used for drying. In the roller drying arrangements shown in Fig. 12-101, only a fraction $a$ of the drum's periphery is available from the point of pickup to the point where the solids are peeled off.

Let $q_E$ be the heat loss per unit area from the ends. The ratio of the end areas to cylindrical surface, from a drum of diameter $D$ and length $L$, is $2(1/4 \cdot \pi D^2)/\pi DL$ or $D/2L$. Equation (12-113) for the maximum drying rate under roller drying conditions thus becomes

$$N_W = \frac{aU(T_H - T_S) - h_C(T_S - T_G) - Dq_E/2L}{\Delta H_{VS}} \tag{12-114}$$

The total evaporation from the drum is $N_W a(\pi DL)$. Equation (12-114) could be refined further, as it neglects the effect caused by the small portion of the drum's surface being covered by the slurry in the feed trough, as well as thermal conduction through the axial shaft to the bearing mounts. The use of Eq. (12-114) to estimate the maximum drying rate is illustrated in Example 12-22.

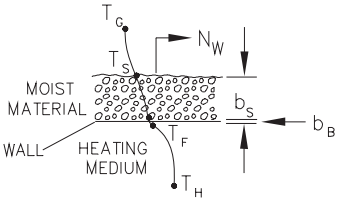

**FIG. 12-103** Temperature profile in conductive drying.

***Example 12-22 Heat-Transfer Calculations on a Drum Dryer*** A single rotating drum of 1.250-m diameter and 3 m wide is internally heated by saturated steam at 0.27 MPa. As the drum rotates, a film of slurry 0.05 mm thick is picked up and dried. The dry product is removed by a knife, as shown in Fig. 12-101*a*. About three-quarters of the drum's surface is available for evaporating moisture. Estimate the maximum drying rate when the outside air temperature $T_G$ is 15°C and the surface temperature is 90°C; and compare the effectiveness of the unit with a dryer without end effects and in which all the surface could be used for drying.

*Data:*
Heat-transfer coefficient $h_C = 50$ W/(m$^2 \cdot$ K)
Thickness of cylinder wall $b_B = 10$ mm
Thermal conductivity of wall $\lambda_B = 40$ W/(m $\cdot$ K)
Thermal conductivity of slurry film $\lambda_s = 0.10$ W/(m $\cdot$ K)
Film transfer coefficient for condensing steam $h_H = 2.5$ kW/(m$^2 \cdot$ K)
*Overall heat-transfer coefficient U:* The thermal resistances are as follows:

Steam side $1/2.5 = 0.40$ m$^2 \cdot$ K/kW
Wall $0.01/0.04 = 0.25$ m$^2 \cdot$ K/kW
Film side $5.0 \times 10^{-5}/0.1 \times 10^{-3} = 0.5$ m$^2 \cdot$ K/kW
$\therefore$ Overall resistance $= 0.40 + 0.25 + 0.5 = 1.15$ m$^2 \cdot$ K/kW

$$U = 1/1.15 = 0.870 \text{ kW/(m}^2 \cdot \text{K)}$$

*Wall temperature $T_B$:* At 0.27 MPa, the steam temperature is 130°C. If it is assumed that the temperature drops between the steam and the film surface are directionally proportional to the respective thermal resistances, it follows that

$$\frac{T_H - T_B}{T_H - T_S} = \frac{0.40 + 0.25}{1.15} = 0.565$$

$$\therefore T_B = T_H - 0.565(T_H - T_S)$$
$$= 130 - 0.565\,(130 - 90)$$
$$= 107.4°\text{C}$$

*Heat losses from ends $q_E$:* For an emissivity ~1 and an air temperature of 15°C with a drum temperature of 107.4°C, one finds [see Eq. (12-120)]

$$q_E = 798 \text{ W/(m}^2 \cdot \text{s)}$$

*Maximum drying rate $N_W$:* From Eq. (12-114),

$$N_W = \frac{aU(T_H - T_S) - h_C(T_S - T_G) - Dq_E/2L}{\Delta H_{VS}}$$
$$= \frac{0.75 \times 0.870(130 - 90) - 0.05(90 - 15) - (1.25 \times 0.798)/6}{2382}$$
$$= 0.0093 \text{ kg/(m}^2 \times \text{s)}$$

The ideal maximum rate is given by Eq. (12-113) for an endless surface:

$$N_N = \frac{U(T_H - T_S) - h_C(T_S - T_G)}{\Delta H_{VS}}$$
$$= \frac{0.870(130 - 90) - 0.05(90 - 15)}{2382}$$
$$= 0.0130 \text{ kg/(m}^2 \cdot \text{s)}$$

Therefore the effectiveness of the dryer is $0.0093/0.0130 = 0.714$.

The predicted thermal efficiency $\eta$ is

$$\eta = 1 - \frac{h_C(T_S - T_G) + Dq_E/2L}{aU(T_H - T_S)}$$
$$= 1 - \frac{0.05(90 - 15) + (1.25 \times 0.798)/6}{0.75 \times 0.869(130 - 90)}$$
$$= 0.850$$

These estimates may be compared with the range of values found in practice, as shown in Table 12-46 (Nonhebel and Moss, *Drying of Solids in the Chemical Industry,* Butterworths, London, 1971, p. 168).

The typical performance is somewhat less than the estimated maximum evaporative capacity, although values as high as 25 g/(m$^2 \cdot$ s) have been reported. As the solids dry out, the thermal resistance of the film increases and the evaporation falls off accordingly. Heat losses through the bearing of the drum shaft have been neglected, but the effect of radiation is accounted for in the value of $h_C$ taken. In the case of drying organic pastes, the heat losses have been determined to be 2.5 kW/m$^2$ over the whole surface, compared with 1.75 kW/m$^2$ estimated here for the cylindrical surface. The inside surface of the drum has been assumed to be clean, and scale would reduce the heat transfer markedly.

For constant hygrothermal conditions, the base temperature $T_B$ is directly proportional to the thickness of the material over the hot surface. When the wet-bulb

**TABLE 12-46 Drum Dryer Operating Information**

| | This estimate | Typical range |
|---|---|---|
| Specific evaporation, g/(m$^2$·s) | 9.3 | 7–11 |
| Thermal efficiency | 0.85 | 0.4–0.7 |

temperature is high and the layer of material is thick enough, the temperature $T_B$ will reach the boiling point of the moisture. Under these conditions, a mixed vapor-air layer interposes between the material and the heating surface. This is known as the *Leidenfrost effect*, and the phenomenon causes a greatly increased thermal resistance to heat transfer to hinder drying.

**Thin-Film Dryers** Evaporation and drying take place in a single unit, normally a vertical chamber with a vertical rotating agitator which almost touches the internal surface. The feed is distributed in a thin layer over the heated inner wall and may go through liquid, slurry, paste, and wet solid forms before emerging at the bottom as a dry solid. These dryers are based on wiped-film or scraped-surface (Luwa-type) evaporators and can handle viscous materials and deal with the "cohesion peak" experienced by many materials at intermediate moisture contents. They also offer good containment. Disadvantages are complexity, limited throughput, and the need for careful maintenance. Continuous or semibatch operation is possible. A typical unit is illustrated in Fig. 12-104.

**Sheet Dryers**

***Synonyms and Examples*** Cylinder dryer, drum dryer (note: this term is used by the paper industry, not to be confused with the drum dryers for pastes in this text), stenter dryers, and tenter dryers.

***Description*** The construction of dryers where both the feed and the product are in the form of a sheet, web, or film is markedly different from that for dryers used in handling particulate materials. The main users are the paper and textile industries. Almost invariably the material is formed into a very long sheet (often hundreds or thousands of meters long) which is dried in a continuous process. The sheet is wound onto a bobbin at the exit from the dryer; this may be several meters in diameter and several meters wide. Alternatively, the sheet may be chopped into shorter sections.

The heat-transfer calculations [Eqs. (12-114) through (12-115)] used in the Drum Drying subsection are directly applicable for sheet drying when a sheet is in contact with a roller.

**Cylinder Dryers and Paper Machines** The most common type of dryer in papermaking is the cylinder dryer (Fig. 12-105), which is a contact dryer. The paper web is taken on a convoluted path during which it wraps around the surface of cylinders that are internally heated by steam or hot water. In papermaking, the sheet must be kept taut, and a large number of cylinders are used, with only short distances between them and additional small unheated rollers to maintain the tension. Normally, a continuous sheet of felt is also used to hold the paper onto the cylinders, and this also becomes damp and is dried on a separate cylinder.

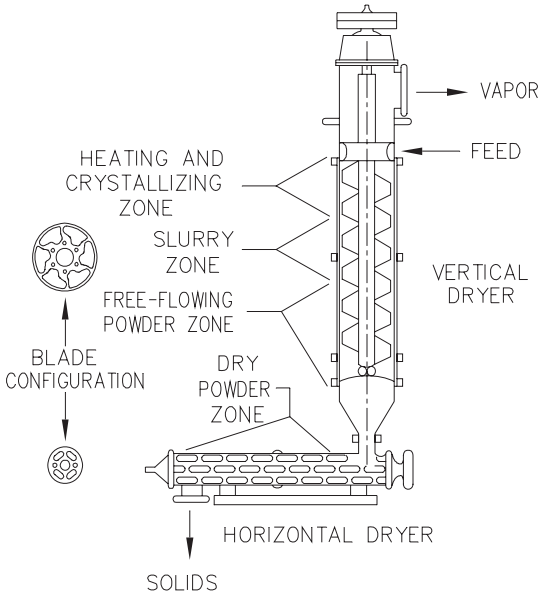

**FIG. 12-104** Continuous thin-film dryer.

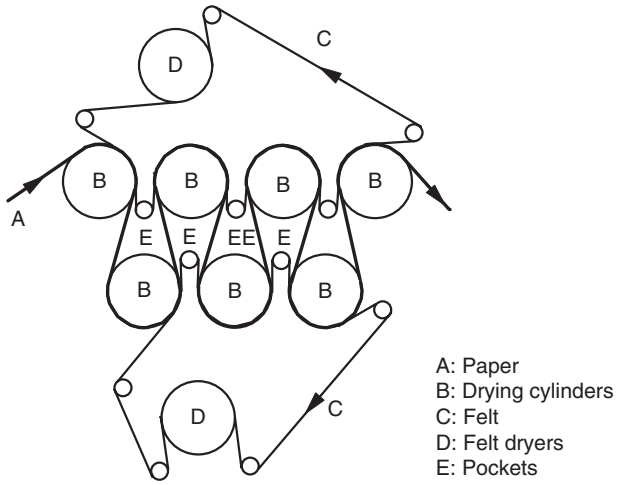

**FIG. 12-105** Cylinder dryer (paper machine).

Most of the heating is conductive, through contact with the drums. However, infrared assistance is frequently used in the early stages of modern paper machines. This gets the paper sheet up to the wet-bulb temperature more rapidly, evaporates greater surface moisture, and enables reduction of the number of cylinders for a given throughput. Hot air jets (jet foil dryer) may also be used to supplement heating at the start of the machine. Infrared and dielectric heating may also be used in the later stages to assist the drying of the interior of the sheet.

Although paper is the most common application, multicylinder dryers can also be used for polymer films and other sheet-type feeds.

Convective dryers may be used as well in papermaking. In the Yankee dryer (Fig. 12-106), high-velocity hot airstreams impinging on the web surface give heating by cross-convection. The "Yankees" are barbs holding the web in place. Normally the cylinder is also internally heated, giving additional conduction heating of the lower bed surface. In the rotary through-dryer (Fig. 12-107), the drum surface is perforated and hot air passes from the outside to the center of the drum, so that it is a through-circulation convective dryer.

Another approach to drying of sheets has been to suspend or "float" the web in a stream of hot gas, using the Coanda effect, as illustrated in Fig. 12-108. Air is blown from both sides, and the web passes through as an almost flat sheet (with a slight "ripple"). The drying time is reduced because the heat transfer from the impinging hot air jets is faster than that from stagnant hot air in a conventional oven. It is essential to control the tension of the web very accurately. The technique is particularly useful for drying coated paper, as the expensive surface coating can stick to cylinder dryers.

**Stenters (Tenters) and Textile Dryers** These are the basic type of dryer used for sheets or webs in the textile industry. The sheet is held by its edges by clips (clip stenter) or pins (pin stenter), which not only suspend

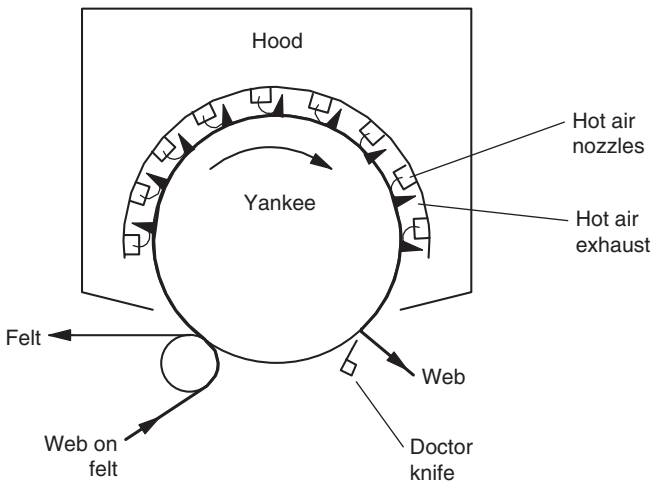

**FIG. 12-106** Yankee dryer.

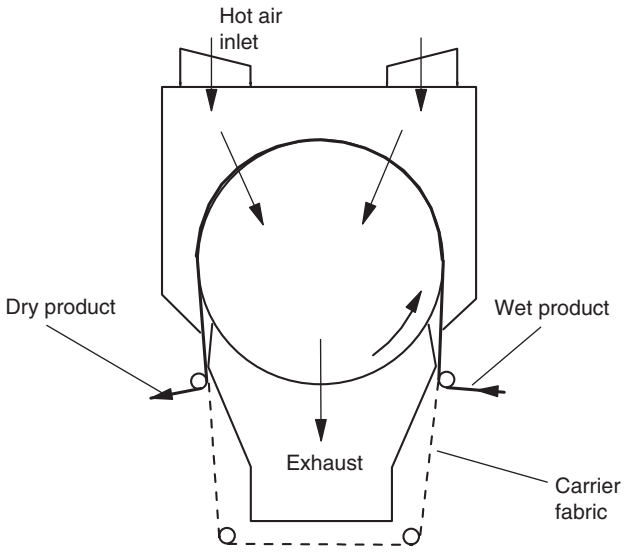

**FIG. 12-107** Rotary through-dryer.

the sheet but also keep it taut and regulate its width—a vital consideration in textile drying. Drying is by convection; hot air is introduced from one or both sides, passes over the surface of the sheet, and permeates through it. Infrared panels may also be used to supply additional heat. A schematic diagram of the unit is shown in Fig. 12-109. A typical unit is 1.4 m wide and handles 2 to 4 tons/h of material.

Heavy-duty textiles with thick webs may need a long residence time, and the web can be led up and down in "festoons" to reduce dryer length. Substantial improvements in drying rates have been obtained with radio-frequency heating assistance.

Air impingement dryers as in Fig. 12-108 may also be used for textiles.

***Example 12-23 Impinging Air Drying of Sheets*** Estimate the dryer length needed to dry a continuous thin polyethylene sheet moving at 0.1 m/s using impinging air from a wet-basis moisture of 40 to 10 percent. Assume that moisture is evenly distributed on the top surface of the sheet and that the sheet nonhygroscopic (i.e., there is no bound water). Ambient air at 22°C and 50 percent relative humidity is heated to 120°C. The impinging air dryer has an array of jets that are 7 cm apart from one another, 1 cm in diameter, and 5 cm above the sheet. The air velocity through each jet is 10 m/s. Estimate the dryer size reductions possible if (a) the impinging air were predried, using a dessicant wheel, to 10 percent relative humidity, (b) the inlet moisture content was reduced to 35 percent, and (c) the air temperature was increased to 130°C.

Physical properties: Pr = 0.71; $D_{water/air} = 2.7 \times 10^{-5}$ m$^2$/s; kinematic viscosity of air = $2.2 \times 10^{-5}$ m$^2$/s; Sc = 0.64 (= 2.2/2.7); $k_{air} = 0.03$ W/(m · K); $\Delta H_{vap} = 2450$ kJ/kg. Both belt and polyethylene sheet are 1 kg/m$^2$ with a specific heat of 2 J/(g · K) and both enter the dryer at 22°C.

*Solution* For this example, we will create an incremental calculation using a spreadsheet.

We will make use of a well-known correlation for prediction of heat- and mass-transfer coefficients for air impinging on a surface from arrays of holes (jets). This correlation uses relevant geometric properties such as the diameter of the holes, the distance between the holes, and the distance between the holes and the sheet [Martin, "Heat and Mass Transfer Between Impinging Gas Jets and Solid Surfaces," *Advances in Heat Transfer,* vol. 13, Academic Press, Cambridge, Mass., 1977, pp. 1–66].

$$\frac{\text{Sh}}{\text{Sc}^{0.42}} = \frac{\text{Nu}}{\text{Pr}^{0.42}} = \left[1 + \left(\frac{H/D}{0.6/\sqrt{f}}\right)^6\right]^{-0.05} \times \sqrt{f}\,\frac{1 - 2.2\sqrt{f}}{1 + 0.2(H/D - 6)\sqrt{f}} \times \text{Re}^{2/3} \tag{12-115}$$

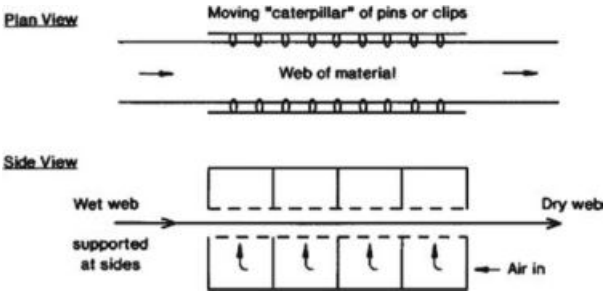

**FIG. 12-109** Stenter or tenter for textile drying.

where $D$ = inside diameter of nozzle, m

$$f = \frac{\pi}{2\sqrt{3}}\left(\frac{D}{L_D}\right)^2$$

$H$ = distance from nozzle to sheet, m
$L_D$ = average distance between nozzles, m
Nu = Nusselt number
Pr = Prandtl number
Re = Reynolds number = $\dfrac{wD}{\nu}$
Sc = Schmidt number
Sh = Sherwood number
$w$ = velocity of air at nozzle exit, m/s
$\nu$ = kinematic viscosity of air, m$^2$/s

The heat- and mass-transfer coefficients were then calculated from the definitions of the Nusselt and Sherwood numbers.

$$\text{Nu} = \frac{hD}{k_{\text{th}}}$$

where $k_{\text{th}}$ = thermal conductivity of air, W/(m · K)
$D$ = diameter of holes in air bars, m

$$\text{Sh} = \frac{k_m^* D}{\text{diff}}$$

where diff = diffusion coefficient of water vapor in air, m$^2$/s.

Plugging in the values of $H = 5$ cm, $D = 1$ cm, $L = 7$ cm, and the values of Pr, Sc, $D_{water/air}$, and $k_{air}$ gives heat- and mass-transfer coefficients of 74 W/(m$^2$ · K) and 0.0705 m/s, respectively.

Now we write an energy balance equation for the temperature of the sheet, which we assume to be a single value through the thickness of the sheet (it is the same as in Example 12-14):

$$(C_{p,\text{solids}} + C_{p,\text{water}} \cdot w_{\text{avg,dry-basis}}) \cdot \frac{m_{\text{sheet}}}{A} \cdot \frac{dT_{\text{sheet}}}{dt} = h \cdot (T_{\text{air}} - T_{\text{sheet}}) - F \cdot \Delta H_{\text{vap}} \tag{12-116}$$

We also write a mass balance:

$$\frac{dm_w}{dt}\frac{1}{A} = k_c \cdot \left(C_w^{\text{surface}} - C_w^{\text{bulk}}\right) \tag{12-117}$$

The specific heat values ($C_{p,\text{solids}}$ and $C_{p,\text{water}}$), the basis weight of the sheet ($\dfrac{m_{\text{sheet}}}{A}$), the heat- and mass-transfer coefficients ($h$ and $k_c$), heat of vaporization ($\Delta H_{\text{vap}}$), and the bulk water concentration in the air ($C_w^{\text{bulk}}$) are all constant. Values of the sheet temperature, the drying flux ($F$), the water concentration in the air immediately adjacent to the sheet ($C_w^{\text{surface}}$), and the mass loading of water ($\dfrac{m_{\text{water}}}{A}$) on the sheet all change with time. We convert the time into distance from the dryer feed point by using the sheet velocity.

The concentration of water vapor (also called the *volumetric humidity*) immediately adjacent to the wet sheet is calculated using equations from the psychrometry section. Specifically, Eq. (12-5) is used to calculate the vapor pressure of the water at the sheet temperature, and Table 12-1 is used to calculate the volumetric humidity from the vapor pressure and sheet temperature.

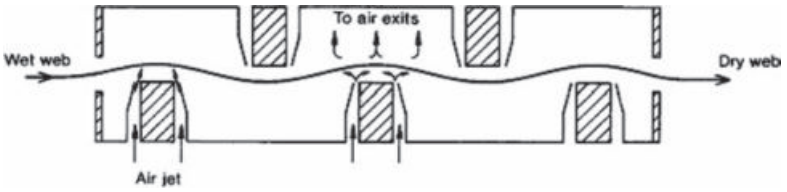

**FIG. 12-108** Air flotation (impingement) dryer.

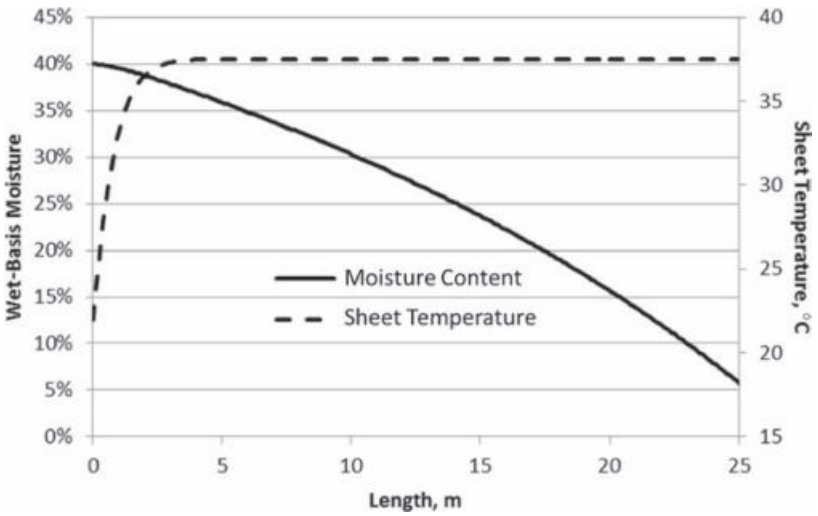

**FIG. 12-110** Simulation results for sheet drying example.

The two equations above were solved in stepwise explicit manner with a spreadsheet. Each row represents a small time step. The temperature from the previous time step was used to calculate all the changing quantities in the new time step.

Results from this calculation are shown in Fig. 12-110. For the base conditions, the results show that a dryer length of 23.0 m is needed.

In Table 12-47, the results for all the cases are shown.

The results show us the relative sensitivity of the process to some typical methods to increase the drying rate and therefore reduce the dryer size. The biggest handle is the reduction of the initial moisture content. This is a nonlinear effect with wet-basis moisture content. In practice, this is often accomplished by a mechanical dewatering process upstream of thermal drying. The dry-basis moisture content is 0.667 for the base case and 0.35/0.65 = 0.538. So a reduction from 40 percent to 35 percent on a wet basis equates to a drying load reduction of nearly 20 percent,

$$(1 - 0.538/0.667) \times 100 \text{ percent.}$$

The heat-transfer calculations [Eqs. (12-110) through (12-113)] used in the Drum Drying subsection are directly applicable for heating/drying of sheets in contact with rollers.

**Freeze Dryers*** In freeze drying (lyophilization), the feed material is frozen and ice sublimes directly to vapor. This gives gentle drying, preserves heat-sensitive materials, and preserves the solid structure without shrinkage and deformation. The process must operate at temperatures and vapor partial pressures below the triple point (0.006 bar and 0.01°C for water), normally by operating at high vacuum (vacuum freeze drying—see Fig. 12-111), although atmospheric freeze drying with highly dehumidified air is sometimes possible. Because of the low driving forces, freeze drying is generally an expensive option in both equipment and operating cost, with typical process times of hours or days.

***Applications*** Freeze drying is mainly used for high-value products where the gain in product quality justifies the high cost, particularly in the food, beverage, and pharmaceutical industries. The major advantages are as follows:

- Preservation of original flavor, aroma, color, shape, and texture (or development of special food textures and flavor effects)
- Retention of original distribution of soluble substances such as sugars, salts, and acids, which can migrate to the product surface in conventional drying
- Negligible shrinkage, resulting in excellent and near-instantaneous rehydration characteristics
- Negligible product loss
- Minimal risk of cross-contamination

Freeze drying is used for selected vegetables, fruits, meat, fish, and beverage products, such as instant coffee ( flavor and aroma retention), strawberries (color preservation), and chives (shape preservation). For pharmaceuticals, solutions of sterile products may be dried in glass vials, or blocks or slabs of material may be dried on trays.

***The freeze-drying process*** Industrial freeze drying is carried out in three steps:

1. Freezing of the feed material
2. Primary drying, i.e., sublimation drying of the main ice content, corresponding to the constant-rate period in conventional drying
3. Secondary drying, i.e., desorption drying of the internal or bound moisture or hydrates, corresponding to the falling-rate period in conventional drying

Unlike many conventional processes, the primary drying period is usually the longest. The secondary drying period is relatively short and may run at a higher temperature.

**Freezing** The freezing methods applied for solid products are all conventional freezing methods such as blast freezing, individual quick freezing (IQF), or similar. To ensure good stability of the final product during storage, a product temperature of −20 to −30°C should be achieved to ensure that more than 95 percent of the free water is frozen. Freezing may be performed within the dryer or externally. External freezing can debottleneck a dryer being used for repeated cycles, e.g., in the food industry where 2 to 3 batches may be run per day.

**TABLE 12-47 Results for Example 12-23: Impinging Air Drying of Sheets**

| | Cases | | | |
|---|---|---|---|---|
| | 1 | 2 | 3 | 4 |
| Air temperature, °C | 120 | 130 | 120 | 120 |
| Relative humidity of air (before heating), percent | 40 | 40 | 10 | 40 |
| Initial wet-basis moisture content, percent | 40 | 40 | 40 | 35 |
| Dryer length needed, m | 23 | 20.9 | 22 | 17.8 |

*Special thanks are due to Prof. A. Basseri, University of Turin, Italy, for his input to this subsection.

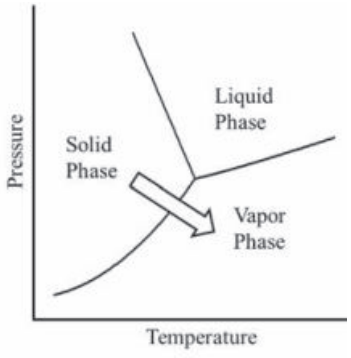

**FIG. 12-111** Phase diagram for freeze drying.

The free water freezes to pure ice crystals, leaving the soluble substances as high concentrates or even crystallized. Solid products maintain their natural cell structure, as long as the ice crystals are small enough to avoid damaging the cells. For liquid feeds (with no cell structure) the product structure is formed by the freezing process as an intercrystalline matrix of the concentrated product around the ice crystals.

Freezing rate is a key parameter; small ice crystals are obtained by quick freezing, while slow freezing gives larger ice crystals. The structure of the matrix can affect the freeze-drying performance as well as the appearance, mechanical strength, and solubility rate. Small ice crystals lead to light color (high surface reflection of light) and a good mechanical strength of the freeze-dried product, but give diffusion restrictions for vapor transport inside the product (particularly for solutions) and hence slower drying. Large ice crystals lead to the opposite results. An optimum may be achieved by initial fast freezing followed by annealing at a higher temperature, allowing crystal growth and a more porous structure and significantly reducing primary drying time, as shown in Table 12-48.

Thus the freezing method must be carefully adapted to the quality criteria of the finished product. Common methods include

- Drum freezing, by which a thin slab of 1.5 to 3 mm is frozen within 1.5 to 3 min
- Belt freezing, by which a slab of 6 to10 mm passing through different freezing zones is frozen during 10 to 20 min
- Shelf freezing in situ in the dryer, particularly for pharmaceuticals
- Foaming, used to influence the structure and mainly to control the density of the freeze-dried product

**Batch Freeze Dryers** Freeze dryers are normally multishelf units with the product in trays or multiple glass vials. The main components are (1) the vacuum chamber, heating plates, and vapor traps, all built into the freeze dryer and (2) the external systems, such as the transport system for the product trays, the deicing system, and the support systems for supply of heat, vacuum, and refrigeration.

In some units, the trays are carried in tray trolleys suspended in an overhead rail system for easy transport and quick loading and unloading, as illustrated in Fig. 12-112. Heat transfer is by conduction from the shelf below and radiation from the shelves above and below. As driving forces are low, a large heating surface is desirable. The heating plates should be at uniform temperatures, not exceeding 2°C to 3°C across the dryer, so the distribution of the heating medium (usually silicone thermal oil) to the heating plates and the flow rate inside the plates are very important factors.

If the product has been frozen externally, the operation vacuum should be reached quickly (within 10 min) to avoid the risk of product melting, and the heating plates are cooled to approximately 25°C. When the operating vacuum is achieved, the heating plate temperature is raised quickly to the desired operating temperature. Important features of a modern freeze-drying plant include a built-in vapor trap, allowing a large opening for vapor flow to the condenser, and a *continuous deicing* (CDI) system, reducing the ice layer on the condenser to a maximum of 6 to 8 mm. At 1 mbar pressure, the vapor flow rate is typically about 1 $m^3/(s \times m^2$ of tray area).

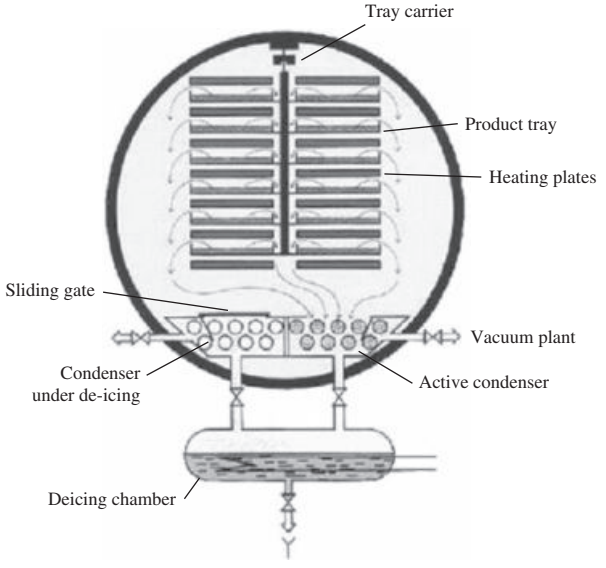

**FIG. 12-112** Cross-section of RAY batch freeze dryer. (*GEA*)

**Cycle Operating Conditions** Low shelf temperatures give slower drying and increase the refrigeration load; about 75 percent of the energy costs relate to the refrigeration plant, and if the set temperature is 10°C lower than optimum, its energy consumption will increase by approximately 50 percent. However, although the product is kept cool by the sublimation, it must be kept below the temperature where product "collapse" or "meltback" occurs. This value can be measured at small scale with a freeze-drying microscope, and it can be chosen as an upper limit for the shelf temperature in primary drying. A control strategy is generally based on applied pressure and shelf temperature. In secondary drying, there is no danger of meltback, and higher shelf temperatures may be usable. Final moisture is typically 2 to 3 percent. Typical vacuum levels are 0.4 to 1.3 mbar absolute (40 to 130 Pa) for foods and 10 to 20 Pa for pharmaceuticals. Table 12-48 shows a typical cycle for a pharmaceutical product.

**Continuous Freeze Drying** The utility requirements for batch freeze dryers vary considerably over the cycle. During sublimation drying, the requirements are 2 to 2.5 times the average requirement, and the external systems must be designed accordingly. To overcome this peak load and to meet the market request for high unit capacities, continuous freeze dryer designs have been developed and implemented for coffee drying. These require vacuum locks for product both entering and leaving the dryer. As the tray stacks move through the freeze dryer, they can pass through different temperature zones to give a heating profile, selected so that overheating of dry surfaces is avoided.

**Design Methods** The size of the freeze-drying plant is based on the batch size and average sublimation capacity required as well as on the product type and form. The evaporation temperature of the refrigeration plant depends on the required vacuum. At 1 mbar it will be –35 to –40°C depending on the vapor trap performance. Sample data are shown in Table 12-49.

There is extensive specialized literature on freeze drying, and hands-on courses are available, e.g., from Biopharma.

**Electromagnetic Drying Methods**

***Examples and Synonyms*** Infrared, radiofrequency, microwave, electromagnetic heating, dielectric heating

***Description*** Electromagnetic drying methods employ radiation (infrared, radiofrequency, and microwave) to produce heating. In the instances of radiofrequency and microwave heating, electromagnetic radiation is absorbed by dipolar liquids, such as water or liquids containing dissolved salts. In infrared heating, heat radiates from an extremely hot element.

Generally, dielectric methods heat volumetrically and are suitable for thicker materials whereas infrared energy is considered a surface-heating method.

Since these are heating methods, drying systems also need to enable moisture removal either by using air or heating the material above the boiling temperature. These heating methods are often used in conjunction with hot air.

**Dielectric Methods (Radiofrequency and Microwave)** Schiffmann (1995) states that dielectric/radiofrequency heating operates in the range of 1 to 100 MHz, while microwave frequencies range from 300 MHz to 300 GHz. The electromagnetic spectrum shown in Fig. 12-113 illustrates the relative differences in wavelength and frequency between radio waves and microwaves. All electromagnetic waves are characterized by both wavelength and frequency. An example of a simplified electromagnetic wave is shown in Fig. 12-114. An electromagnetic wave is a combination of an electric component *E* and a magnetic component *H*. Note that *E* and *H* are perpendicular to each other and both are perpendicular to the direction of travel. The devices used for generating microwaves are called *magnetrons* and *klystrons* whereas the devices used to generate dielectric frequencies are referred to as *oscillators* and *triodes* or *tetrodes*.

Water molecules are dipolar (i.e., they have an asymmetric charge center) and are normally randomly oriented. The rapidly changing polarity of a microwave or radiofrequency field attempts to pull these dipoles into alignment with the field. As the field changes polarity, the dipoles return to a

**TABLE 12-48 Example Pharmaceuticals Freeze-Drying Cycles, with and Without Annealing During Freezing**

*Other sizes available.

random orientation before being pulled the other way. This buildup and decay of the field, and the resulting stress on the molecules, causes a conversion of electric field energy to stored potential energy, then to random kinetic or thermal energy. Hence dipolar molecules such as water absorb energy in these frequency ranges. The power developed per unit volume $P_v$ by this mechanism is

$$P_v = kE^2 f\varepsilon' \tan\delta = kE^2 f\varepsilon'' \tag{12-118}$$

where $k$ is a dielectric constant, depending on the units of measurement, $E$ is the electric field strength ($V/m^3$), $f$ is the frequency, $\varepsilon'$ is the relative dielectric constant or relative permeability, tan $\delta$ is the loss tangent or dissipation factor, and $\varepsilon''$ is the loss factor.

The field strength and the frequency are dependent on the equipment, while the dielectric constant, dissipation factor, and loss factor are material-dependent. The electric field strength is also dependent on the location of the material within the microwave/radiofrequency cavity [Turner and Ferguson, "A Study of the Power Density Distribution Generated during the Combined Microwave and Convective Drying of Softwood," *Drying Technol.* **12**(5–7): 1411–1430 (1995)], which is one reason why domestic microwave ovens have rotating turntables (so that the food is exposed to a range of microwave intensities). This mechanism is the major one for the generation of heat within materials by these electromagnetic fields.

There is also a heating effect due to ionic conduction. The water inside a material may contain ions such as sodium, chloride, and hydroxyl; these ions are accelerated and decelerated by the changing electric field. The collisions that occur as a result of the rapid accelerations and decelerations lead to an increase in the random kinetic (thermal) energy of the material. This type of heating is not significantly dependent on either temperature or frequency. The power developed per unit volume $P_v$ from this mechanism is

$$P_v = E^2 qn\mu \tag{12-119}$$

where $q$ is the amount of electric charge on each of the ions, $n$ is the charge density ($ions/m^3$), and $\mu$ is the level of mobility of the ions.

Schiffmann (1995) indicates that the dielectric constant of water is more than an order of magnitude higher than that of most underlying materials, and the overall dielectric constant of most materials is usually nearly proportional to moisture content up to the critical moisture content, often around 20 to 30 percent. Hence microwave and radiofrequency methods preferentially heat and dry wetter areas in most materials, a process which tends to give more-uniform final moisture contents. The dielectric constant of air is very low compared with that of water, so lower density usually means lower heating rates. For water and other small molecules, the effect of increasing temperature is to decrease the heating rate slightly, hence leading to a self-limiting effect.

Other effects (frequency, conductivity, specific heat capacity, etc.) are discussed by Schiffmann (1995), but are less relevant because the range of available frequencies (which do not interfere with radio transmissions) is small (2.45 GHz, 910 MHz). Higher frequencies lead to lower penetration depths into a material than lower frequencies do. Sometimes the 2.45-GHz frequency has a penetration depth as low as 2.5 cm (1 in). For in-depth heating (*volumetric heating*), radio frequencies with lower frequencies and longer wavelengths are often used. Note that not all frequencies are available to use in all geographies as designated by the International Telecommunication Union, as seen in Table 12-50.

Also note that microwave and radiofrequency generators are often used in conjunction with other dryer types to enhance drying rates, especially in thicker materials. Achieving uniform heating is challenging when using these electromagnetic heating methods.

***Infrared Methods*** Infrared (IR) radiation is commonly used in the dehydration of coated films and to even out the moisture content profiles in the drying of paper and boards. The mode of heating is essentially on the material surface, and IR sources are relatively inexpensive compared with dielectric sources.

The heat flux obtainable from an IR source is given by

$$q = F\alpha\varepsilon\left(T^4_{\text{source}} - T^4_{\text{drying material}}\right) \tag{12-120}$$

where $q$ = heat flux, $W/m^2$; $\alpha$ = Stefan-Boltzmann constant = $5.67 \times 10^{-8}$ $W/(m^2 \cdot K^4)$; $\varepsilon$ = emissivity (0 to 1); $F$ = view factor; and $T$ = absolute temperature of the source or drying material.

The emissivity is a property of the material. The limiting value is 1 (blackbody); shiny surfaces have a low value of emissivity. The view factor is a fractional value that depends on the geometric orientation of the source with respect to the heating object.

It is very important to recognize the $T^4$ dependence on the heat flux. IR sources need to be very hot to give appreciable heat fluxes. Therefore, IR sources should not be used with flammable materials. Improperly designed IR systems can also overheat materials and equipment.

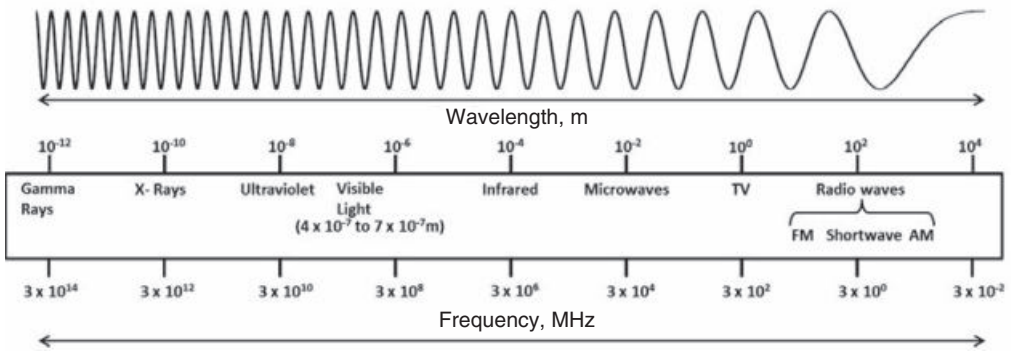

**FIG. 12-113** Electromagnetic spectrum.

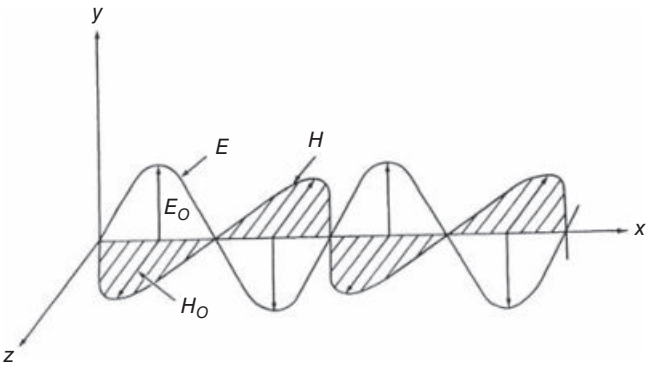

**FIG. 12-114** Illustration of a simple EM wave. Here $E$ and $H$ represent the electrical and magnetic components of the wave, respectively. $E_0$ and $H_0$ show their respective amplitudes. (*Reprinted with permission from Mujumdar, A.S., Handbook of Industrial Drying, 2nd ed., Marcel Dekker Inc., New York, 1995.*)

***Example 12-24 Sheet Drying with Convection and Infrared*** In the same sheet drying problem as in Example 12-23, the belt has been removed, and now the sheet to be dried will be suspended in air using tensioning rollers (see Fig. 12-104). The same impinging air heat-transfer process occurs at the bottom of the web, but now flat infrared heat panels will be installed along the length of the dryer above the sheet.

Calculate the dryer length needed to dry the material from the inlet at 40 percent wet basis to the outlet at 10 percent dry basis without infrared and with the infrared on with panel temperatures at 300, 500, and 700°C. Assume the emissivity and view factors are unity.

We will use the energy and mass balance equations as before, except we will include the infrared term. We will assume that the web is thin enough that we can neglect temperature gradients through its thickness.

$$(C_{p,\text{solids}} + C_{p,\text{water}} \cdot w_{\text{avg,dry-basis}}) \cdot \frac{m_{\text{sheet}}}{A} \cdot \frac{dT_{\text{sheet}}}{dt} = h \cdot (T_{\text{air}} - T_{\text{sheet}}) + F_{\text{View}} \alpha\varepsilon \left(T_{\text{source}}^4 - T^4\right) - F \cdot \Delta H_{\text{vap}} \tag{12-121}$$

We also write a mass balance:

$$\frac{dm_w}{dt}\frac{1}{A} = k_c \cdot \left(C_w^{\text{surface}} - C_w^{\text{bulk}}\right) \tag{12-122}$$

Results are shown in Table 12-51.

The calculation indicates that the drying rate can be greatly accelerated by the infrared. However, there are some idealizations such as the view factor and emissivity value. Running infrared panels can introduce problems since they apply heat to anything they "see" and they need to be extremely hot. The panels must be shut off if the line stops, or else the material may be damaged or pose a fire risk. Infrared heating needs special considerations if the process is expected to create volatile or flammable materials.

**TABLE 12-50 Frequency Designation by the International Telecommunication Union (Schiffmann, 1995)**

| Center frequency (MHz) | Frequency range (MHz) | Maximum radiation limit* |
|---|---|---|
| 6.780 | 6.765–6.795 | Under consideration |
| 13.560 | 13.553–13.567 | Unrestricted |
| 27.120 | 26.957–27.283 | Unrestricted |
| 40.680 | 40.660–40.700 | Unrestricted |
| 433.920 | 433.050–434.790 | Under consideration |
| 915.000 | 902–928 | Unrestricted |
| 2450 | 2400–2500 | Unrestricted |
| 5800 | 5725–5875 | Unrestricted |
| 24,125 | 24,000–24,250 | Under consideration |
| 61,250 | 61,000–61,500 | Under consideration |
| 122,500 | 122,000–123,000 | Under consideration |
| 245,000 | 240,000–246,000 | Under consideration |

*The term *unrestricted* applies to the fundamental and all other frequency components falling within the designated band. Special measures to achieve compatibility may be necessary where other equipment satisfying immunity requirements is placed close to ISM equipment.

**TABLE 12-51 Results for Example 12-24: Sheet Drying with Convection and Infrared**

| Distance, m | IR panel temperature, °C |
|---|---|
| 23.0 | None |
| 13.4 | 300 |
| 6.4 | 500 |
| 3.0 | 700 |

## OPERATION AND TROUBLESHOOTING

**Troubleshooting** Dryer troubleshooting is not extensively covered in the literature, but a systematic approach has been proposed in Kemp and Gardiner, "An Outline Method for Troubleshooting and Problem-Solving in Dryers," *Drying Technol.* **19**(8): 1875–1890 (2001). The main steps of the algorithm are as follows:

- *Problem definition*—definition of the dryer problem to be solved
- *Data gathering*—collection of relevant information, e.g., plant operating data
- *Data analysis,* e.g., heat and mass balance, *and identification of the cause of the problem*
- *Conclusions and actions*—selection and implementation of a solution in terms of changes to process conditions, equipment, or operating procedures
- *Performance auditing*—monitoring to ensure that the problem was permanently solved

The algorithm might also be considered as a "plant doctor." The doctor collects data, or symptoms, and makes a diagnosis of the cause(s) of the problem. Then alternative solutions, or treatments, are considered and a suitable choice is made. The results of the treatment are reviewed (i.e., the process is monitored) to ensure that the "patient" has returned to full health. See Fig. 12-115.

The algorithm is an excellent example of the "divergent-convergent" (brainstorming) method of problem solving. It is important to list all possible causes and solutions, no matter how ridiculous they may initially seem; there may actually be some truth in them, or they may lead to a new and better idea.

***Problem Categorization*** In the problem definition stage, it is extremely useful to categorize the problem, as the different broad groups require different types of solution. Five main categories of dryer problems can be identified:

1. Drying process performance (outlet moisture content too high, throughput too low)
2. Materials handling (dried material too sticky to get out of dryer, causing blockage)
3. Product quality (too many fines in product, bulk density too low/high, discoloration, etc.)
4. Mechanical breakdown (catastrophic sudden failure)
5. Safety, health, and environmental issues (drying air temperature too high, buildup of material in dryer, etc.)

**FIG. 12-115** Schematic diagram of algorithm for dryer troubleshooting.

Experience suggests that the majority of problems are of the first three types, and these are about equally split over a range of industries and dryer types. Ideally, unforeseen safety, health, and environmental issues will be rare, as these will have been identified in the safety case before the dryer is installed or during commissioning. Likewise, major breakdowns should be largely avoided by a planned maintenance program.

***Drying Performance Problems*** Performance problems can be further categorized as

1. Heat and mass balance deficiencies (not enough heat input to do the evaporation)
2. Drying kinetics (drying too slowly, or solids residence time in dryer is too short)
3. Equilibrium moisture limitations (reaching a limiting value, or regaining moisture in storage)

For the heat and mass balance, the main factors are

- Solids throughput
- Inlet and outlet moisture content
- Temperatures and heat supply rate
- Leaks and heat losses

As well as problem-solving, these techniques can be used for performance improvement and debottlenecking.

Drying kinetics, which are affected by temperature, particle size, and structure, are limited by external heat and mass transfer to and from the particle surface in the early stages; but internal moisture transport is the main parameter at lower moisture.

Equilibrium moisture content increases with higher relative humidity, or with lower temperature. Problems that depend on the season of the year, or vary between day and night (both suggesting a dependence on ambient temperature and humidity), are often related to equilibrium moisture content.

***Materials Handling Problems*** The vast majority of handling problems in a dryer concern sticky feedstocks. Blockages can be worse than performance problems as they can close down a plant completely, without warning. Most stickiness, adhesion, caking, and agglomeration problems are due to *mobile liquid bridges* (surface moisture holding particles together). These are extensively described in particle technology textbooks. Unfortunately, these forces tend to be at a maximum when the solid forms the continuous phases and surface moisture is present, which is the situation for most filter and centrifuge cakes at discharge. By comparison, slurries (where the liquid forms the continuous phase) and dry solids (where all surface moisture has been eliminated) are relatively free-flowing and incur fewer problems.

Other sources of problems include electrostatics (most marked with fine and dry powders) and *immobile liquid bridges*, the so-called "sticky-point phenomenon." This latter is sharply temperature-dependent, with only a weak dependence on moisture content, in contrast to mobile liquid bridges. It occurs for only a small proportion of materials, but is particularly noticeable in amorphous powders and foods and is often linked to the glass transition temperature.

***Product Quality Problems*** (These do not include the moisture level of the main solvent.) Many dryer problems either concern product quality or cannot be solved without considering the effect of any changes on product quality. Thus it is a primary consideration in most troubleshooting, although product quality measurements are specific to the particular product, and it is difficult to generalize. However, typical properties may include color, taste (not easily quantifiable), bulk density, viscosity of a paste or dispersion, dispersibility, or rate of solution. Others are more concerned with particle size, size distribution (e.g., coarse or fine fraction), or powder handling properties such as rate of flow through a standard orifice. These property measurements are nearly always made off-line, either by the operator or by the laboratory, and many are very difficult to characterize in a rigorous quantitative manner. (See also the Fundamentals subsection.)

Storage problems, very common in industry, result if the product from a dryer is free-flowing when packaged, but has caked and formed solid lumps by the time it is received by the customer. Sometimes the entire internal contents of a bag or drum have welded together into a huge lump, making it impossible to discharge.

Depending on the situation, there are at least three different possible causes:

1. *Equilibrium moisture content:* hygroscopic material is absorbing moisture from the air on cooling.
2. *Incomplete drying:* product is continuing to lose moisture in storage.
3. *Psychrometry:* humid air is cooling and reaching its dew point.

The three types of problem have some similarities and common features, but the solution to each one is different. Therefore, it is essential to understand which mechanism is actually in play.

*Option 1:* The material is hygroscopic and is absorbing moisture back from the air in storage, where the cool air has a higher relative humidity than the hot dryer exhaust. *Solution:* Pack and seal the solids immediately on discharge in tough impermeable bags (usually double- or triple-lined to reduce the possibility of tears and pinholes), and minimize the ullage (airspace above the solids in the bags) so that the amount of moisture that can be absorbed is too low to cause any significant problem. Dehumidifying the air to the storage area is also possible, but often very expensive.

*Option 2:* The particles are emerging with some residual moisture, and they continue to dry after being stored or bagged. As the air and solids cool, the moisture in the air comes out as dew and condenses on the surface of the solids, causing caking by mobile liquid bridges. *Solution:* If the material is meeting its moisture content specification, cool the product more effectively before storage, to stop the drying process. If the outlet material is wetter than stated in the specification, alter dryer operating conditions or install a postdryer.

*Option 3:* Warm, wet air is getting into the storage area or the bags, either because the atmosphere is warm with a high relative humidity (especially in the tropics) or because dryer exhaust air has been allowed to enter. As in option 2, when the temperature falls, the air goes below its dew point and condensation occurs on the walls of the storage area or inside the bags, or on the surface of the solids, leading to caking. *Solution:* Avoid high-humidity air in the storage area. Ensure the dryer exhaust is discharged a long way away. If the ambient air humidity is high, consider cooling the air supply to storage to bring it below its dew point and reduce its absolute humidity.

**Dryer Operation**

***Start-Up Considerations*** It is important to start up the heating system before introducing product into the dryer. This will minimize condensation and subsequent product buildup on dryer walls. It is also important to minimize off-quality production by not overdrying or underdrying during the start-up period. Proper control system design can aid in this regard. The dryer turndown ratio is also an important consideration during start-up. Normally the dryer is started up at the lowest end of the turndown ratio, and it is necessary to match heat input with capacity load.

***Shutdown Considerations*** The sequence for dryer shutdown is also very important and depends on the type of dryer. The sequence must be thoroughly thought through to prevent significant off-quality product or a safety hazard. The outlet temperature during shutdown is a key operating variable to follow.

***Energy Considerations*** The first consideration is to minimize the moisture content of the dryer feed, e.g., with dewatering equipment, and to establish as high an outlet product moisture target as possible. Other energy considerations vary widely by dryer type. In general, heating with gas, fuel oil, and steam is significantly more economical than heating with electricity. Hence radiofrequency (RF), microwave, and infrared drying is energy-intensive. Direct heating is more efficient than indirect in most situations. Sometimes air recycle (direct or indirect) can be effective in reducing energy consumption. And generally operating at high inlet temperatures is more economical.

***Recycle*** In almost all situations, the process system must be able to accommodate product recycle. The question is how to handle it most effectively, considering the product quality, equipment size, and energy.

***Improvement Considerations*** *The first consideration is to evaluate mass and energy balances to identify problem areas.* See the Experimental Methods part of this subsection for guidance on how to conduct a mass and energy balance on an industrial dryer. This will identify air leaks and excessive equipment heat losses and will enable determination of overall energy efficiency.

A simplified heat balance will show what might need to be done to debottleneck a convective (hot gas) dryer, i.e., increase its production rate $F$.

$$F(X_I - X_O)\lambda_{evap} \approx GC_{PG}(T_{GI} - T_{GO}) - Q_{wl}$$

Before proceeding along this line, however, it is necessary to establish that the dryer is genuinely heat and mass balance–limited. If the system is controlled by kinetics or equilibria, changing the parameters may have undesirable side effects, e.g., increasing the product moisture content.

The major alternatives are then as follows (assuming gas specific heat capacity $C_{PG}$ and latent heat of evaporation $\lambda_{evap}$ are fixed):

1. Increase the gas flow rate $G$, as it usually increases pressure drop, so new fans and gas cleaning equipment may be required.
2. Increase the inlet gas temperature $T_{GI}$ which is usually limited by risk of thermal damage to product.
3. Decrease the outlet gas temperature $T_{GO}$. But note that this increases NTUs, outlet humidity, and relative humidity and reduces both the temperature and humidity driving forces. Hence it may require a longer drying time and a larger dryer, and it may also increase equilibrium and outlet moistures.
4. Reduce inlet moisture content $X_I$, say, by dewatering by gas blowing, centrifuging, vacuum or pressure filtration, or a predryer.
5. Reduce heat losses $Q_{wl}$ by insulation, removing leaks, etc.

**Dryer Safety** This subsection discusses some of the key considerations in dryer safety. General safety considerations are discussed in Sec. 23, Process Safety, and should be referred to for additional guidance.

Fires, explosions, and, to a lesser extent, runaway decompositions are the primary hazards associated with drying operations. The outbreak of fire is a result of ignition which may or may not be followed by an explosion. A hazardous situation is possible if

1. The product is combustible.
2. The product is wetted by a flammable solvent.
3. The dryer is direct-fired.

An explosion can be caused by dust or flammable vapors, both of which are fires that rapidly propagate, causing a pressure rise in a confined space.

***Dust Explosions*** Dispersion dryers can be more hazardous than layer-type dryers if one is drying a solid combustible material which is then dispersed in air, particularly if the product is a fine particle size. If this finely dispersed product is then exposed to an ignition source, an explosion can result. The following conditions (van't Land, *Industrial Drying Equipment,* Marcel Dekker, New York, 1991) will be conducive to fire and explosion hazard:

1. Small particle sizes, generally less than 75 μm, which are capable of propagating a flame
2. Dust concentrations within explosive limits, generally 10 to 60 $g/m^3$
3. Ignition source energy of 10 to 1000 mJ or as low as 5 mJ for highly explosive dust sources
4. Atmosphere supporting combustion

Since most product and hence dust compositions vary widely, it is generally necessary to do quantitative testing in approved test equipment.

***Flammable Vapor Explosions*** This can be a problem for products wetted by flammable solvents if the solvent concentration exceeds 0.2 percent v/v in the vapor phase. The ignition energy of vapor-air mixtures is lower (<1 mJ) than that of dust-air suspensions. Many of these values are available in the literature, but testing may sometimes be required.

***Ignition Sources*** There are many possible sources of an ignition, and they need to be identified and addressed by both designers and operators. A few of the most common ignition sources are

1. Spontaneous combustion
2. Electrostatic discharge
3. Electric or frictional sparks
4. Incandescent solid particles from heating system

Safety hazards must be addressed with proper dryer design specifications. The following are a few key considerations in dryer design.

*Inert system design* The dryer atmosphere is commonly made inert with nitrogen, but superheated steam or self-inertized systems are also possible. Self-inertized systems are not feasible for flammable solvent systems. These systems must be operated with a small overpressure to ensure no oxygen ingress. And continuous on-line oxygen concentration monitoring is required to ensure that oxygen levels remain well below the explosion hazard limit.

*Relief venting* Relief vents that are properly sized relieve and direct dryer explosions to protect the dryer and personnel if an explosion does occur. Normally they are simple pop-out panels with a minimum length of ducting to direct the explosion away from personnel or other equipment.

*Suppression systems* Suppression systems typically use an inert gas such as carbon dioxide to minimize the explosive peak pressure rise and fire damage. The dryer operating pressure must be properly monitored to detect the initial pressure rise followed by shutdown of the dryer operating systems and activation of the suppression system.

*Clean design* Care should be taken in the design of both the dryer and dryer ancillary equipment (cyclones, filters, etc.) to eliminate ledges, crevices, and other obstructions that can lead to dust and product buildup. Smooth drying equipment walls will minimize deposits. This can go a long way in prevention. No system is perfect, of course, and a routine cleaning schedule is also recommended.

*Start-up and shutdown* Start-up and shutdown situations must be carefully considered in designing a dryer system. These situations can create higher than normal dust and solvent concentrations. This coupled with elevated temperatures can create a hazard well beyond that of normal continuous operation.

**Environmental Considerations** Environmental considerations are continuing to be an increasingly important aspect of dryer design and operation as environmental regulations are tightened. The primary environmental problems associated with drying are particulate and *volatile organic compound* (VOC) emissions. Noise can be an issue with certain dryer types.

***Environmental Regulations*** These vary by country, and it is necessary to know the specific regulations in the country in which the dryer will be installed. It is also useful to have some knowledge of the direction of regulations so that the environmental control system is not obsolete by the time it becomes operational.

Particulate emission problems can span a wide range of hazards. Generally, there are limits on both toxic and nontoxic particles in terms of annual and peak emissions limits. Particles can present toxic, bacterial, viral, and other hazards to human, animal, and plant life.

Likewise, VOC emissions can span a wide range of hazards and issues from toxic gases to smelly gases.

***Environmental Control Systems*** We should consider environmental hazards before the drying operation is even addressed. The focus should be on minimizing the hazards created in the upstream processing operations. After potential emissions are minimized, these hazards must be dealt with during dryer system design and then subsequently with proper operational and maintenance procedures.

***Particle Emission Control Equipment*** The four most common methods of particulate emissions control are as follows:

1. *Cyclone separators* The advantage of cyclones is they have relatively low capital and operating costs. The primary disadvantage is that they become increasingly ineffective as the particle size decreases. As a general rule of thumb, we can say that they are 100 percent efficient with particles larger than 20 μm and 0 percent efficient with particles smaller than 1 μm. Cyclones can also be effective precleaning devices to reduce the load on downstream bag filters.
2. *Scrubbers* The more general classification is wet dedusters, the most common of which is the wet scrubber. The advantage of wet scrubbers is that they can remove fine particles that the cyclone does not collect. The disadvantages are that they are more costly than cyclones and they can turn air contamination into water contamination, which may then require additional cleanup before the cleaning water is put into the sewer.
3. *Bag filters* The advantages of filters are that they can remove very fine particles; and bag technologies continue to improve and enable ever-smaller particles to be removed without excessive pressure drops or buildup. The primary disadvantages are higher cost relative to cyclones and greater maintenance costs, especially if frequent bag replacement is necessary.
4. *Electrostatic precipitators* The capital cost of these systems is relatively high, and maintenance is critical to effective operation.

***VOC Control Equipment*** The four most prevalent equipment controls are

1. *Scrubbers* Similar considerations as above apply.
2. *Absorbers* These systems use a high-surface-area absorbent, such as activated carbon, to remove the VOC absorbate.
3. *Condensers* These systems are generally only feasible for recovering solvents from nonaqueous wetted products.
4. *Thermal and catalytic incinerators* These can be quite effective and are generally a low capital and operating cost solution, except in countries with high energy costs.

***Noise*** Noise analysis and abatement is a very specialized area. Generally, the issue with dryers is associated with the fans, particularly for systems requiring fans that develop very high pressures. Noise is a very big issue that needs to be addressed with pulse combustion dryers, and it can be an issue with very large dryers such as rotary dryers and kilns.

Additional considerations regarding environmental control and waste management are addressed in Sec. 22, Waste Management, and Sec. 23, Process Safety.

**Control and Instrumentation** The purpose of the control and instrumentation system is to provide a system that enables the process to produce the product at the desired moisture target and to meet other quality control targets discussed earlier (density, particle size, color, solubility, etc.). This segment discusses key considerations for dryer control and instrumentation. Additional more-detailed information can be found in Sec. 8, Process Control.

Proper control of product quality starts with the dryer selection and design. Sometimes two-stage or multistage systems are required to meet product quality targets. Multistage systems enable us to better control temperature and moisture profiles during drying. Assuming the proper dryer design has been selected, we must then design the control and instrumentation system to meet all product quality targets.

***Manual versus Automatic Control*** Dryers can be controlled either manually or automatically. Generally, lab-, pilot-, and small-scale production units are controlled manually. These operations are usually batch systems, and manual operation provides lower cost and greater flexibility. The preferred mode for large-scale, continuous dryers is automatic.

***Key Control Variables*** Product moisture and product temperature are key control variables. Ideally both moisture and temperature measurement are done on-line, but frequently moisture measurement is done off-line and temperature (or exhaust air temperature) becomes the primary control variable. And generally the inlet temperature will control the rate of production, and the outlet temperature will control the product moisture and other product quality targets.

***Common Control Schemes*** Two relatively simple, but common control schemes in many dryer systems (Fig. 12-116) are as follows:

1. The outlet air temperature is controlled by feed rate regulation with the inlet temperature controlled by gas heater regulation.
2. The outlet air temperature is controlled by heater regulation with the feed rate held constant.

Alternatively, product temperatures can replace air temperatures with the advantage of better control and the disadvantage of greater maintenance of the product temperature sensors.

***Other Instrumentation and Control***

*Pressure* Pressure and equipment pressure drops are important to proper dryer operation. Most dryers are operated under vacuum. This prevents dusting to the environment, but excess leakage in decreases dryer efficiency. Pressure drops are especially important for stable fluid-bed operation.

*Air (gas) flow rate* Obviously gas flows are another important parameter for proper dryer operation. Pitot tubes are useful when a system has no permanent gas flow sensors. Averaging pitot tubes work well in permanent installations. The devices work best in straight sections of ductwork which are sometimes difficult to find and make accurate measurement a challenge.

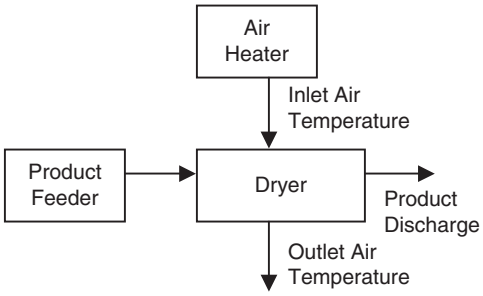

**FIG. 12-116** Typical dryer system.

*Product feed rate* It's important to know that product feed rates and feed rate changes are sometimes used to control finished-product moistures. Weigh belt feeders are common for powdered products, and there is a wide variety of equipment available for liquid feeds. Momentum devices are inexpensive but less accurate.

*Humidity* The simplest method is sometimes the best. Wet- and dry-bulb temperature measurement to get air humidity is simple and works well for the occasional gas humidity measurement. The problem with permanent humidity measurement equipment is the difficulty of getting sensors robust enough to cope with a hot, humid, and sometimes dusty environment. If these are used, be careful about placement and inspection to ensure that product does not accumulate on the sensor.

***Interlocks*** Interlocks are another important feature of a well-designed control and instrumentation system. Interlocks are intended to prevent damage to the dryer system or to personnel, especially during the critical periods of start-up and shutdown. The following are a few key interlocks to consider in a typical dryer system.

*Drying chamber damage* This type of damage can occur when the chamber is subjected to significant vacuum when the exhaust fans are started up before the supply fans.

*Personnel injury* This interlock is to prevent injury due to entering the dryer during operation, but more typically to prevent dryer start-up with personnel in the main chamber or inlet or exhaust air ductwork on large dryers. This typically involves microswitches on access doors coupled with proper door lock devices and tags.

*Assurance of proper start-up and shutdown* These interlocks ensure, e.g., that the hot air system is started up before the product feed system and that the feed system is shut down before the hot air system.

*Heater system* There are a host of important heater system interlocks to prevent major damage to the entire drying system. Additional details can be found in Sec. 23, Process Safety.

## Nomenclature and Units

| Symbol | Definition | SI units | U.S. Customary System units |
|---|---|---|---|
| $A$ | Absorption factor | | |
| $A$ | Area | $m^2$ | $ft^2$ |
| $C$ | Number of chemical species | | |
| $D$ | Distillate flow rate | kg·mol/s | lb·mol/h |
| $D$ | Diffusion coefficient | $m^2/s$ | $ft^2/h$ |
| $E$ | Efficiency | | |
| $E$ | Energy flux | $kW/m^2$ | Btu/($ft^2$·h) |
| $\mathcal{E}$ | Energy transfer rate | kW | Btu/h |
| $F$ | Feed flow rate | kg·mol/s | lb·mol/h |
| $H$ | Column height | m | ft |
| $H$ | Enthalpy | J/(kg·mol) | Btu/(lb·mol) |
| $H$ | Liquid holdup | kg·mol | lb·mol |
| $\mathbb{H}$ | Height of a transfer unit | m | ft |
| $K$ | Vapor-liquid equilibrium ratio ($K$ value) | | |
| $K_D$ | Chemical equilibrium constant for dimerization | | |
| $K_d$ | Liquid-liquid distribution ratio | | |
| $L$ | Liquid flow rate | kg·mol/s | lb·mol/h |
| $N$ | Number of equilibrium stages | | |
| $N_c$ | Number of relationships | | |
| $N_i$ | Number of design variables | | |
| $N_{min}$ | Minimum number of equilibrium stages | | |
| $N_p$ | Number of phases | | |
| $N_r$ | Number of repetition variables | | |
| $N_v$ | Number of variables | | |
| $\mathcal{N}$ | Rate of mass transfer | kg·mol/s | lb·mol/h |
| $N$ | Molar flux | kg·mol/($m^2$·s) | lb·mol/($ft^2$·h) |
| $\mathbb{N}$ | Number of transfer units | | |
| $P$ | Pressure | Pa | psia |
| $P^{sat}$ | Vapor pressure | Pa | psia |
| $Q$ | Heat-transfer rate | kW | Btu/h |
| $Q_c$ | Condenser duty | kW | Btu/h |
| $Q_r$ | Reboiler duty | kW | Btu/h |
| $R$ | External-reflux ratio | | |
| $R_{min}$ | Minimum-reflux ratio | | |
| $S$ | Sidestream flow rate | kg·mol/s | lb·mol/h |
| $S$ | Stripping factor | | |
| $S$ | Vapor-sidestream ratio | | |
| Sc | Schmidt number | | |
| $T$ | Temperature | K | °R |
| $U$ | Liquid-sidestream rate | kg·mol/s | lb·mol/h |
| $V$ | Vapor flow rate | kg·mol/s | lb·mol/h |
| $W$ | Vapor-sidestream rate | kg·mol/s | lb·mol/h |
| $X$ | Relative mole fraction in liquid phase | | |
| $Y$ | Relative mole fraction in vapor phase | | |
| $a$ | Activity | | |
| $a$ | Area | $m^2$ | $ft^2$ |
| $b$ | Component flow rate in bottoms | kg·mol/s | lb·mol/h |
| $c$ | Number of chemical species | | |
| $c$ | Molar density | $kg·mol/m^3$ | $lb·mol/ft^3$ |
| $d$ | Component flow rate in distillate | kg·mol/s | lb·mol/h |
| $d$ | Mass-transfer driving force | | |
| $e$ | Rate of heat transfer | kW | Btu/h |
| $f$ | Component flow rate in feed | kg·mol/s | lb·mol/h |
| $f$ | Fugacity | Pa | psia |

| Symbol | Definition | SI units | U.S. Customary System units |
|---|---|---|---|
| $h$ | Height | m | ft |
| $h$ | Heat-transfer coefficient | $kW/m^2$ | Btu/($ft^2$·h) |
| $\kappa$ | Mass-transfer coefficient | m/s | ft/h |
| $l$ | Component flow rate in liquid | kg·mol/s | lb·mol/h |
| $p$ | Pressure | kPa | psia |
| $q$ | Measure of thermal condition of feed | | |
| $q$ | Heat flux | $kW/m^2$ | Btu/ $ft^2$·h) |
| $q_c$ | Condenser duty | kW | Btu/h |
| $q_r$ | Reboiler duty | kW | Btu/h |
| $r$ | Sidestream ratio | | |
| $s$ | Liquid-sidestream ratio | | |
| $t$ | Time | s | H |
| $u$ | Velocity | m/s | ft/h |
| $v$ | Component flow rate in vapor | kg·mol/s | lb·mol/h |
| $w$ | Weight fraction | | |
| $x$ | Mole fraction in liquid | | |
| $y$ | Mole fraction in vapor | | |
| $z$ | Mole fraction in feed | | |

### Greek Symbols

| | | | |
|---|---|---|---|
| $\alpha$ | Relative volatility | | |
| $\gamma$ | Activity coefficient | | |
| $\varepsilon$ | TBK efficiency | | |
| $\xi$ | Dimensionless time | | |
| $\rho$ | Density | $kg/m^3$ | $lb/ft^3$ |
| $\mu$ | Viscosity | $N/m^2$ | |
| $\sigma$ | Surface tension | N/m | |
| $\theta$ | Time for batch distillation | s | h |
| $\Theta$ | Parameter in Underwood equations | | |
| $\Phi$ | Fugacity coefficient of pure component | | |
| $\hat{\Phi}$ | Fugacity coefficient in mixture | | |
| $\Phi_A$ | Fraction of a component in feed vapor that is not absorbed | | |
| $\Phi_S$ | Fraction of a component in entering liquid that is not stripped | | |
| $\Psi$ | Factor in Gilliland correlation | | |

### Subscripts and Superscripts

| | |
|---|---|
| EQ | Equilibrium |
| $f$ | Froth |
| $hk$ | Heavy key |
| $i$ | Component index |
| $j$ | Stage index |
| $L$ | Liquid |
| $lk$ | Light key |
| $MV$ | Murphree vapor |
| $o$ | Overall |
| $s$ | Superficial |
| $t$ | Mixture or total |
| $V$ | Vapor |
| $*$ | Equilibrium composition |

### Acronyms

| | |
|---|---|
| HETP | Height equivalent to a theoretical plate |
| n.b.p. | Normal boiling point (1-atm pressure) |
| NTU | Number of transfer units |

# INTRODUCTION TO DISTILLATION OPERATIONS

## GENERAL PRINCIPLES

Separation operations achieve their objective by the creation of two or more coexisting zones that differ in temperature, pressure, composition, and/or phase state. Each molecular species in the mixture to be separated responds in a unique way to differing environments offered by these zones. Consequently, as the system moves toward equilibrium, each species establishes a different concentration in each zone, and this results in a separation between the species.

The separation operation called *distillation* uses vapor and liquid phases at essentially the same temperature and pressure for the coexisting zones. Various kinds of devices such as *random* or *structured packings* and *plates* or *trays* are used to bring the two phases into intimate contact. Trays are stacked one above the other and enclosed in a cylindrical shell to form a *column.* Packings are also generally contained in a cylindrical shell between hold-down and support plates. The column may be operated continuously or in batch mode, depending on a number of factors, such as scale and flexibility of operations and the solids content of feed. A typical tray-type continuous distillation column plus major external accessories is shown schematically in Fig. 13-1.

The *feed* material, which is to be separated into fractions, is introduced at one or more points along the column shell. Because of the difference in density between vapor and liquid phases, liquid runs down the column, cascading from tray to tray, while vapor flows up the column, contacting liquid at each tray.

Liquid reaching the bottom of the column is partially vaporized in a heated *reboiler* to provide *boil-up,* which is sent back up the column. The remainder of the bottom liquid is withdrawn as *bottoms,* or bottom product. Vapor reaching the top of the column is cooled and condensed to liquid in the *overhead condenser.* Part of this liquid is returned to the column as *reflux* to provide liquid overflow. The remainder of the overhead stream is withdrawn as *distillate,* or overhead product. In some cases only part of the vapor is condensed so that a vapor distillate can be withdrawn.

This overall flow pattern in a distillation column provides countercurrent contacting of vapor and liquid streams on all the trays through the column. Vapor and liquid phases on a given tray approach thermal, pressure, and composition equilibria to an extent dependent on the efficiency of the contacting tray.

The *lighter* (lower-boiling temperature) components tend to concentrate in the vapor phase, while the *heavier* (higher-boiling temperature) components concentrate in the liquid phase. The result is a vapor phase that becomes richer in light components as it passes up the column and a liquid phase that becomes richer in heavy components as it cascades downward. The overall separation achieved between the distillate and the bottoms depends primarily on the *relative volatilities* of the components, the number of contacting trays in each column section, and the ratio of the liquid-phase flow rate to the vapor-phase flow rate in each section.

If the feed is introduced at one point along the column shell, the column is divided into an upper section, which is often called the *rectifying* section, and a lower section, which is often referred to as the *stripping* section. In *multiple-feed* columns and in columns from which a liquid or vapor *sidestream* is withdrawn, there are more than two column sections between the two end-product streams. The notion of a column section is a useful concept for finding alternative *systems* (or *sequences*) of columns for separating multicomponent mixtures, as described in the subsection Distillation Systems.

All separation operations require energy input in the form of heat or work. In the conventional distillation operation, as typified in Fig. 13-1, energy needed to separate the species is added in the form of heat to the reboiler at the bottom of the column, where the temperature is highest. Heat is also removed from a condenser at the top of the column, where the temperature is lowest. This often results in a large energy-input requirement and low overall thermodynamic efficiency, especially if the heat removed in the condenser is wasted. Complex distillation operations that offer higher thermodynamic efficiency and lower energy-input requirements have been developed and are also discussed in the subsection Distillation Systems.

Batch distillation is preferred for small feed flows or seasonal production, which is carried out intermittently in "batch campaigns." In this mode, the feed is charged to a still that provides vapor to a column where the separation occurs. Vapor leaving the top of the column is condensed to provide liquid reflux back to the column as well as a distillate stream containing the product. Under normal operation, this is the only stream leaving the device. In addition to the batch rectifier just described,

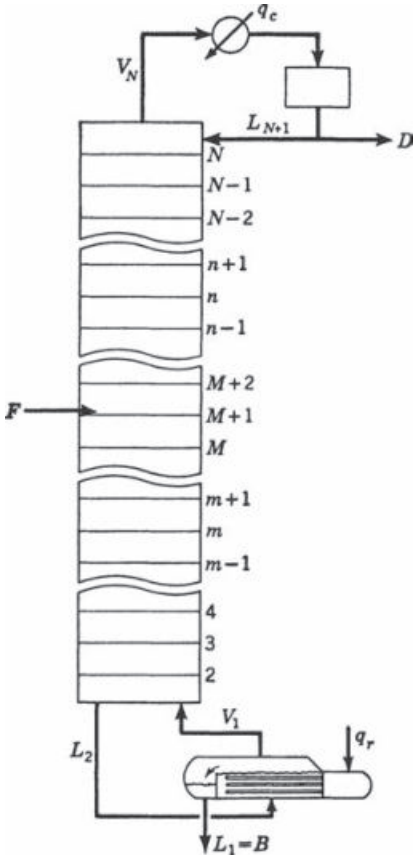

**FIG. 13-1** Schematic diagram and nomenclature for a simple continuous distillation column with one feed, a total overhead condenser, and a partial reboiler.

other batch configurations are possible as discussed in the subsection Batch Distillation. Many of the concepts and methods discussed for continuous distillation are useful for developing models and design methods for batch distillation.

## EQUILIBRIUM AND NONEQUILIBRIUM-STAGE CONCEPTS

The transfer processes taking place in an actual distillation column are a complicated interplay between the thermodynamic phase equilibrium properties of the mixture, the rates of intra- and interphase mass and energy transport, and multiphase flows. Simplifications are needed to develop tractable models. The landmark concept of the *equilibrium-stage model* was developed by Sorel in 1893; in this model, the liquid in each stage is considered to be well mixed, and the vapor and liquid streams leaving each stage are in thermodynamic equilibrium with each other. This is needed so that thermodynamic phase equilibrium relations can be used to determine the temperature and composition of the equilibrium streams at a given pressure. A hypothetical column composed of equilibrium stages (instead of actual contact trays) is designed to accomplish the separation specified for the actual column. The number of hypothetical equilibrium stages required is then converted to a number of actual trays by means of *tray efficiencies,* which describe the extent to which the performance of an actual contact tray duplicates the performance of an equilibrium stage. Alternatively and preferably, tray inefficiencies can be accounted for by using rate-based models that are described later in this section.

When we use the equilibrium-stage concept, we separate the design of a distillation column into three major steps: (1) Thermodynamic data and methods needed to predict equilibrium-phase compositions are assembled. (2) The number of equilibrium stages and the energy input required to accomplish a specified separation, or the separation that will be accomplished in a given number of equilibrium stages for a given energy input, are calculated. (3) The number of equilibrium stages is converted to an equivalent number of actual contact trays or height of packing, and the column diameter is determined. Much of the third step is eliminated if a rate-based model is used. This section deals primarily with equilibrium and rate-based models of distillation. Section 4 covers the first step, but a summary of methods and some useful data are included in this section. Section 14 covers equipment design.

## RELATED SEPARATION OPERATIONS

The simple and complex distillation operations just described all have two things in common: (1) Both rectifying and stripping sections are provided so that a separation can be achieved between two components that are adjacent in volatility; and (2) the separation is effected only by the addition and removal of energy and not by the addition of any mass separating agent (MSA) such as in liquid-liquid extraction.

Sometimes, alternative single- or multiple-stage vapor-liquid separation operations, of the types shown in Fig. 13-2, may be more suitable than distillation for the specified task.

A single-stage flash, as shown in Fig. 13-2*a,* may be appropriate if (1) the relative volatility between the two components to be separated is very large; (2) the recovery of only one component in one of the two product streams is to be achieved, without regard to the separation of the other components; or (3) only a partial separation is to be made. A common example is the separation of light gases such as hydrogen and methane from aromatics. The desired temperature and pressure of a flash may be established by the use of heat exchangers, a valve, a compressor, or a pump upstream of the vessel, used to separate the product vapor and liquid phases. Depending on the original condition of the feed, it may be partially condensed or partially vaporized in a so-called flash operation.

If the recovery of only one component is required rather than a sharp separation between two components of adjacent volatility, their absorption or stripping in a single section of stages may be sufficient. If the feed is vapor at separation conditions, absorption is used either with a liquid MSA absorbent of relatively low volatility, as in Fig. 13-2*b,* or with reflux produced by an overhead partial condenser, as in Fig. 13-2*c.* The choice usually depends on the ease of partially condensing the overhead vapor or of recovering and recycling the absorbent. If the feed is liquid at separation conditions, stripping is used, either with an externally supplied vapor stripping agent of relatively high volatility, as shown in Fig. 13-2*d,* or with boil-up produced by a partial reboiler, as in Fig. 13-2*e.* The choice depends on the ease of partially reboiling the bottoms or of recovering and recycling the stripping agent.

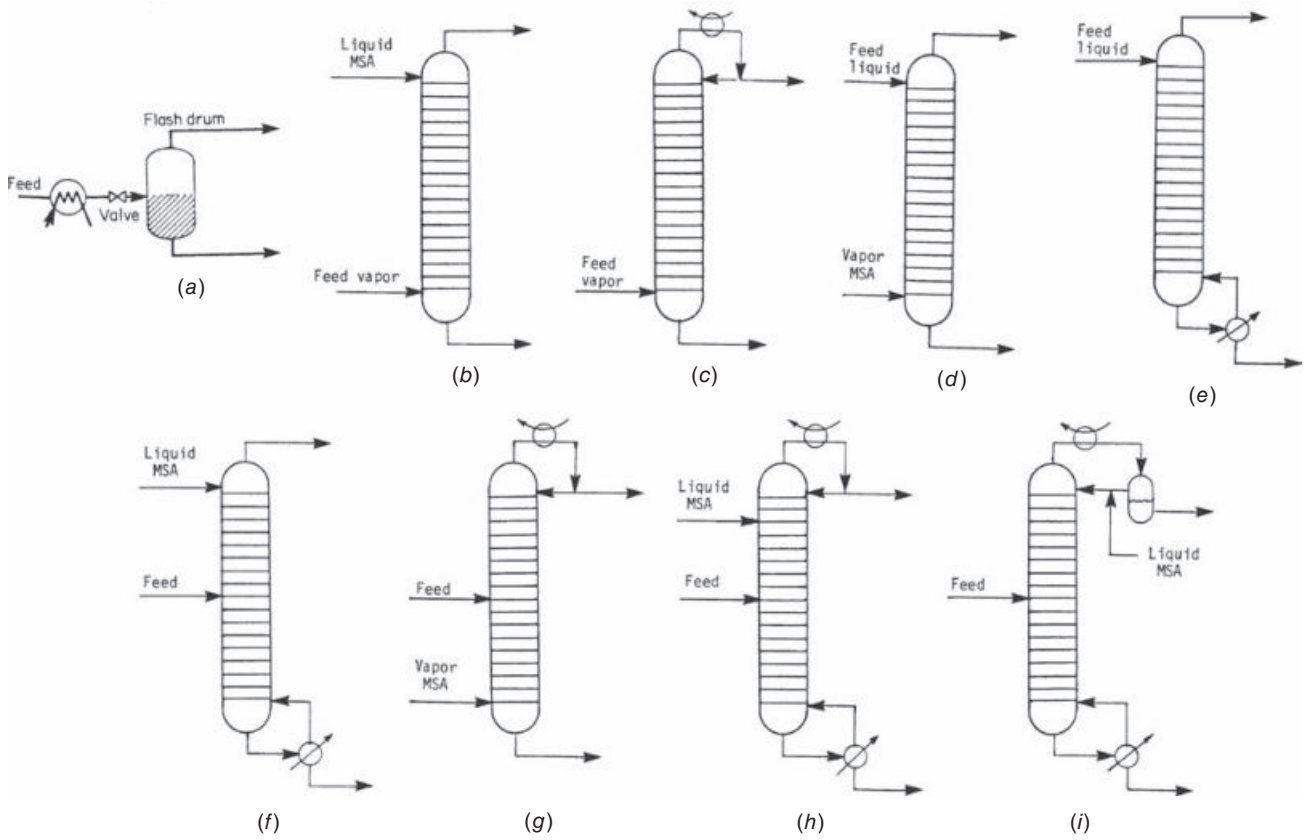

**FIG. 13-2** Separation operations related to distillation. (*a*) Flash vaporization or partial condensation. (*b*) Absorption. (*c*) Rectifier. (*d*) Stripping. (*e*) Reboiled stripping. (*f*) Reboiled absorption. (*g*) Refluxed stripping. (*h*) Extractive distillation. (*i*) Azeotropic distillation.

If a relatively sharp separation is needed between two components of adjacent volatility, but either an undesirably low temperature is required to produce reflux at the column operating pressure or an undesirably high temperature is required to produce boil-up, then refluxed stripping, as shown in Fig. 13-2*g,* or reboiled absorption, as shown in Fig. 13-2*f,* may be used. In either case, the choice of MSA follows the same consideration given for simple absorption and stripping.

When the volatility difference between the two components to be separated is so small that a very large number of stages would be required, then extractive distillation, as shown in Fig. 13-2*h,* should be considered. Here, an MSA is selected that increases the volatility difference enough to reduce the stage requirement to a reasonable number. Usually, the MSA is a polar compound of low volatility that leaves in the bottoms, from which it is recovered and recycled. It is introduced in an appreciable amount near the top stage of the column so as to affect the volatility difference over most of the stages. Some reflux to the top stage is used to minimize the MSA content in the distillate. An alternative to extractive distillation is azeotropic distillation, which is shown in Fig. 13-2*i* in just one of its many modes. In a common mode, an MSA that forms a heterogeneous minimum-boiling azeotrope with one or more components of the feed is used. The azeotrope is taken overhead, and the MSA-rich phase is decanted and returned to the top of the column as reflux.

Many other multistaged configurations are possible. One important variation of a stripper, shown in Fig. 13-2*d,* is a refluxed stripper, in which an overhead condenser is added. Such a configuration is sometimes used to steam-strip sour water containing $NH_3$, $H_2O$, phenol, and HCN.

All the separation operations shown in Fig. 13-2, as well as the simple and complex distillation operations described earlier, are referred to here as distillation-type separations because they have much in common with respect to calculations of (1) thermodynamic properties, (2) vapor-liquid equilibrium stages, and (3) column sizing. In fact, as will be evident from the remaining treatment of this section, the trend is toward single generalized digital computer program packages that compute many or all distillation-type separation operations.

This section also includes a treatment of distillation-type separations from a rate-based point of view that uses principles of mass- and heat-transfer rates. Section 14 also presents details of that subject as applied to absorption and stripping.

## THERMODYNAMIC DATA AND MODELS

Reliable thermodynamic data are essential for the accurate design or analysis of distillation columns. The failure of equipment to perform at specified levels is often attributable, at least in part, to the lack of such data.

This subsection summarizes and presents examples of phase equilibrium data currently available to the designer. The thermodynamic concepts used are presented in Sec. 4 Thermodynamics.

### PHASE EQUILIBRIUM DATA

For a binary mixture, pressure and temperature fix the equilibrium vapor and liquid compositions. Thus, experimental data are often presented in the form of tables of vapor mole fraction $y$ and liquid mole fraction $x$ for one constituent over a range of temperature $T$ for a fixed pressure $P$ or over a range of pressure for a fixed temperature. Compilations of such data may be found in Hala, Wichterle, Polak, and Boublik (*Vapour-Liquid Equilibrium Data at Normal Pressures,* Pergamon, Oxford, 1968); Hirata, Ohe, and Nagahama (*Computer Aided Data Book of Vapor-Liquid Equilibria,* Elsevier, Amsterdam, 1975); Wichterle, Linek, and Hala (*Vapor-Liquid Equilibrium Data Bibliography,* Elsevier, Amsterdam, 1973, Supplement I, 1976, Supplement II, 1979); Ohe (*Vapor-Liquid Equilibrium Data,* Elsevier, Amsterdam, 1989); Ohe (*Vapor-Liquid Equilibrium Data at High Pressure,* Elsevier, Amsterdam, 1990); Walas (*Phase Equilibria in Chemical Engineering,* Butterworth, Boston, 1985); and, particularly, Gmehling and Onken [*Vapor-Liquid Equilibrium Data Collection,* DECHEMA Chemistry Data ser., vol. 1 (parts 1–10), Frankfurt, 1977]. Extensive databases of phase equilibrium measurements are readily available in most process simulators, together with models for correlating, interpolating, and extrapolating (care is needed here) the data. Many of these simulators also provide graphical display of the data for easy visualization and interpretation.

For application to distillation (a nearly isobaric process), binary-mixture data are often plotted, for a fixed pressure, as $y$ versus $x$, with a line of 45° slope included for reference, and as $T$ versus $y$ and $x$, as shown in Figs. 13-3 to 13-8. In some binary systems, one of the components is more volatile than the other over the entire composition range. This is the case in Figs. 13-3 and 13-4 for the benzene-toluene system at pressures of both 101.3 and 202.6 kPa (1 and 2 atm), where benzene is more volatile than toluene.

For other binary systems, one of the components is more volatile over only a part of the composition range. Two systems of this type, ethyl acetate–ethanol and chloroform-acetone, are shown in Figs. 13-5 to 13-7. Figure 13-5 shows that chloroform is less volatile than acetone below a concentration of 66 mol% chloroform and that ethyl acetate is more volatile than ethanol below a concentration of 53 mol% ethyl acetate. Above these concentrations, volatility is reversed. Such mixtures are known as azeotropic mixtures, and the composition in which the reversal occurs, which is the composition in which vapor and liquid compositions are equal, is the azeotropic composition, or azeotrope. The azeotropic liquid may be homogeneous or heterogeneous (two immiscible liquid phases). Non-azeotrope-forming mixtures such as benzene and toluene in Figs. 13-3 and 13-4 can be separated by simple distillation into two essentially pure products. By contrast, simple distillation of azeotropic mixtures will at best yield the azeotrope and one essentially pure species. The distillate and bottoms products obtained depend on the feed composition and whether a minimum-boiling azeotrope is formed as with the ethyl acetate–ethanol mixture in Fig. 13-6 or a maximum-boiling azeotrope is formed as with the chloroform-acetone mixture in Fig. 13-7. For example, if a mixture of 30 mol% chloroform and 70 mol% acetone is fed to a simple distillation column, such as that shown in Fig. 13-1, operating at 101.3 kPa (1 atm), the distillate could approach pure acetone and the bottoms could approach the maximum-boiling azeotrope.

An example of heterogeneous-azeotrope formation is shown in Fig. 13-8 for the water–normal butanol system at 101.3 kPa. At liquid compositions between 0 and 3 mol% butanol and between 40 and 100 mol% butanol, the liquid phase is homogeneous. Phase splitting into two separate liquid phases (one with 3 mol% butanol and the other with 40 mol% butanol) occurs for any overall liquid composition between 3 and 40 mol% butanol. A minimum-boiling heterogeneous azeotrope occurs at 92°C (198°F) when the vapor composition is equal to the overall composition of the two coexisting equilibrium liquid phases at 25 mol% butanol.

For mixtures containing more than two species, an additional degree of freedom is available for each additional component. Thus, for a four-component system, the equilibrium vapor and liquid compositions are fixed only if the pressure, temperature, and mole fractions of two components are set. Representation of multicomponent vapor-liquid equilibrium data in tabular or graphical form of the type shown earlier for binary systems is

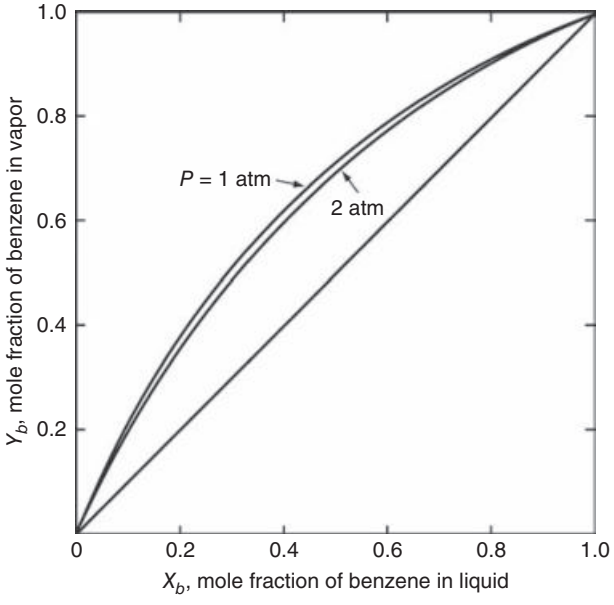

**FIG. 13-3** Isobaric *y-x* curves for benzene-toluene. (*Brian,* Staged Cascades in Chemical Processing, *Prentice-Hall, Englewood Cliffs, N.J., 1972.*)

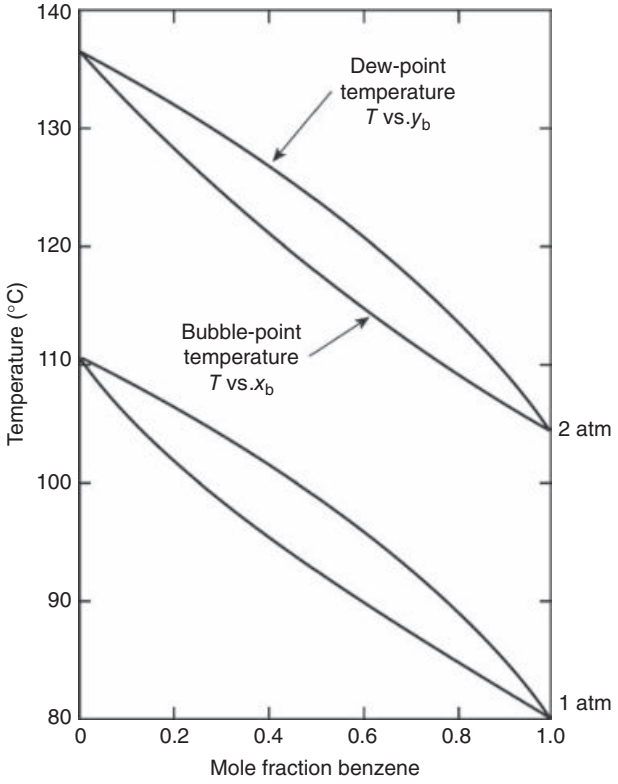

**FIG. 13-4** Isobaric vapor-liquid equilibrium curves for benzene-toluene. (*Brian,* Staged Cascades in Chemical Processing, *Prentice-Hall, Englewood Cliffs, N.J., 1972.*)

either difficult or impossible. Instead, such data, as well as binary-system data, are commonly represented in terms of *K* values (vapor-liquid equilibrium ratios), which are defined by

$$K_i = \frac{y_i}{x_i} \tag{13-1}$$

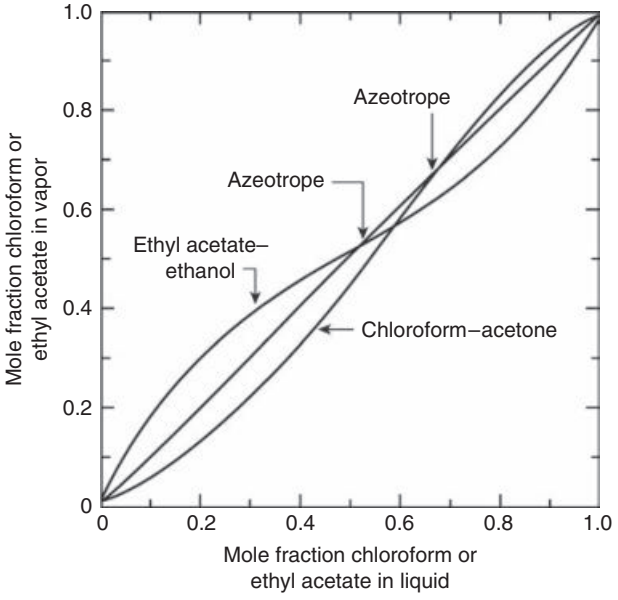

**FIG. 13-5** Vapor-liquid equilibria for the ethyl acetate–ethanol and chloroform-acetone systems at 101.3 kPa (1 atm).

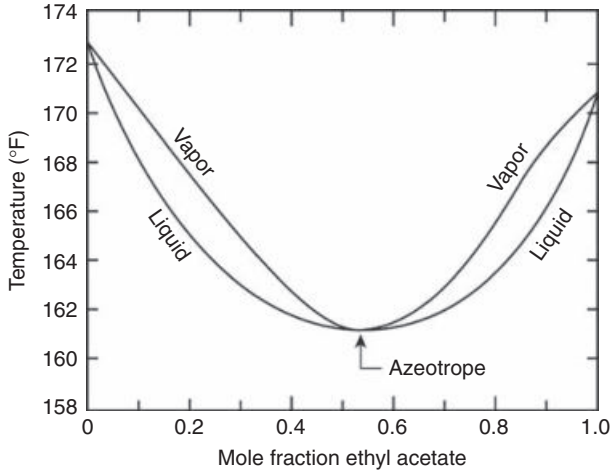

**FIG. 13-6** Liquid boiling points and vapor condensation temperatures for minimum-boiling azeotrope mixtures of ethyl acetate and ethanol at 101.3-kPa (1-atm) total pressure.

and are correlated empirically or theoretically in terms of temperature, pressure, and phase compositions in the form of tables, graphs, and equations. The *K* values are widely used in multicomponent distillation calculations, and the ratio of the *K* values of two species, called the relative volatility,

$$\alpha_{ij} = \frac{K_i}{K_j} \tag{13-2}$$

is a convenient index of the relative ease or difficulty of separating components *i* and *j* by distillation. Rarely is distillation used on a large scale if the relative volatility is less than 1.05, with *i* more volatile than *j*.

## GRAPHICAL *K* VALUE CORRELATIONS

As discussed in Sec. 4, the *K* value of a species is a complex function of temperature, pressure, and equilibrium vapor- and liquid-phase compositions. However, for mixtures of compounds of similar molecular structure and size, the *K* value depends mainly on temperature and pressure. For example, several major graphical *K* value correlations are available for light-hydrocarbon systems. The easiest to use are the DePriester charts [*Chem. Eng. Prog. Symp. Ser. 7,* **49:** 1 (1953)], which cover 12 hydrocarbons (methane, ethylene,

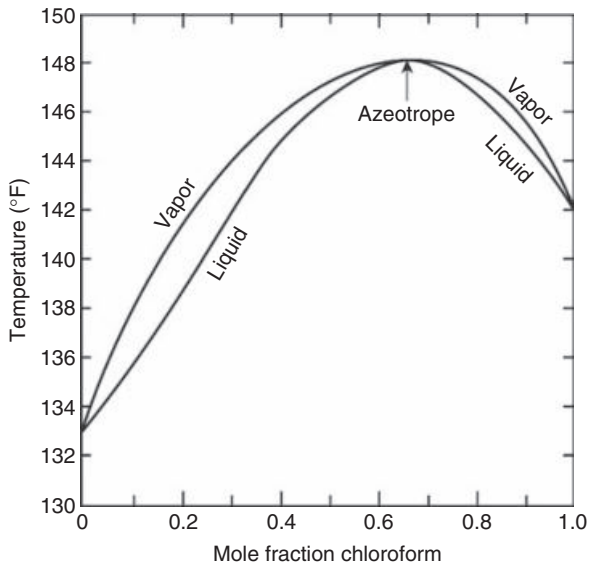

**FIG. 13-7** Liquid boiling points and vapor condensation temperatures for maximum-boiling azeotrope mixtures of chloroform and acetone at 101.3-kPa (1-atm) total pressure.

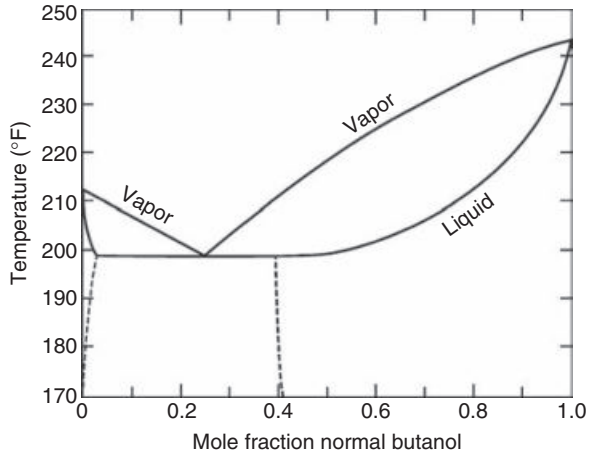

**FIG. 13-8** Vapor-liquid equilibrium data for an *n*-butanol–water system at 101.3 kPa (1 atm); phase splitting and heterogeneous-azeotrope formation.

ethane, propylene, propane, isobutane, isobutylene, *n*-butane, isopentane, *n*-pentane, *n*-hexane, and *n*-heptane). These charts are a simplification of the Kellogg charts (*Liquid-Vapor Equilibria in Mixtures of Light Hydrocarbons, MWK Equilibrium Constants, Polyco Data,* 1950) and include additional experimental data. The Kellogg charts, and hence the DePriester charts, are based primarily on the Benedict-Webb-Rubin equation of state [*Chem. Eng. Prog.* **47:** 419 (1951); **47:** 449 (1951)], which can represent both the liquid and the vapor phases and can predict *K* values quite accurately when the equation constants are available for the components in question.

A trial-and-error procedure is required with any *K* value correlation that takes into account the effect of composition. One cannot calculate *K* values until phase compositions are known, and those cannot be known until the *K* values are available to calculate them. For *K* as a function of *T* and *P* only, the DePriester charts provide good starting values for the iteration. These nomographs are shown in Fig. 2-10*a* and *b*. The SI versions of these charts were developed by Dadyburjor [*Chem. Eng. Prog.* **74**(4): 85 (1978)].

The Kellogg and DePriester charts and their subsequent extensions and generalizations use the molar average boiling points of the liquid and vapor phases to represent the composition effect. An alternative measure of composition is the convergence pressure of the system, which is defined as that pressure at which the *K* values for all the components in an isothermal mixture converge to unity. It is analogous to the critical point for a pure component in the sense that the two phases become indistinguishable. The behavior of a complex mixture of hydrocarbons for a convergence pressure of 34.5 MPa (5000 psia) is illustrated in Fig. 13-9.

Two major graphical correlations based on convergence pressure as the third parameter (besides temperature and pressure) are the charts published by the Gas Processors Association (GPA, *Engineering Data Book,* 9th ed., Tulsa, Okla., 1981) and the charts of the American Petroleum Institute (API, *Technical Data Book—Petroleum Refining,* New York, 1966) based on the procedures from Hadden and Grayson [*Hydro-carbon Process., Pet. Refiner* **40**(9): 207 (1961)]. The former uses the method proposed by Hadden [*Chem. Eng. Prog. Symp. Ser. 7,* **49:** 53 (1953)] for the prediction of convergence pressure as a function of composition.

The GPA convergence pressure charts are primarily for alkane and alkene systems, but they include charts for nitrogen, carbon dioxide, and hydrogen sulfide. The charts may not be valid when appreciable amounts of naphthenes or aromatics are present; the API charts use special procedures for such cases. Useful extensions of the convergence pressure concept to more varied mixtures include the nomographs of Winn [*Chem. Eng. Prog. Symp. Ser. 2,* **48:** 121 (1952)], Hadden and Grayson [*Hydro-carbon Process., Pet. Refiner* **40**(9): 207 (1961)], and Cajander, Hipkin, and Lenoir [*J. Chem. Eng. Data* **5:** 251 (1960)].

## ANALYTICAL *K* VALUE CORRELATIONS

The widespread availability and use of digital computers for distillation calculations have given impetus to the development of analytical expressions for *K* values. McWilliams [*Chem. Eng.* **80**(25): 138 (1973)] presents a regression equation and accompanying regression coefficients that represent the DePriester charts of Fig. 2-10. Regression equations and coefficients for various versions of the GPA convergence pressure charts are available from the GPA.

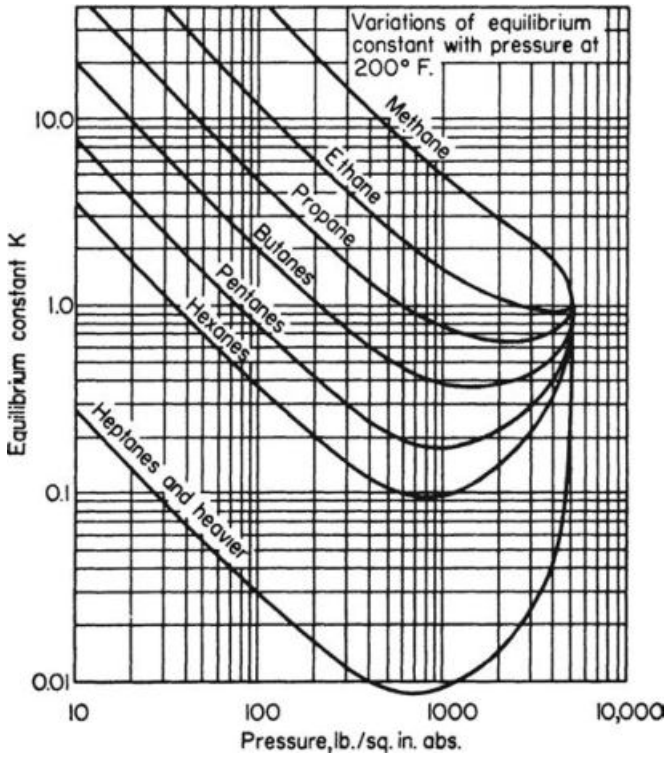

**FIG. 13-9** Typical variation of *K* values with total pressure at constant temperature for a complex mixture. Light hydrocarbons in admixture with crude oil. [*Katz and Hachmuth*, Ind. Eng. Chem., ***29:*** *1072 (1937).*]

Preferred analytical correlations are less empirical and most often are theoretically based on one of two exact thermodynamic formulations, as derived in Sec. 4. When a single pressure-volume-temperature (*P-V-T*) equation of state is applicable to both vapor and liquid phases, the formulation used is

$$K_i = \frac{\hat{\Phi}_i^L}{\hat{\Phi}_i^V} \tag{13-3}$$

where the mixture fugacity coefficients $\hat{\Phi}_i^L$ for the liquid and $\hat{\Phi}_i^V$ for the vapor are derived by classical thermodynamics from the *P-V-T* expression. Consistent equations for enthalpy can be similarly derived.

Until recently, equations of state that have been successfully applied to Eq. (13-3) have been restricted to mixtures of nonpolar compounds, namely, hydrocarbons and light gases. These equations include those of Benedict-Webb-Rubin (BWR), Soave (SRK) [*Chem. Eng. Sci.* **27:** 1197 (1972)], who extended the remarkable Redlich-Kwong equation, and Peng-Robinson (PR) [*Ind. Eng. Chem. Fundam.* **15:** 59 (1976)]. The SRK and PR equations belong to a family of so-called cubic equations of state. The Starling extension of the BWR equation (*Fluid Thermodynamic Properties for Light Petroleum Systems,* Gulf, Houston, 1973) predicts *K* values and enthalpies of the normal paraffins up through *n*-octane, as well as isobutane, isopentane, ethylene, propylene, nitrogen, carbon dioxide, and hydrogen sulfide, including the cryogenic region. Computer programs for *K* values derived from the SRK, PR, and other equations of state are widely available in all computer-aided process design and simulation programs. The ability of the SRK correlation to predict *K* values even when the pressure approaches the convergence pressure is shown for a multicomponent system in Fig. 13-10. Similar results are achieved with the PR correlation. The Wong-Sandler mixing rules for cubic equations of state now permit such equations to be extended to mixtures of organic chemicals, as shown in a reformulated version by Orbey and Sandler [*AIChE J.* **41**(3): 683–690 (1995)].

An alternative *K* value formulation that has received wide application to mixtures containing polar and/or nonpolar compounds is

$$K_i = \frac{\gamma_i^L \Phi_i^L}{\hat{\Phi}_i^V} \tag{13-4}$$

where different equations of state may be used to predict the pure-component liquid fugacity coefficient $\Phi_i^L$ and the vapor-mixture fugacity

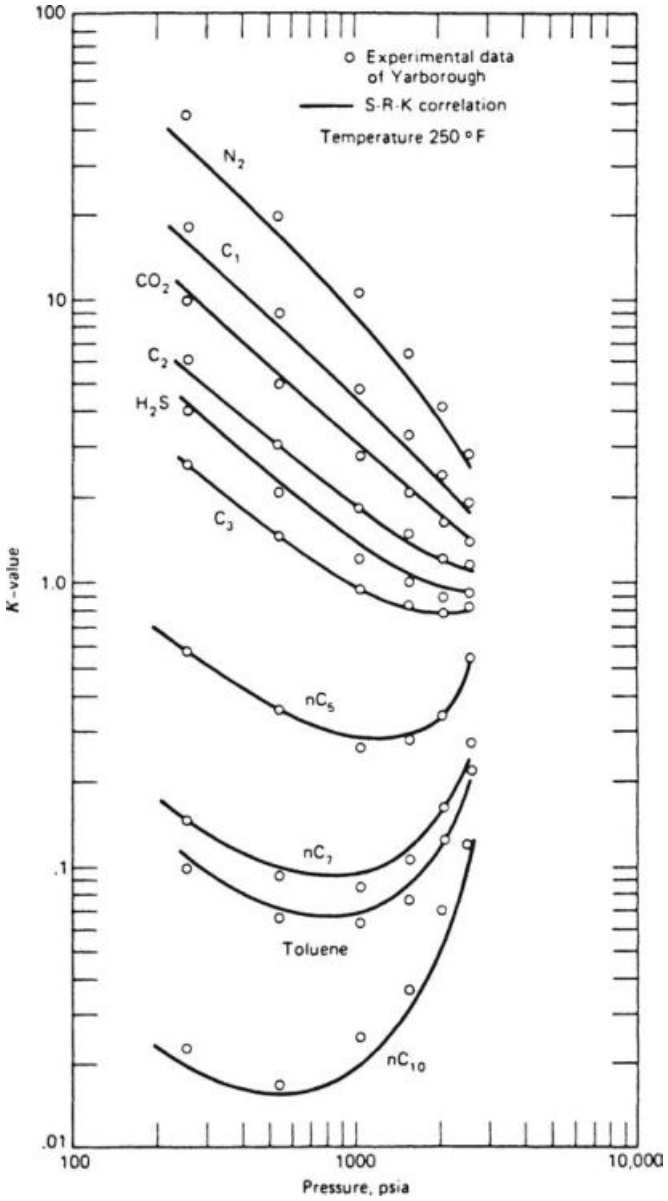

**FIG. 13-10** Comparison of experimental $K$ value data and SRK correlation. [*Henley and Seader,* Equilibrium-Stage Separation Operations in Chemical Engineering, *Wiley, New York, 1981; data of Yarborough,* J. Chem. Eng. Data, ***17:*** *129 (1972).*]

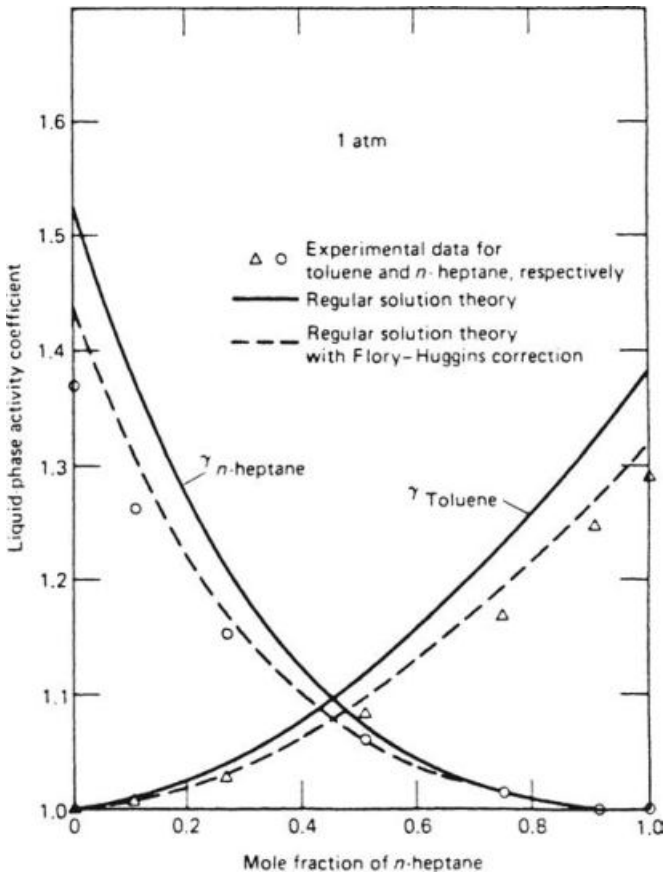

**FIG. 13-11** Liquid-phase activity coefficients for an $n$-heptane–toluene system at 101.3 kPa (1 atm). [*Henley and Seader,* Equilibrium-Stage Separation Operations in Chemical Engineering, *Wiley, New York, 1981; data of Yerazunis et al.,* AIChE J., ***10:*** *660 (1964).*]

coefficient, and any one of a number of mixture free-energy models may be used to obtain the liquid activity coefficient $\gamma_i^L$. At low to moderate pressures, accurate prediction of the latter is crucial to the application of Eq. (13-4).

When either Eq. (13-3) or Eq. (13-4) can be applied, the former is generally preferred because it involves only a single equation of state applicable to both phases and thus would seem to offer greater consistency. In addition, the quantity $\Phi_i^L$ in Eq. (13-4) is hypothetical for any components that are supercritical. In that case, a modification of Eq. (13-4) that uses Henry's law is sometimes applied.

For mixtures of hydrocarbons and light gases, Chao and Seader (CS) [*AIChE J.* **7:** 598 (1961)] applied Eq. (13-4) by using an empirical expression for $\Phi_i^L$ based on the generalized corresponding-states *P-V-T* correlation of Pitzer et al., the Redlich-Kwong equation of state for $\hat{\Phi}_i^V$, and the regular solution theory of Scatchard and Hildebrand for $\gamma_i^L$. The predictive ability of the last-named theory is exhibited in Fig. 13-11 for the heptane-toluene system at 101.3 kPa (1 atm). Five pure-component constants for each species ($T_c$, $P_c$, $\omega$, $\delta$, and $v^L$) are required to use the CS method which, when applied within the restrictions discussed by Lenoir and Koppany [*Hydrocarbon Process.* **46**(11): 249 (1967)], gives good results. Revised coefficients of Grayson and Streed (GS) (Paper 20-P07, Sixth World Pet. Conf. Frankfurt, June 1963) for the $\Phi_i^L$ expression permit the application of the CS correlation to higher temperatures and pressures and give improved predictions for hydrogen. Jin, Greenkorn, and Chao [*AIChE J.* **41:** 1602 (1995)] present a revised correlation for the standard-state liquid fugacity of hydrogen, applicable from 200 to 730 K.

For mixtures containing polar substances, more complex predictive equations for $\gamma_i^L$ that involve binary-interaction parameters for each pair of components in the mixture are required for use in Eq. (13-4), as discussed in Sec. 4. Four popular expressions are the Wilson, NRTL, UNIFAC, and UNIQUAC equations. The preferred expressions for representing activity coefficients are the NRTL and UNIQUAC equations. Extensive listings of binary-interaction parameters for use in all but the UNIFAC equation are given by Gmehling and Onken [*Vapor-Liquid Equilibrium Data Collection,* DECHEMA Chemistry Data ser., vol. 1 (parts 1–10), Frankfurt, 1977]. They obtained the parameters for binary systems at 101.3 kPa (1 atm) from best fits of the experimental $T$-$y$-$x$ equilibrium data by setting $\Phi_i^V$ and $\Phi_i^L$ to their ideal-gas, ideal-solution limits of 1.0 and $P^{\text{sat}}/P$, respectively, with the vapor pressure $P^{\text{sat}}$ given by a three-constant Antoine equation, whose values they tabulate.

The Wilson equation is particularly useful for systems that are highly nonideal but do not undergo phase splitting, as exemplified by the ethanol-hexane system, whose activity coefficients are shown in Fig. 13-12.

Carboxylic acids (e.g., formic acid and acetic acid) tend to dimerize in the vapor phase according to the chemical equilibrium expression

$$K_D = \frac{P_D}{P_M^2} = 10^{A+B/T} \tag{13-5}$$

where $K_D$ is the chemical equilibrium constant for dimerization, $P_D$ and $P_M$ are partial pressures of dimer and monomer, respectively, in torr, and $T$ is in Kelvin. Values of $A$ and $B$ for the first four normal aliphatic acids are

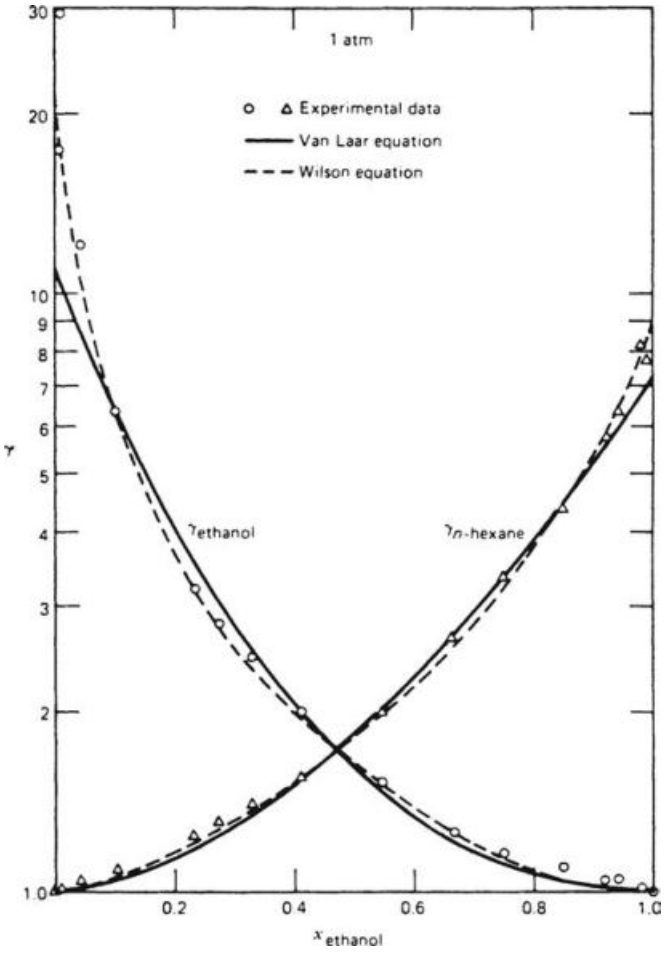

**FIG. 13-12** Liquid-phase activity coefficients for an ethanol–*n*-hexane system. [*Henley and Seader,* Equilibrium-Stage Separation Operations in Chemical Engineering, *Wiley, New York, 1981; data of Sinor and Weber,* J. Chem. Eng. Data, ***5:*** *243–247 (1960).*]

| | *A* | *B* |
|---|---|---|
| Formic acid | −10.743 | 3083 |
| Acetic acid | −10.421 | 3166 |
| *n*-Propionic acid | −10.843 | 3316 |
| *n*-Butyric acid | −10.100 | 3040 |

As shown by Marek and Standart [*Collect. Czech. Chem. Commun.* **19:** 1074 (1954)], it is preferable to correlate and use liquid-phase activity coefficients for the dimerizing component by considering separately the partial pressures of the monomer and dimer. For example, for a binary system of components 1 and 2, when only compound 1 dimerizes in the vapor phase, the following equations apply if an ideal gas is assumed:

$$P_1 = P_D + P_M \tag{13-6}$$

$$y_1 = \frac{P_M + 2P_D}{P} \tag{13-7}$$

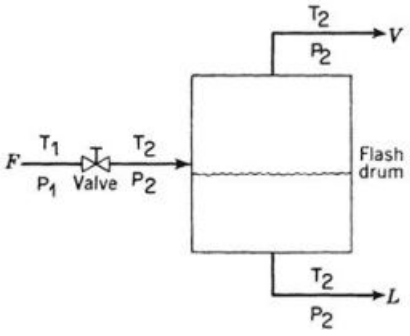

**FIG. 13-13** Equilibrium flash separator.

These equations when combined with Eq. (13-5) lead to the following equations for liquid-phase activity coefficients in terms of measurable quantities:

$$\gamma_1 = \frac{Py_1}{P_1^{\text{sat}} x_1}\left\{\frac{1+(1+4K_D P_1^{\text{sat}})^{0.5}}{1+[1+4K_D P y_1(2-y_1)]^{0.5}}\right\} \tag{13-8}$$

$$\gamma_2 = \frac{Py_1}{P_2^{\text{sat}} x_2}\left(\frac{2(1-y_1+[1+4K_D P y_1(2-y_1)]^{0.5}}{(2-y_1)\{1+[1+4K_D P y_1(2-y_1)]^{0.5}\}}\right) \tag{13-9}$$

Detailed procedures, including computer programs for evaluating binary-interaction parameters from experimental data and then using these parameters to predict *K* values and phase equilibria, are given in terms of the UNIQUAC equation by Prausnitz et al. (*Computer Calculations for Multicomponent Vapor-Liquid and Liquid-Liquid Equilibria,* Prentice-Hall, Englewood Cliffs, N.J., 1980) and in terms of the UNIFAC group contribution method by Fredenslund, Gmehling, and Rasmussen (*Vapor-Liquid Equilibria Using UNIFAC,* Elsevier, Amsterdam, 1980). Both use the method of Hayden and O'Connell [*Ind. Eng. Chem. Process Des. Dev.* **14:** 209 (1975)] to compute $\hat{\Phi}_i^V$ in Eq. (13-4). When the system temperature is greater than the critical temperature of one or more components in the mixture, Prausnitz et al. use a Henry's law constant $H_{i,M}$ in place of the product $\gamma_i^L \Phi_i^L$ in Eq. (13-4). Otherwise $\Phi_i^L$ is evaluated from vapor pressure data with a Poynting saturated-vapor fugacity correction. When the total pressure is less than about 202.6 kPa (2 atm) and all components in the mixture have a critical temperature that is greater than the system temperature, then $\Phi_i^L = P_i^{\text{sat}}/P$ and $\Phi_i^V = 1.0$. Equation (13-4) then reduces to

$$K_i = \frac{\gamma_i^L P_i^{\text{sat}}}{P} \tag{13-10}$$

which is referred to as a modified Raoult's law *K* value. If, furthermore, the liquid phase is ideal, then $\gamma_i^L = 1.0$ and

$$K_i = \frac{P_i^{\text{sat}}}{P} \tag{13-11}$$

which is referred to as a Raoult's law *K* value that is dependent solely on the vapor pressure $P_i^{\text{sat}}$ of the component in the mixture. The UNIFAC method is being periodically updated with new group contributions; for example, see Gmehling et al. [*Ind. Eng. Chem. Res.* **42:** 183 (2003)].

## SINGLE-STAGE EQUILIBRIUM FLASH CALCULATIONS

The simplest continuous distillation process is the adiabatic single-stage equilibrium flash process pictured in Fig. 13-13. Feed temperature and the pressure drop across the valve are adjusted to vaporize the feed to the desired extent, while the drum provides disengaging space to allow the vapor to separate from the liquid. The expansion across the valve is at constant enthalpy, and this fact can be used to calculate $T_2$ (or $T_1$ to give a desired $T_2$).

A degrees-of-freedom analysis indicates that the variables subject to the designer's control are $C + 3$ in number. The most common way to use these is to specify the feed rate, composition, and pressure ($C + 1$ variables) plus the drum temperature $T_2$ and pressure $P_2$. This operation will give one point on the *equilibrium flash curve* shown in Fig. 13-14. This curve shows the relation at constant pressure between the fraction $V/F$ of the feed flashed and the drum temperature. The temperature at $V/F = 0.0$ when the first bubble

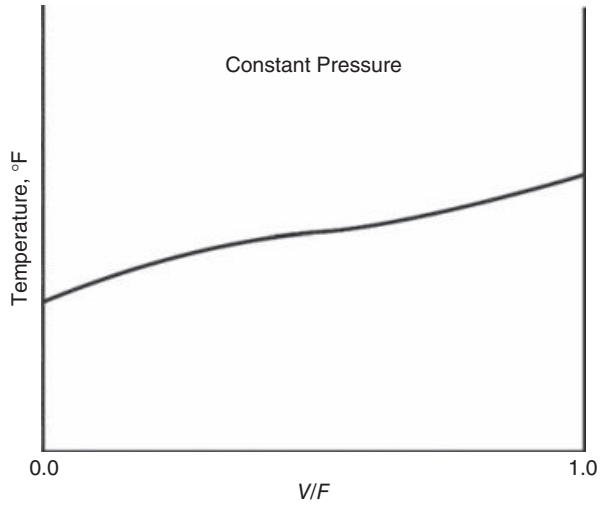

**FIG. 13-14** Equilibrium flash curve.

of vapor is about to form (saturated liquid) is the *bubble point* temperature of the feed mixture, and the value at $V/F = 1.0$ when the first droplet of liquid is about to form (saturated vapor) is the *dew point* temperature.

## BUBBLE POINT AND DEW POINT

For a given drum pressure and feed composition, the bubble and dew point temperatures bracket the temperature range of the equilibrium flash. At the bubble point temperature, the total vapor pressure exerted by the mixture becomes equal to the confining drum pressure, and it follows that $\sum y_i = 1.0$ in the bubble formed. Since $y_i = K_i x_i$ and since the $x_i$'s still equal the feed compositions (denoted by $z_i$), calculation of the bubble point temperature involves a trial-and-error search for the temperature which, at the specified pressure, makes $\sum K_i z_i = 1.0$. If instead the temperature is specified, one can find the bubble point pressure that satisfies this relationship.

At the dew point temperature, $y_i$ still equals $z_i$, and the relationship $\sum x_i = \sum z_i / K_i = 1.0$ must be satisfied. As in the case of the bubble point, a trial-and-error search for the dew point temperature at a specified pressure is involved. Or, if the temperature is specified, the dew point pressure can be calculated.

## ISOTHERMAL FLASH

The calculation for a point on the flash curve that is intermediate between the bubble point and the dew point is referred to as an isothermal flash calculation because $T_2$ is specified. Except for an ideal binary mixture, procedures for calculating an isothermal flash are iterative. A popular and recommended method is the following, due to Rachford and Rice [*J. Pet. Technol.* **4**(10): sec. 1, p. 19, and sec. 2, p. 3 (1952)]. The component mole balance ($Fz_i = Vy_i + Lx_i$), phase distribution relation ($K_i = y_i/x_i$), and total mole balance ($F = V + L$) can be combined to give

$$x_i = \frac{z_i}{1+(V/F)(K_i-1)} \tag{13-12}$$

$$y_i = \frac{K_i z_i}{1+(V/F)(K_i-1)} \tag{13-13}$$

Since $\sum x_i - \sum y_i = 0$,

$$f\left(\frac{V}{F}\right) = \sum_i \frac{z_i(1-K_i)}{1+(V/F)(K_i-1)} = 0 \tag{13-14}$$

Equation (13-14) is solved iteratively for $V/F$, followed by the calculation of values of $x_i$ and $y_i$ from Eqs. (13-12) and (13-13) and $L$ from the total mole balance. Any one of a number of numerical root-finding procedures such as the Newton-Raphson, secant, false-position, or bisection method can be used to solve Eq. (13-14). Values of $K_i$ are constants if they are independent of liquid and vapor compositions. Then the resulting calculations are straightforward. Otherwise, the $K_i$ values must be periodically updated for composition effects, perhaps after each iteration, using prorated values of $x_i$ and $y_i$ from Eqs. (13-12) and (13-13). Generally the iterations are continued until the change in the absolute value of $V/F$ is sufficiently small and until the absolute value of the residual $f(V/F)$ is close to zero. When converged, $\sum x_i$ and $\sum y_i$ will each be very close to a value of 1, and, if desired, $T_1$ can be computed from an energy balance around the valve if no heat exchanger is used. Alternatively, if $T_1$ is fixed, as mentioned earlier, a heat exchanger must be added before, after, or in place of the valve with the required heat duty being calculated from an energy balance. The limits of applicability of Eqs. (13-12) to (13-14) are the bubble point, at which $V = 0$ and $x_i = z_i$, and the dew point, at which $L = 0$ and $y_i = z_i$. At these limits, Eq. (13-14) reduces to the bubble point equation

$$\sum_i K_i x_i = 1 \tag{13-15}$$

and the dew point equation, respectively,

$$\sum_i \frac{y_i}{K_i} = 1 \tag{13-16}$$

For a *binary feed,* specification of the flash drum temperature and pressure fixes the equilibrium-phase compositions, which are related to the $K$ values by

$$x_1 = \frac{1-K_2}{K_1-K_2} \quad \text{and} \quad y_1 = \frac{K_1K_2-K_1}{K_2-K_1}$$

The mole balance can be rearranged to

$$\frac{V}{F} = \frac{z_1(K_1-K_2)/(1-K_2)-1}{K_1-1}$$

If $K_1$ and $K_2$ are functions of temperature and pressure only (ideal solutions), the flash curve can be calculated directly without iteration.

## ADIABATIC FLASH

In Fig. 13-13, if $P_2$ and the feed-stream conditions (that is, $F$, $z_i$, $T_1$, $P_1$) are known, then the calculation of $T_2$, $V$, $L$, $y_i$, and $x_i$ is referred to as an adiabatic flash. In addition to Eqs. (13-12) to (13-14) and the total mole balance, the following energy balance around both the valve and the flash drum combined must be included:

$$H^F F = H^V V + H^L L \tag{13-17}$$

By taking a basis of $F = 1.0$ mol and eliminating $L$ with the total mole balance, Eq. (13-17) becomes

$$f_2\{V, T_2\} = H^F - V(H^V - H^L) - H^L = 0 \tag{13-18}$$

With $T_2$ now unknown, Eq. (13-14) becomes

$$f_1\{V, T_2\} = \sum_i \frac{z_i(1-K_i)}{1+V(K_i-1)} = 0 \tag{13-19}$$

A number of iterative procedures have been developed for solving Eqs. (13-18) and (13-19) simultaneously for $V$ and $T_2$. Frequently, and especially if the feed contains components of a narrow range of volatility, convergence is rapid for a tearing method in which a value of $T_2$ is assumed, Eq. (13-19) is solved iteratively by the isothermal flash procedure, and, using that value of $V$, Eq. (13-18) is solved iteratively for a new approximation of $T_2$, which is then used to initiate the next cycle until $T_2$ and $V$ converge. However, if the feed contains components of a wide range of volatility, it may be best to invert the sequence and assume a value for $V$, solve Eq. (13-19) for $T_2$, solve Eq. (13-18) for $V$, and then repeat the cycle. If the $K$ values and/or enthalpies are sensitive to the unknown phase compositions, it may be necessary to solve Eqs. (13-18) and (13-19) simultaneously by a Newton or other suitable iterative technique. Alternatively, the two-tier method of Boston and Britt [*Comput. Chem. Eng.* **2:** 109 (1978)], which is also suitable for difficult isothermal flash calculations, may be applied.

**Other Flash Specifications** Flash drum specifications in addition to ($P_2$, $T_2$) and ($P_2$, adiabatic) are possible but must be applied with care, as discussed by Michelsen [*Comp. Chem. Eng.* **17:** 431 (1993)]. Most computer-aided process design and simulation programs permit a wide variety of flash specifications.

**Three-Phase Flash** Single-stage equilibrium flash calculations become considerably more complex when an additional liquid phase can

form, as in mixtures of water with hydrocarbons, water with ethers, and water with higher alcohols (containing four or more carbon atoms). Procedures for computing such situations are referred to as three-phase flash methods, which are given for the general case by Henley and Rosen (*Material and Energy Balance Computations,* Wiley, New York, 1968, chap. 8). When the two liquid phases are almost mutually insoluble, they can be considered separately, and relatively simple procedures apply, as discussed by Smith (*Design of Equilibrium Stage Processes,* McGraw-Hill, New York, 1963). Condensation of such mixtures may result in one liquid phase being formed before the other. Computer-aided process design and simulation programs all contain a Gibbs free-energy routine that can compute a three-phase flash by minimization of the Gibbs free energy. Many important and subtle aspects of three-phase flash calculations are discussed by Michelsen [*Fluid Phase Equil.* **9**(1): 21 (1982)], McDonald and Floudas [*AIChE J.* **41:** 1798 (1995)], and Wasylkiewicz et al. [*Ind. Eng. Chem. Research* **35:** 1395 (1996)].

**Complex Mixtures** Feed analyses in terms of component compositions are usually not available for complex hydrocarbon mixtures with a final normal boiling point above about 38°C (100°F) (*n*-pentane). One method of handling such a feed is to break it down into pseudocomponents (narrow-boiling fractions) and then estimate the mole fraction and *K* value for each such component. Edmister [*Ind. Eng. Chem.* **47:** 1685 (1955)] and Maxwell (*Data Book on Hydrocarbons,* Van Nostrand, Princeton, N.J., 1958) give charts that are useful for this estimation. Once *K* values are available, the calculation proceeds as described above for multicomponent mixtures. Another approach to complex mixtures is to obtain an American Society for Testing and Materials (ASTM) or true-boiling point (TBP) curve for the mixture and then use empirical correlations to construct the atmospheric-pressure equilibrium flash vaporization (EFV) curve, which can then be corrected to the desired operating pressure. A discussion of this method and the necessary charts is presented in a later subsection Petroleum and Complex-Mixture Distillation.

## GRAPHICAL METHODS FOR BINARY DISTILLATION

Multistage distillation under continuous, steady-state operating conditions is widely used in practice to separate a variety of mixtures. Table 13-1, taken from the study of Mix, Dweck, Weinberg, and Armstrong [*AIChE Symp. Ser.* **76**(192): 10 (1980)], lists key components along with typical stage requirements to perform the separation for 27 industrial distillation processes. The design of multistage columns can be accomplished by graphical techniques when the feed mixture contains only two components. The *y-x* diagram method developed by McCabe and Thiele [*Ind. Eng. Chem.* **17:** 605 (1925)] uses only phase equilibrium and mole balance relationships. The method assumes an adiabatic column (no heat losses through the column walls) and constant latent heat for the binary mixture at all compositions (which requires, among other things, equal latent heat for both components). The method is exact only for those systems in which the energy effects on vapor and liquid rates leaving the stages are negligible. However, the approach is simple and gives a useful first estimate of the column design, which can be refined by using the enthalpy composition diagram method of Ponchon [*Tech. Mod.* **13**(20): 55 (1921)] and Savarit [*Arts Metiers* **75**(18): 65, 142, 178, 241, 266, 307 (1922)]. This approach uses the energy balance in addition to mole balance and phase equilibrium relationships and is rigorous when enough calorimetric data are available to construct the diagram without assumptions.

With the widespread availability of computers, the preferred approach to design is equation-based since it provides answers rapidly and repeatedly without the tedium of redrawing graphs. Such an approach is especially useful for sensitivity analysis, which gives insight into how a design changes under variations or uncertainty in design parameters such as thermodynamic properties; feed flow rate, composition, temperature, and pressure; and desired product compositions. Nevertheless, diagrams are useful for quick approximations, for interpreting the results of equation-based methods, and for demonstrating the effect of various design variables. The *x-y* diagram is the most convenient for these purposes, and its use is developed in detail here. The use of the enthalpy composition diagram is given by Smith (*Design of Equilibrium Stage Processes,* McGraw-Hill, New York, 1963) and Henley and Seader (*Equilibrium-Stage Separation Operations in Chemical Engineering,* Wiley, New York, 1981). An approximate equation-based approach based on the enthalpy composition diagram was proposed by Peters [*Ind. Eng. Chem.* **14:** 476 (1922)] with additional aspects developed later by others. Doherty and Malone (*Conceptual Design of Distillation Systems*, McGraw-Hill, New York, 2001, app. A) describe this method for binary mixtures and extend it to multicomponent systems. The approach is exact when the enthalpy composition surfaces are linear.

**TABLE 13-1 Key Components and Typical Number of (Real) Stages Required to Perform the Separation for Distillation Processes of Industrial Importance**

| Key components | Typical number of trays |
|---|---|
| Hydrocarbon systems | |
| Ethylene-ethane | 73 |
| Propylene-propane | 138 |
| Propyne–1–3-butadiene | 40 |
| 1–3 Butadiene-vinyl acetylene | 130 |
| Benzene-toluene | 34, 53 |
| Benzene-ethyl benzene | 20 |
| Benzene–diethyl benzene | 50 |
| Toluene–ethyl benzene | 28 |
| Toluene-xylenes | 45 |
| Ethyl benzene–styrene | 34 |
| *o*-Xylene-*m*-xylene | 130 |
| Organic systems | |
| Methonol-formaldehyde | 23 |
| Dichloroethane-trichloroethane | 30 |
| Acetic acid–acetic anhydride | 50 |
| Acetic anhydride–ethylene diacetate | 32 |
| Vinyl acetate–ethyl acetate | 90 |
| Ethylene glycol–diethylene glycol | 16 |
| Cumene-phenol | 38 |
| Phenol-acetophenone | 39, 54 |
| Aqueous systems | |
| HCN-water | 15 |
| Acetic acid–water | 40 |
| Methanol-water | 60 |

| Isopropanol-water | 12 |
| Vinyl acetate–water | 35 |
| Ethylene oxide–water | 50 |
| Ethylene glycol–water | 16 |

### PHASE EQUILIBRIUM DIAGRAMS

Three types of binary phase equilibrium curves are shown in Fig. 13-15. The *y-x* diagram is almost always plotted for the component that is the more volatile (denoted by the subscript 1) in the region where distillation is to

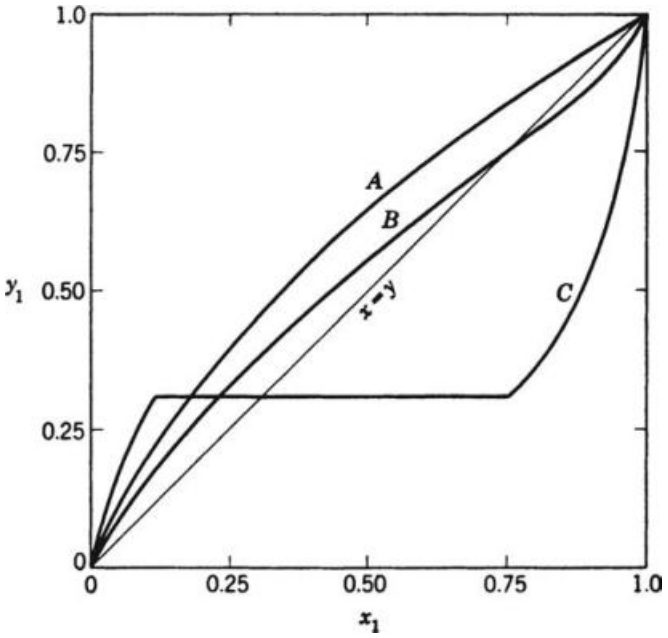

**FIG. 13-15** Typical binary equilibrium curves. Curve *A,* system with normal volatility. Curve *B,* system with homogeneous azeotrope (one liquid phase). Curve *C,* system with heterogeneous azeotrope (two liquid phases in equilibrium with one vapor phase).

take place. Curve *A* shows the common case in which component 1 remains more volatile over the entire composition range. Curve *B* is typical of many systems (e.g., ethanol-water) in which the component that is more volatile at low values of $x_1$ becomes less volatile than the other component at high values of $x_1$. The vapor and liquid compositions are identical for the homogeneous azeotrope where curve *B* crosses the 45° diagonal (that is, $x_1 = y_1$). A heterogeneous azeotrope is formed by curve *C,* in which there are two equilibrium liquid phases and one equilibrium vapor phase.

An azeotrope limits the separation that can be obtained between components by simple distillation. For the system described by curve *B,* the maximum overhead-product concentration that could be obtained from a feed with $z_1 = 0.25$ is the azeotropic composition. Similarly, a feed with $x_1 = 0.9$ could produce a bottom-product composition no lower than the azeotrope.

The phase rule permits only two variables to be specified arbitrarily in a binary two-phase mixture at equilibrium. Consequently, the curves in Fig. 13-15 can be plotted at either constant temperature or constant pressure, but not both. The latter is more common. The *y-x* diagram can be plotted in mole, weight, or volume fractions. The units used later for the phase flow rates must, of course, agree with those used for the equilibrium data. Mole fractions, which are almost always used, are applied here.

It is sometimes permissible to assume constant *relative volatility* to approximate the equilibrium curve quickly. Then by applying Eq. (13-2) to components 1 and 2,

$$\alpha = \frac{K_1}{K_2} = \frac{y_1 x_2}{x_1 y_2}$$

which can be rewritten as (using $x_2 = 1 - x_1$ and $y_2 = 1 - y_1$)

$$y_1 = \frac{x_1 \alpha}{1 + (\alpha - 1)x_1} \tag{13-20}$$

With a constant value for α, this equation provides a simple, approximate expression for representing the equilibrium $y = x$ diagram. Doherty and Malone (*Conceptual Design of Distillation Systems*, McGraw-Hill, New York, 2001, sec. 2.3) discuss this approximation in greater detail and give a selection of binary mixtures for which the approximation is reasonable. At a constant pressure of 1 atm, these include benzene + toluene, $\alpha = 2.34$; benzene + *p*-xylene, $\alpha = 4.82$; and hexane + *p*-xylene, $\alpha = 7.00$.

## MCCABE-THIELE METHOD

**Operating Lines** The McCabe-Thiele method is based on representation of the material balance equations as operating lines on the *y-x* diagram. The lines are made straight by the assumption of *constant molar overflow,* which eliminates the need for an energy balance. The liquid-phase flow rate is assumed to be constant from tray to tray in each section of the column between addition ( feed) and withdrawal (product) points. If the liquid rate is constant, the vapor rate must also be constant.

The constant-molar-overflow assumption rests on several underlying thermodynamic assumptions. The most important one is equal molar heats of vaporization for the two components. The other assumptions are adiabatic operation (no heat leaks) and no heat of mixing or sensible heat effects. These assumptions are most closely approximated for close-boiling isomers. The result of these assumptions on the calculation method can be illustrated with Fig. 13-16, which shows two material balance envelopes cutting through the top section (above the top feed stream or sidestream) of the column. If the liquid flow rate $L_{n+1}$ is assumed to be identical to $L_{n-1}$, then $V_n = V_{n-2}$ and the component material balance for both envelopes 1 and 2 can be represented by

$$y_n = \left(\frac{L}{V}\right) x_{n+1} + \frac{Dx_D}{V} \tag{13-21}$$

where *y* and *x* have a stage subscript *n* or $n + 1$, but *L* and *V* need to be identified only with the section of the column to which they apply. Equation (13-21) has the analytical form of a straight line where $L/V$ is the slope and $Dx_D/V$ is the *y* intercept at $x = 0$.

The effect of a sidestream withdrawal point is illustrated by Fig. 13-17. The material balance equation for the column section below the sidestream is

$$y_n = \frac{L'}{V'} x_{n+1} + \frac{Dx_D + Sx_S}{V'} \tag{13-22}$$

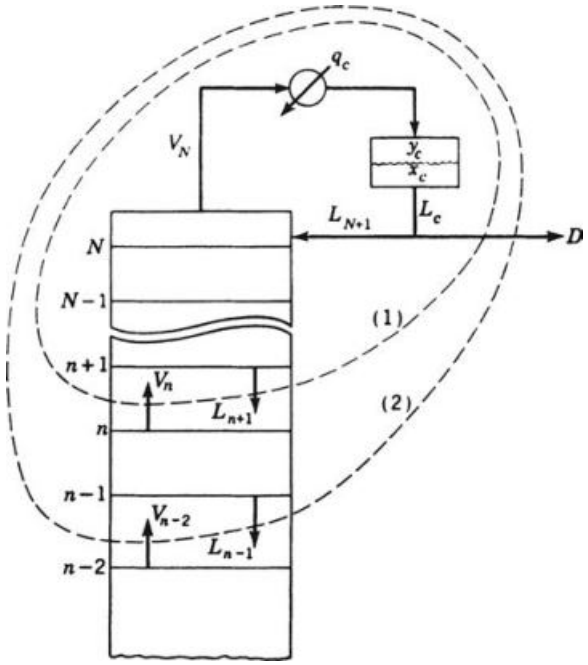

**FIG. 13-16** Two material balance envelopes in the top section of a distillation column.

where the primes designate the *L* and *V* below the sidestream. Since the sidestream must be a saturated phase, $V = V'$ if a liquid sidestream is withdrawn and $L = L'$ if it is a vapor.

If the sidestream in Fig. 13-17 is a feed (not necessarily a saturated liquid or vapor), the balance for the section below the feed becomes

$$y_n = \frac{L'}{V'} x_{n+1} + \frac{Dx_D - Fz_F}{V'} \tag{13-23}$$

Similar equations can be written for the bottom section of the column. For the envelope shown in Fig. 13-18,

$$y_m = \frac{L'}{V'} x_{m+1} - \frac{Bx_B}{V'} \tag{13-24}$$

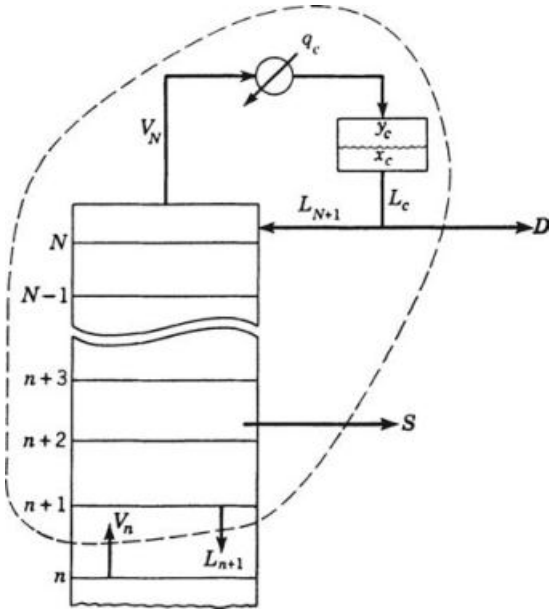

**FIG. 13-17** Material balance envelope that contains two external streams *D* and *S*, where *S* represents a sidestream product withdrawn above the feed plate.

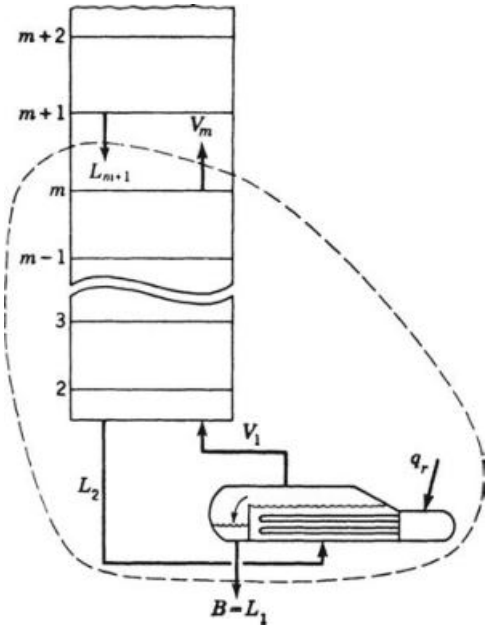

**FIG. 13-18** Material balance envelope around the bottom end of the column. The partial reboiler is equilibrium stage 1.

where the subscript $m$ is used to identify the stage number in the bottom section.

Equations such as (13-21) through (13-24), when plotted on the $y$-$x$ diagram, furnish a set of *operating lines.* A point on an operating line represents two *passing streams,* and the operating line itself is the locus of all possible pairs of passing streams within the column section to which the line applies.

An operating line can be located on the $y$-$x$ diagram if (1) two points on the line are known or (2) one point and the slope are known. The known points on an operating line are usually its intersection with the $y$-$x$ diagonal and/or its intersection with another operating line.

The slope $L/V$ of the operating line is termed the *internal reflux ratio.* This ratio in the operating line equation for the top section of the column [see Eq. (13-21)] is related to the *external reflux ratio* $R = L_{N+1}/D$ by

$$\frac{L}{V} = \frac{L_{N+1}}{V_N} = \frac{RD}{(1+R)D} = \frac{R}{1+R} \tag{13-25}$$

when the reflux stream $L_{N+1}$ is a saturated liquid.

**Thermal Condition of the Feed** The slope of the operating line changes whenever a feed stream or a sidestream is passed. To calculate this change, it is convenient to introduce a quantity $q$, which is defined by the following equations for a feed stream $F$:

$$L' = L + qF \tag{13-26}$$

$$V = V' + (1-q)F \tag{13-27}$$

The primes denote the streams below the stage to which the feed is introduced. The value of $q$ is a measure of the thermal condition of the feed and represents the moles of saturated liquid formed in the feed stage per mole of feed. The value of $q$ for a particular feed can be estimated from

$$q = \frac{\text{energy to convert 1 mol of feed to saturated vapor}}{\text{molar heat of vaporization}}$$

It takes on the following values for various thermal conditions of the feed:

| | |
|---|---|
| Subcooled liquid feed: | $q > 1$ |
| Saturated liquid feed: | $q = 1$ |
| Partially flashed feed: | $0 < q < 1$ |
| Saturated vapor feed: | $q = 0$ |
| Superheated vapor feed: | $q < 0$ |

Equations analogous to (13-26) and (13-27) can be written for a sidestream, but the value of $q$ will be either 1 or 0, depending on whether the sidestream is taken from the liquid or the vapor stream.

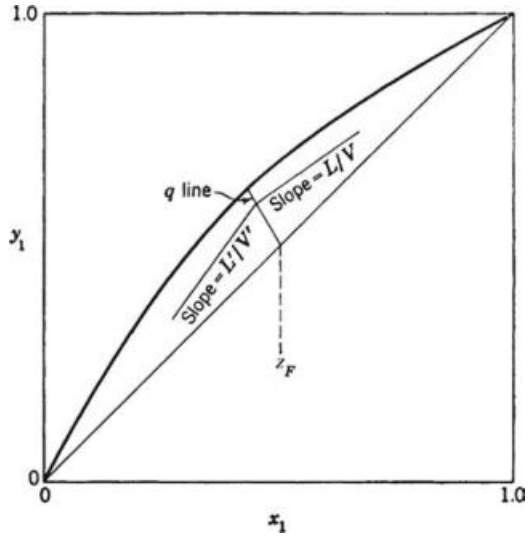

**FIG. 13-19** Typical intersection of the two operating lines at the $q$ line for a feed stage. The $q$ line shown is for a partially flashed feed.

The quantity $q$ can be used to derive the "$q$ line equation" for a feed stream or a sidestream. The $q$ line is the locus of all points of intersection of the two operating lines, which meet at the feed stream or sidestream stage. This intersection must occur along that section of the $q$ line between the equilibrium curve and the $y = x$ diagonal. At the point of intersection, the same $y, x$ point must satisfy both the operating line equation above the feed stream (or sidestream) stage and the one below the feed stream (or sidestream) stage. Subtracting one equation from the other gives for a feed stage

$$(V - V')y = (L - L')x + Fz_F$$

which, when combined with Eqs. (13-26) and (13-27), gives the $q$ line equation

$$y = \frac{q}{q-1}x - \frac{z_F}{q-1} \tag{13-28}$$

A $q$ line construction for a partially flashed feed is given in Fig. 13-19. It is easily shown that the $q$ line must intersect the diagonal at $z_F$. The slope of the $q$ line is $q/(q-1)$. All five $q$ line cases are shown in Fig. 13-20. Note that when $q = 1$, the $q$ line has infinite slope and is vertical.

The derivation of Eq. (13-28) assumes a single-feed column and no sidestream. However, the same result is obtained for other column configurations. Typical $q$ line constructions for sidestream stages are shown in Fig. 13-21. Note that the $q$ line for a sidestream must always intersect the diagonal at the composition ($y_S$ or $x_S$) of the sidestream. Figure 13-21 also shows the intersections of the operating lines with the diagonal construction line. The top operating line must always intersect the diagonal at

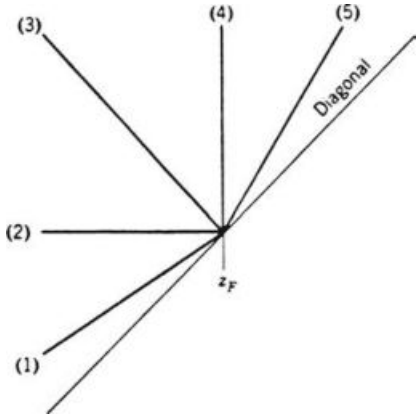

**FIG. 13-20** All five cases of $q$ lines: (1) superheated vapor feed, (2) saturated vapor feed, (3) partially vaporized feed, (4) saturated liquid feed, and (5) subcooled liquid feed. Slope of $q$ line is $q/(q-1)$.

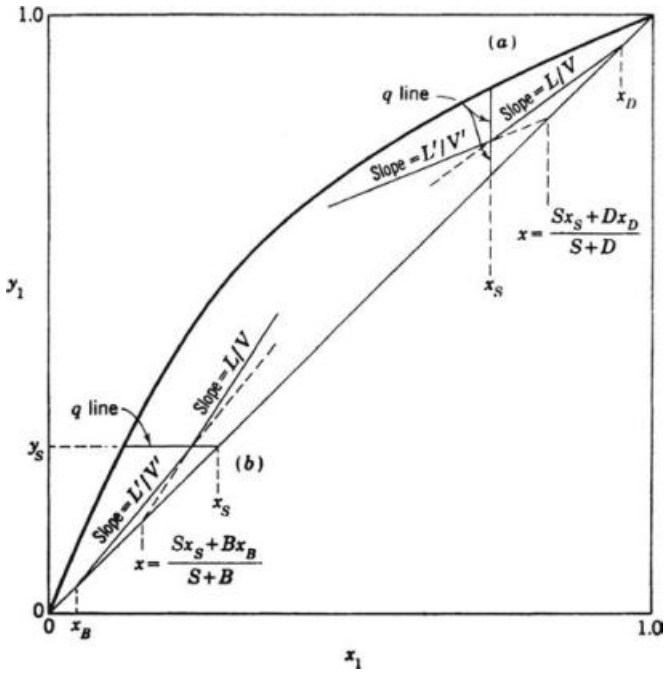

**FIG. 13-21** Typical construction for a sidestream showing the intersection of the two operating lines with the $q$ line and with the $x$-$y$ diagonal. ($a$) Liquid sidestream near the top of the column. ($b$) Vapor sidestream near the bottom of the column.

the overhead-product composition $x_D$. This can be shown by substituting $y = x$ in Eq. (13-21) and using $V - L = D$ to reduce the resulting equation to $x = x_D$. Similarly (except for columns in which open steam is introduced at the bottom), the bottom operating line must always intersect the diagonal at the bottom-product composition $x_B$.

**Equilibrium-Stage Construction** The use of the equilibrium curve and the operating lines to "step off" equilibrium stages is illustrated in Fig. 13-22. The plotted portions of the equilibrium curve (curved) and the operating line (straight) cover the composition range existing in the column section shown in the lower right-hand corner of the figure. If $y_n$ and $x_n$ represent the compositions (in terms of the more volatile component) of the equilibrium vapor and liquid leaving stage $n$, then point $(y_n, x_n)$ on the equilibrium curve must represent the equilibrium stage $n$. The operating line is the locus for compositions of all possible pairs of passing streams within the section, and therefore a horizontal line (dashed) at $y_n$ must pass through the point $(y_n, x_{n+1})$ on the operating line since $y_n$ and $x_{n+1}$ represent passing streams. Likewise, a vertical line (dashed) at $x_n$ must intersect the operating line at point $(y_{n-1}, x_n)$. The equilibrium stages above and below stage $n$ can be located by a vertical line through $(y_n, x_{n+1})$ to find $(y_{n+1}, x_{n+1})$ and a horizontal line through $(y_{n-1}, x_n)$ to find $(y_{n-1}, x_{n-1})$. This procedure can be repeated by alternating the use of equilibrium and operating lines upward or downward through the column to find the total number of equilibrium stages.

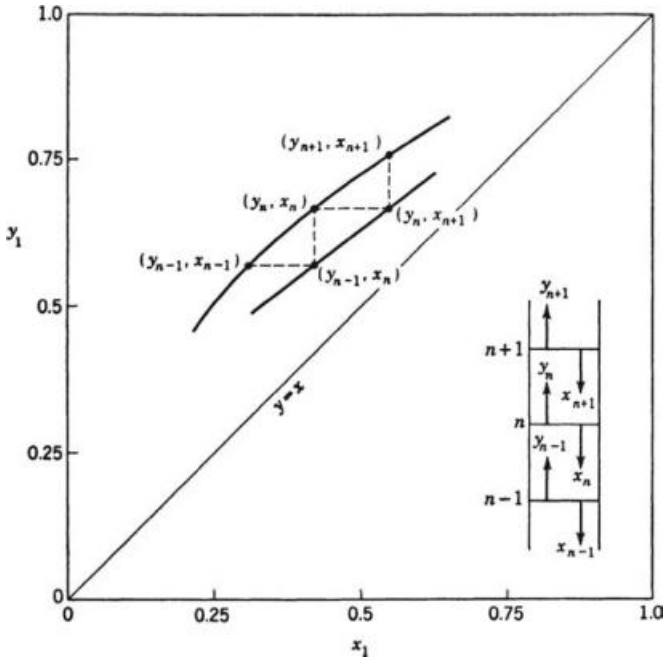

**FIG. 13-22** Illustration of how equilibrium stages can be located on the $x$-$y$ diagram through the alternating use of the equilibrium curve and the operating line.

**Total Column Construction** The graphical construction for an entire column is shown in Fig. 13-23. The process, pictured in the lower right-hand corner of the diagram, is an existing column with a number of actual trays equivalent to eight equilibrium stages. A partial reboiler (equivalent to an equilibrium stage) and a total condenser are used. This column configuration has $C + 2N + 9$ design variables (degrees of freedom), which must be specified to define one unique operation [see subsection Degrees of Freedom and Design Variables, especially Fig. 13-59 and Eq. (13-109)]. These may be used as follows as the basis for a graphical solution:

| Specifications | Degrees of freedom |
|---|---|
| Stage pressures (including reboiler) | $N$ |
| Condenser pressure | 1 |
| Stage heat leaks (except reboiler) | $N-1$ |
| Pressure and heat leak in reflux divider | 2 |
| Feed stream | $C+2$ |
| Feed-stage location | 1 |
| Total number of stages $N$ | 1 |
| One overhead purity | 1 |
| Reflux temperature | 1 |
| Eternal reflux ratio | 1 |
| | $C+2N+9$ |

Pressures can be specified at any level below the safe working pressure of the column. The condenser pressure will be set at 275.8 kPa (40 psia), and all pressure drops within the column will be neglected. The equilibrium curve in Fig. 13-23 represents data at that pressure. All heat leaks will be assumed to be zero. The feed composition is 40 mol% of the more volatile component 1, and the feed rate is 0.126 kg·mol/s (1000 lb·mol/h) of saturated liquid ($q = 1$). The feed-stage location is fixed at stage 4, and the total number of stages is fixed at eight.

The overhead purity is specified as $x_D = 0.95$. The reflux temperature is the bubble point temperature (saturated reflux), and the external reflux ratio is set at $R = 4.5$.

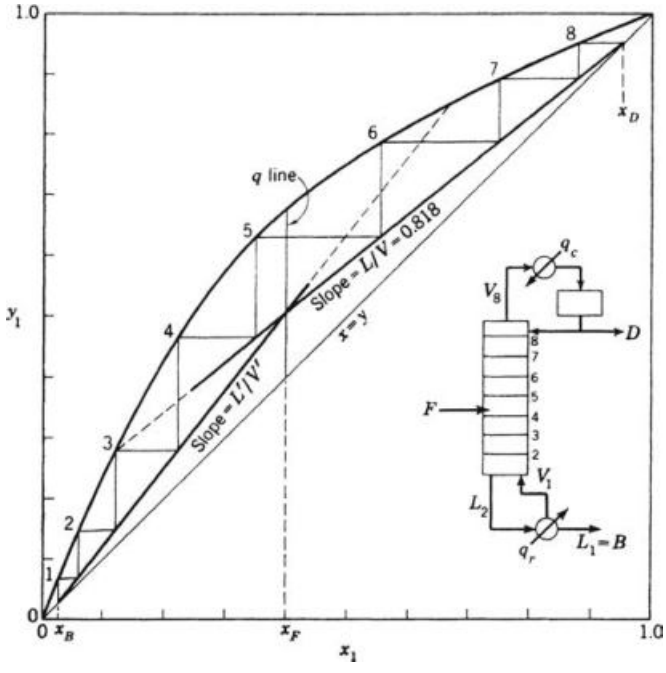

**FIG. 13-23** Construction for a column with a bubble point feed, a total condenser, and a partial reboiler.

We need answers to the following two questions: First, what bottom-product composition $x_B$ will the column produce under these specifications? Second, what is the value of the top vapor rate $V_N$ in this operation, and will it exceed the maximum vapor rate capacity for this column, which is assumed to be 0.252 kg·mol/s (2000 lb·mol/h) at the top-tray conditions?

The solution is started by using Eq. (13-25) to convert the external reflux ratio of 4.5 to an internal reflux ratio of $L/V = 0.818$. The distillate composition $x_D = 0.95$ is then located on the diagonal, and the upper operating line is drawn as shown in Fig. 13-23.

If the $x_B$ value were known, the bottom operating line could be immediately drawn from the $x_B$ value on the diagonal up to its required intersection point with the upper operating line on the feed $q$ line. In this problem, since the number of stages is fixed, the value of $x_B$ that gives a lower operating line that will require exactly eight stages must be found by trial and error. An $x_B$ value is assumed, and the resulting lower operating line is drawn. The stages can be stepped off by starting from either $x_B$ or $x_D$; $x_B$ was used in this case.

Note that the lower operating line is used until the fourth stage is passed, at which time the construction switches to the upper operating line. This is necessary because the vapor and liquid streams passing each other between the fourth and fifth stages must fall on the upper line.

The $x_B$ that requires exactly eight equilibrium stages is $x_B = 0.026$. An overall component balance gives $D = 0.051$ kg·mol/s (405 lb·mol/h). Then

$$V_N = V_B = L_{N+1} + D = D(R+1) = 0.051(4.5+1.0)$$
$$= 0.280 \text{ kg·mol/s (2230 lb·mol/h)}$$

which exceeds the column capacity of 0.252 kg·mol/s (2007 lb·mol/h). This means that the column cannot provide an overhead-product yield of 40.5 percent at 95 percent purity. Either the purity specification must be reduced, or we must be satisfied with a lower yield. If the distillate specification ($x_D = 0.95$) is retained, the reflux rate must be reduced. This will cause the upper operating line to pivot upward around its fixed point of $x_D = 0.95$ on the diagonal. The new intersection of the upper line with the $q$ line will lie closer to the equilibrium curve. The $x_B$ value must then move upward along the diagonal because the eight stages will not "reach" as far as before. The higher $x_B$ composition will reduce the recovery of component 1 in the 95 percent overhead product.

Another entire column with a partially vaporized feed, a liquid sidestream rate equal to $D$ withdrawn from the second stage from the top, and a total condenser is shown in Fig. 13-24. The specified compositions are $z_F = 0.40$, $x_B = 0.05$, and $x_D = 0.95$. The specified $L/V$ ratio in the top section is 0.818. These specifications permit the top operating line to be located and the two top stages stepped off to determine the liquid sidestream composition $x_s = 0.746$. The operating line below the sidestream must intersect the diagonal at the "blend" of the sidestream and the overhead stream. Since $S$ was specified to be equal to $D$ in rate, the intersection point is

$$x = \frac{(1.0)(0.746)+(1.0)(0.95)}{1.0+1.0} = 0.848$$

This point plus the point of intersection of the two operating lines on the sidestream $q$ line (vertical at $x_s = 0.746$) permits the location of the middle operating line. (The slope of the middle operating line could also have been used.) The lower operating line must run from the specified $x_B$ value on the diagonal to the required point of intersection on the feed $q$ line. The stages are stepped off from the top down in this case. The sixth stage from the top is the feed stage, and a total of about 11.4 stages are required to reach the specified $x_B = 0.05$.

Fractional equilibrium stages have meaning. The 11.4 will be divided by a tray efficiency, and the rounding up to an integral number of actual trays should be done after that division. For example, if the average tray efficiency for the process modeled in Fig. 13-24 is 80 percent, then the number of actual trays required is 11.4/0.8 = 14.3, which is rounded up to 15.

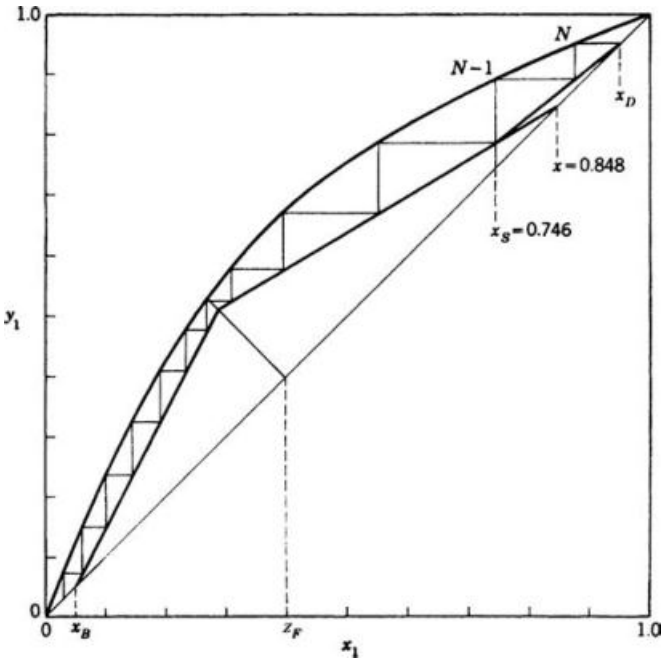

**FIG. 13-24** Graphical solution for a column with a partially flashed feed, a liquid sidestream, and a total condenser.

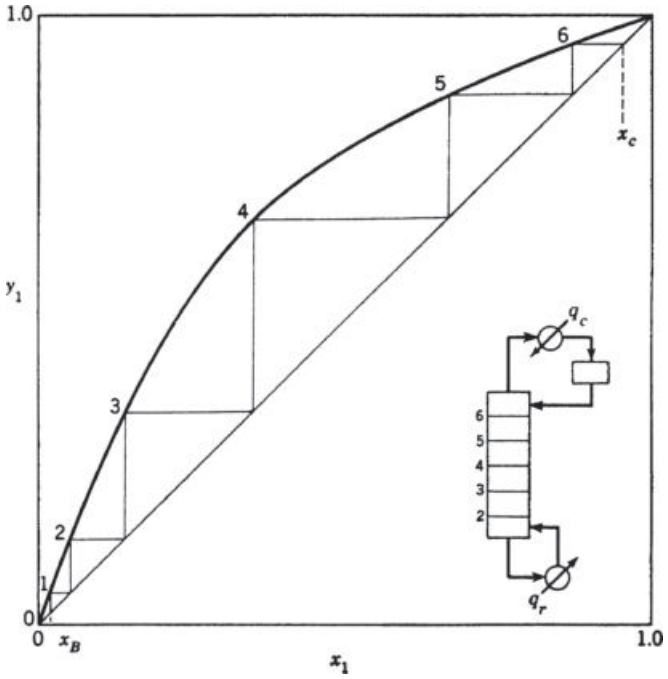
**Feed-Stage Location** The *optimum* feed-stage location is that location which, with a given set of other operating specifications, will result in the widest separation between $x_D$ and $x_B$ for a given number of stages. Or, if the number of stages is not specified, the optimum feed location is the one that requires the lowest number of stages to accomplish a specified separation between $x_D$ and $x_B$. Either of these criteria will always be satisfied if the operating line farthest from the equilibrium curve is used in each step, as in Fig. 13-23.

It can be seen from Fig. 13-23 that the optimum feed location would have been the fifth tray for that operation. If a new column were being designed, that should be the designer's choice. However, when an existing column is being modeled, the feed stage on the diagram should correspond as closely as possible to the actual feed tray in the column. It can be seen that a badly mislocated feed (a feed that requires one to remain with an operating line until it closely approaches the equilibrium curve) can be very wasteful insofar as the effectiveness of the stages is concerned.

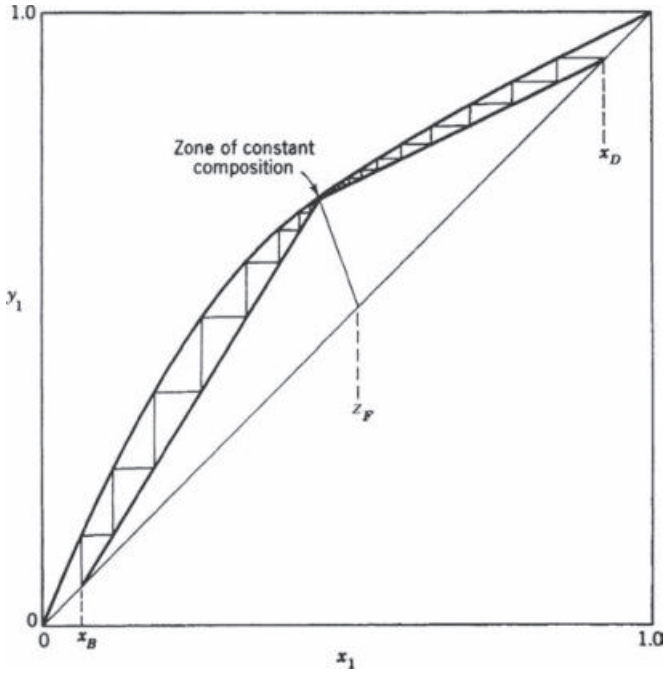
**Minimum Stages** A column operating at total reflux is represented in Fig. 13-25*a*. Enough material has been charged to the column to fill the reboiler, the trays, and the overhead condensate drum to their working levels. The column is then operated with no feed and with all the condensed overhead stream returned as reflux ($L_{N+1} = V_N$ and $D = 0$). Also all the liquid reaching the reboiler is vaporized and returned to the column as vapor. Since $F$, $D$, and $B$ are all zero, $L_{n+1} = V_n$ at all points in the column. With a slope of unity ($L/V = 1.0$), the operating line must coincide with the diagonal throughout the column. Total reflux operation gives the minimum number of stages required to effect a specified separation between $x_B$ and $x_D$.

**Minimum Reflux** The minimum reflux ratio is defined as that ratio which if decreased by an infinitesimal amount would require an infinite number of stages to accomplish a specified separation between two components. The concept has meaning only if a separation between two components is specified and the number of stages is not specified. Figure 13-25*b* illustrates the minimum reflux condition. As the reflux ratio is reduced, the two operating lines swing upward, pivoting around the specified $x_B$ and $x_D$ values, until one or both touch the equilibrium curve. For equilibrium curves shaped like the one shown, the contact occurs at the feed $q$ line, resulting in a *feed pinch point*. Often an equilibrium curve will dip down closer to the diagonal at higher compositions. In such cases, the upper operating line may make contact before its intersection point on the $q$ line reaches the equilibrium curve, resulting in a *tangent pinch point*. Wherever the contact appears, the intersection of the operating line with the equilibrium curve produces a pinch point that contains a very large number of stages, and a zone of constant composition is formed (see Doherty and Malone, *Conceptual Design of Distillation Systems*, McGraw-Hill, New York, 2001, chap. 3, and Sec. 4.6 for additional information).

**Intermediate Reboilers and Condensers** When a large temperature difference exists between the ends of the column due to a wide boiling point difference between the components, intermediate reboilers or condensers may be used to add heat at a lower temperature or remove heat at a higher temperature, respectively. (A distillation column of this type is shown in *Perry's Chemical Engineers' Handbook*, 7th ed., 1986, Fig. 13-2*a*.) A column operating with an intermediate reboiler and an intermediate condenser in addition to a regular reboiler and a condenser is illustrated with the solid lines in Fig. 13-26. The dashed lines correspond to simple distillation with only a bottoms reboiler and an overhead condenser. Total boiling and condensing heat loads are the same for both columns. As shown by Kayihan [*AIChE Symp. Ser.* **76**(192): 1 (1980)], the addition of intermediate reboilers and intermediate condensers increases thermodynamic efficiency but requires additional stages, as is clear from the positions of the operating lines in Fig. 13-26.



(*a*)



(*b*)

**FIG. 13-25** McCabe-Thiele diagrams for limiting cases. (*a*) Minimum stages for a column operating at total reflux with no feeds or products. (*b*) Minimum reflux for a binary system of normal volatility.

**Optimum Reflux Ratio** The general effect of the operating reflux ratio on fixed costs, operating costs, and the sum of these is shown in Fig. 13-27. In ordinary situations, the minimum on the total cost curve will generally occur at an operating reflux ratio in the interval 1.1 to 2 times the minimum value. Generally, the total cost curve rises slowly from its minimum value as the operating reflux ratio increases, and very steeply as the operating reflux ratio decreases. In the absence of a detailed cost analysis for the specific separation of interest, it is recommended to select operating reflux ratios

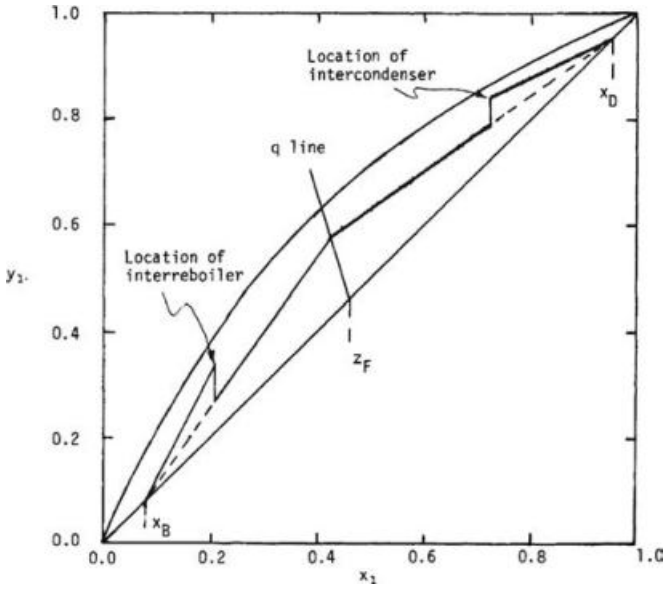


**FIG. 13-26** McCabe-Thiele diagram for columns with and without an intermediate reboiler and an intermediate condenser.

closer to 1.5 to 2.0 times the minimum value (see Doherty and Malone 2001, chap. 6, for additional discussion).

**Difficult Separations** Some binary separations may pose special problems because of extreme purity requirements for one or both products or because of a relative volatility close to 1. The *y-x* diagram is convenient for stepping off stages at extreme purities if it is plotted on log-log paper. However, such cases are best treated by equation-based design methods.

**Equation-Based Design Methods** Exact design equations have been developed for mixtures with constant relative volatility. Minimum stages can be computed with the Fenske equation, minimum reflux from the Underwood equation, and the total number of stages in each section of the column from either the Smoker equation [*Trans. Am. Inst. Chem. Eng.* **34:** 165 (1938); the derivation of the equation is shown, and its use is illustrated by Smith 1963] or Underwood's method. A detailed treatment of these approaches is given in Doherty and Malone (2001, chap. 3). Equation-based methods have also been developed for nonconstant relative volatility mixtures (including nonideal and azeotropic mixtures) by Julka and Doherty [*Chem. Eng. Sci.* **45:** 1801 (1990); *Chem. Eng. Sci.* **48:** 1367 (1993)], and Fidkowski et al. [*AIChE J.* **37:** 1761 (1991)]. Also see Doherty and Malone (2001, chap. 4).

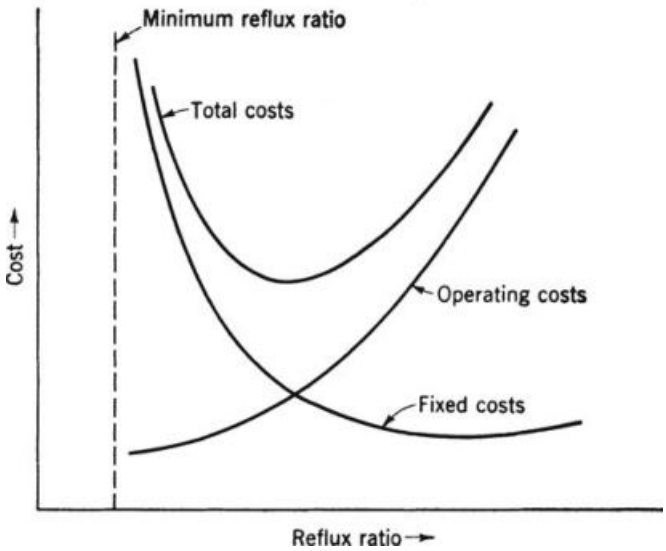

**FIG. 13-27** Location of the optimum reflux for a given feed and specified separation.

**Stage Efficiency** The use of the *Murphree plate efficiency* is particularly convenient on *y-x* diagrams. The Murphree efficiency is defined for the vapor phase as

$$E^{MV} = \frac{y_n - y_{n-1}}{y_n^* - y_{n-1}} \tag{13-29}$$

where $y_n^*$ is the composition of the vapor that would be in equilibrium with the liquid leaving stage $n$ and is the value read from the equilibrium curve. The $y_{n-1}$ and $y_n$ are the actual (nonequilibrium) values for vapor streams leaving the $n-1$ and $n$ stages, respectively. Note that for the $y_{n-1}$ and $y_n$ values, we assume that the vapor streams are completely mixed and uniform in composition. An analogous efficiency can be defined for the liquid phase.

The application of a 50 percent Murphree vapor-phase efficiency on a *y-x* diagram is illustrated in Fig. 13-28. A pseudoequilibrium curve is drawn halfway (on a vertical line) between the operating lines and the true equilibrium curve. The true equilibrium curve is used for the first stage (the partial reboiler is assumed to be an equilibrium stage), but for all other stages the vapor leaving each stage is assumed to approach the equilibrium value $y_n^*$ only 50 percent of the way. Consequently, the steps in Fig. 13-28 represent actual trays.

In general, the application of a constant efficiency to each stage as in Fig. 13-28 will not give the same answer as obtained when the number of equilibrium stages (obtained by using the true equilibrium curve) is divided by the same efficiency factor.

The prediction and use of stage efficiencies are described in detail in Sec. 14. Alternative approaches based on mass-transfer rates are preferred, as described in the subsection Nonequilibrium Modeling.

**Miscellaneous Operations** The *y-x* diagrams for several other column configurations have not been presented here. The omitted items are *partial condensers, rectifying columns* ( feed introduced to the bottom stage), *stripping columns* ( feed introduced to the top stage), total reflux in the top section but not in the bottom section, multiple feeds, and the introduction of *open steam* to the bottom stage to eliminate the reboiler. These configurations are discussed in Smith (1963) and Henley and Seader (1981), who also describe the more rigorous Ponchon-Savarit method, which is not covered here.

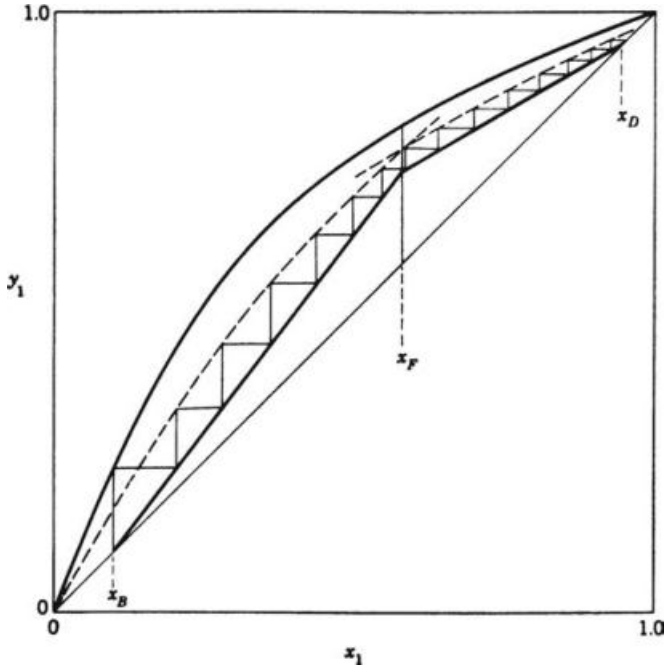

**FIG. 13-28** Application of a 50 percent Murphree vapor-phase efficiency to each stage (excluding the reboiler) in the column. Each step in the diagram corresponds to an actual stage.

## APPROXIMATE MULTICOMPONENT DISTILLATION METHODS

Some approximate calculation methods for the solution of multicomponent, multistage separation problems continue to serve useful purposes even though computers are available to provide more rigorous solutions. The available phase equilibrium and enthalpy data may not be accurate enough to justify the longer rigorous methods. Or in extensive design and optimization studies, a large number of cases can be worked quickly and cheaply by an approximate method to define roughly the optimum specifications, which can then be investigated more exactly with a rigorous method.

Two approximate multicomponent shortcut methods for simple distillation are the Smith-Brinkley (SB) method, which is based on an analytical solution of the finite-difference equations that can be written for staged separation processes when stages and interstage flow rates are known or assumed, and the Fenske-Underwood-Gilliland (FUG) method, which combines Fenske's total reflux equation and Underwood's minimum reflux equation with a graphical correlation by Gilliland that relates actual column performance to total and minimum reflux conditions for a specified separation between two key components. Thus, the SB and FUG methods are rating and design methods, respectively. Both methods work best when mixtures are nearly ideal.

The SB method is not presented here, but it is presented in detail in the 6th edition of *Perry's Chemical Engineers' Handbook.* Extensions of the SB method to nonideal mixtures and complex configurations are developed by Eckert and Hlavacek [*Chem. Eng. Sci.* **33:** 77 (1978)] and Eckert [*Chem. Eng. Sci.* **37:** 425 (1982)], respectively, but are not discussed here. However, the approximate and very useful method of Kremser [*Nat. Pet. News* **22**(21): 43 (1930)] for application to absorbers and strippers is discussed at the end of this subsection.

### FENSKE-UNDERWOOD-GILLILAND (FUG) SHORTCUT METHOD

In this approach, Fenske's equation [*Ind. Eng. Chem.* **24:** 482 (1932)] is used to calculate $N_{min}$, which is the number of plates required to make a specified separation at total reflux, that is, the minimum value of *N.* Underwood's equations [*J. Inst. Pet.* **31:** 111 (1945); **32:** 598 (1946); **32:** 614 (1946); and *Chem. Eng. Prog.* **44:** 603 (1948)] are used to estimate the minimum reflux ratio $R_{min}$. The empirical correlation of Gilliland [*Ind. Eng. Chem.* **32:** 1220 (1940)] shown in Fig. 13-29 then uses these values to give $N$ for any specified $R$, or $R$ for any specified $N$. Limitations of the Gilliland correlation are discussed by Henley and Seader (*Equilibrium-Stage Separation Operations in Chemical Engineering,* Wiley, New York, 1981). The following equation, developed by Molokanov et al. [*Int. Chem. Eng.* **12**(2): 209 (1972)], satisfies the endpoints and fits the Gilliland curve reasonably well:

$$\frac{N - N_{min}}{N+1} = 1 - \exp\left(\frac{1+54.4\Psi}{11+117.2\Psi} \times \frac{\Psi - 1}{\Psi^{0.5}}\right) \tag{13-30}$$

where $\Psi = (R - R_{min})/(R+1)$.

The Fenske total reflux equation can be written as

$$\left(\frac{x_i}{x_r}\right)_D = (\alpha_i)^{N_{min}} \left(\frac{x_i}{x_r}\right)_B \tag{13-31}$$

or as

$$N_{min} = \frac{\log[(Dx_D/Bx_B)_i (Bx_B/Dx_D)_r]}{\log \alpha_i} \tag{13-32}$$

where $i$ is any component and $r$ is an arbitrarily selected reference component in the definition of relative volatilities

$$\alpha_i = \frac{K_i}{K_r} = \frac{y_i x_r}{y_r x_i} \tag{13-33}$$

The particular value of $\alpha_i$ used in Eqs. (13-31) and (13-32) is the effective value calculated from Eq. (13-34) defined in terms of values for each stage in the column by

$$\alpha^N = \alpha_N \alpha_{N-1} \cdots \alpha_2 \alpha_1 \tag{13-34}$$

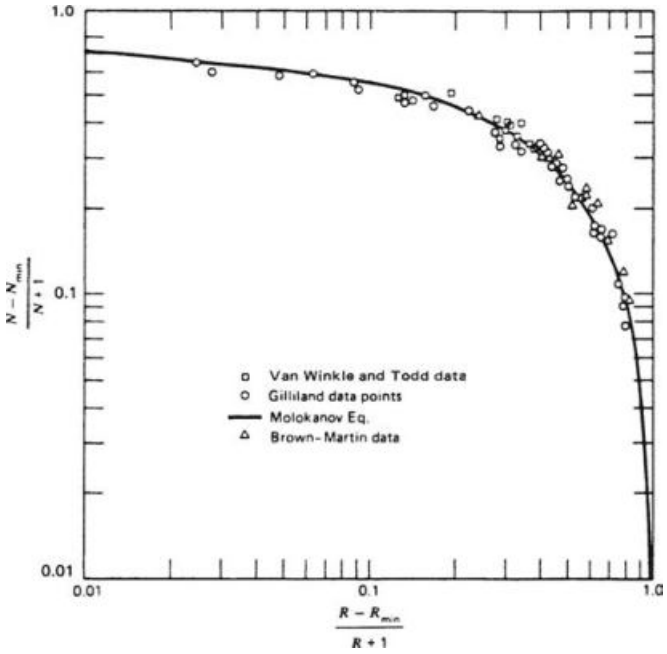

**FIG. 13-29** Comparison of rigorous calculations with Gilliland correlation. [*Henley and Seader,* Equilibrium-Stage Separation Operations in Chemical Engineering, *Wiley, New York, 1981; data of Van Winkle and Todd,* Chem. Eng., ***78(21): 136 (Sept. 20, 1971); data of Gilliland,*** Elements of Fractional Distillation, *4th ed., McGraw-Hill, New York, 1950; data of Brown and Martin,* Trans. Am. Inst. Chem. Eng., ***35:*** *679 (1939).*]

Equations (13-31) and (13-32) are exact relationships between the splits obtained for components $i$ and $r$ in a column at total reflux. However, the value of $\alpha_i$ must always be estimated, and this is where the approximation enters. It is usually estimated from

$$\alpha = (\alpha_{top}\alpha_{bottom})^{1/2} \tag{13-35}$$

or

$$\alpha = (\alpha_{top}\alpha_{middle}\alpha_{bottom})^{1/3} \tag{13-36}$$

As a side note, the separation that will be accomplished in a column with a known number of equilibrium stages can often be reasonably well estimated by specifying the split of one component (designated as the reference component $r$), setting $N_{min}$ equal to 40 to 60 percent of the number of equilibrium stages (not actual trays), and then using Eq. (13-32) to estimate the splits of all the other components. This is an iterative calculation because the component splits must first be arbitrarily assumed to give end compositions that can be used to give initial end-temperature estimates. The $\alpha_{top}$ and $\alpha_{bottom}$ values corresponding to these end temperatures are used in Eq. (13-5) to give $\alpha_i$ values for each component. The iteration is continued until the $\alpha_i$ values do not change from trial to trial.

The Underwood minimum reflux equations of main interest are those that apply when some of the components do not appear in either the distillate or the bottom products at minimum reflux. These equations are

$$\sum_i \frac{\alpha_i (x_{iD})_{min}}{\alpha_i - \Theta} = R_{min} + 1 \tag{13-37}$$

and

$$\sum_i \frac{\alpha_i z_{iF}}{\alpha_i - \Theta} = 1 - q \tag{13-38}$$

The relative volatilities $\alpha_i$ are defined by Eq. (13-33), $R_{min}$ is the minimum reflux ratio, and $q$ describes the thermal condition of the feed (1 for a saturated liquid feed and 0 for a saturated vapor feed). The $z_{iF}$ values are available from the given feed composition. The $\Theta$ is the common root for the top section equations and the bottom section equations developed by Underwood for a column at minimum reflux with separate zones of constant composition in each section. The common root value must fall between $\alpha_{hk}$ and $\alpha_{lk}$, where *hk* and *lk* stand for *heavy key* and *light key,* respectively. The *key components* are the ones the designer wants to separate. In the butane-pentane splitter problem in Example 13-1, the light key is $n$-$C_4$ and the heavy key is $i$-$C_5$.

The $\alpha_i$ values in Eqs. (13-37) and (13-38) are effective values obtained from Eq. (13-35) or Eq. (13-36). Once these values are available, $\Theta$ can be calculated in a straightforward iteration from Eq. (13-38). Since the $\alpha$-$\Theta$ difference can be small, $\Theta$ should be determined to four decimal places to avoid numerical difficulties.

The $(x_{iD})_{min}$ values in Eq. (13-37) are minimum reflux values, that is, the overhead composition that would be produced by the column operating at the minimum reflux with an infinite number of stages. When the light key and the heavy key are adjacent in relative volatility and the specified split between them is sharp, or when the relative volatilities of the other components are not close to those of the two keys, only the two keys will distribute at minimum reflux and the $(x_{iD})_{min}$ values are easily determined. This is often the case, and it is the only one considered here. Other cases in which some of or all of the nonkey components distribute between distillate and bottom products are discussed in detail by Henley and Seader (1981).

The FUG method is convenient for new column design with the following specifications:

1. A value for $R/R_{min}$
2. Desired split on the reference component (usually chosen as the heavy key)
3. Desired split on one other component (usually the light key)

However, the total number of equilibrium stages $N$, $N/N_{min}$, or the external reflux ratio can be substituted for one of these three specifications. Note that the feed location is automatically specified as the optimum one; this is assumed in the Underwood equations. The assumption of saturated liquid reflux is also inherent in the Fenske and Underwood equations (i.e., the reflux is *not* subcooled). An important limitation on the Underwood equations is the assumption of constant molar overflow. As discussed by Henley and Seader (1981), this assumption can lead to a prediction of the minimum reflux that is considerably lower than the actual value. No such assumption is inherent in the Fenske equation. An exact calculation technique for minimum reflux is given by Tavana and Hansen [*Ind. Eng. Chem. Process Des. Dev.* **18:** 154 (1979)]. Approximate explicit expressions for minimum reflux for various types of splits in three- and four-component mixtures were developed by Glinos and Malone [*Ind. Eng. Chem. Process Des. Dev.* **23:** 764 (1984)] as well as lumping rules for applying their expressions to mixtures containing more than four components. These expressions are fairly accurate (usually within 5 percent of the exact value for $R_{min}$) and are extremely convenient for using in the FUG method since they remove the tedious calculation of $R_{min}$ via the Underwood equations. A computer program for the FUG method is given by Chang [*Hydrocarbon Process.* **60**(8): 79 (1980)]. The method is best applied to mixtures that form ideal or nearly ideal solutions, and it should not be used for strongly nonideal or azeotropic mixtures.

***Example 13-1 Application of FUG Method*** A large butane-pentane splitter is to be shut down for repairs. Some of its feed will be diverted temporarily to an available smaller column, which has only 11 trays plus a partial reboiler. The feed enters on the middle tray. Past experience with similar feeds indicates that the 11 trays plus the reboiler are roughly equivalent to 10 equilibrium stages and that the column has a maximum top vapor capacity of 1.75 times the feed rate on a mole basis. The column will operate at a condenser pressure of 827.4 kPa (120 psia). The feed will be at its bubble point ($q$ = 1.0) at the feed tray conditions and has the following composition on the basis of 0.0126 kg·mol/s (100 lb·mol/h):

| Component | $Fx_{iF}$ |
|---|---|
| $C_3$ | 5 |
| $i$-$C_4$ | 15 |
| $n$-$C_4$ | 25 |
| $i$-$C_5$ | 20 |
| $n$-$C_5$ | 35 |
| | 100 |

The original column normally has less than 7 mol% $i$-$C_5$ in the overhead and less than 3 mol% $n$-$C_4$ in the bottom product when operating at a distillate rate of $D/F$ = 0.489. Can these product purities be produced on the smaller column at $D/F$ = 0.489?

Pressure drops in the column will be neglected, and the $K$ values will be read at 827 kPa (120 psia) in both column sections from the DePriester nomograph in Fig. 2-10*b*. When constant molar overflow is assumed in each section, the rates in pound moles per hour in the upper and lower sections are as follows:

| Top section | Bottom section |
|---|---|
| $D = (0.489)(100) = 48.9$ | $B = 100 - 48.9 = 51.1$ |
| $V = (1.75)(100) = 175$ | $V' = V = 175$ |
| $L = 175 - 48.9 = 126.1$ | $L' = L + F = 226.1$ |
| $\frac{V}{L} = 1.388$ | $\frac{V'}{L'} = 0.7739$ |

$$\frac{L}{L'} = \frac{126.1}{226.1} = 0.5577$$

$$R = \frac{126.1}{48.9} = 2.579$$

NOTE: To convert pound-moles per hour to kilogram-moles per second, multiply by $1.26 \times 10^{-4}$.

Application of the FUG method is demonstrated on the splitter. Specifications necessary to model the existing column include these:

1. $N = 10$, total number of equilibrium stages
2. Optimum feed location (which may or may not reflect the actual location)
3. Maximum $V/F$ at the top tray of 1.75
4. Split on one component given in the following paragraphs

The solution starts with an assumed arbitrary split of all the components to give estimates of top and bottom compositions that can be used to get initial end temperatures. The $\alpha_i$'s evaluated at these temperatures are averaged with the $\alpha$ at the feed-stage temperature (assumed to be the bubble point of the feed) by using Eq. (13-36). The initial assumption for the split on $i$-$C_5$ is $Dx_D/Bx_B = 3.15/16.85$. As mentioned earlier, $N_{min}$ usually ranges from $0.4N$ to $0.6N$, and the initial $N_{min}$ value assumed here will be $(0.6)(10) = 6.0$. Equation (13-32) can be rewritten as

$$\left(\frac{Dx_D}{Fx_F - Dx_D}\right) = \alpha_i^{6.0}\left(\frac{3.15}{16.85}\right) = \alpha_i^{6.0}(0.1869)$$

or

$$Dx_{iD} = \frac{0.1869\alpha_i^{6.0}}{1 + 0.1869\alpha_i^{6.0}} Fx_{iF}$$

The evaluation of this equation for each component is as follows:

| Component | $\alpha_i$ | $\alpha_i^{6.0}$ | $0.1869\ \alpha_i^{6.0}$ | $Fx_{iF}$ | $Dx_{iD}$ | $Bx_{iB}$ |
|---|---|---|---|---|---|---|
| $C_3$ | 5.00 | | | 5 | 5.0 | 0.0 |
| $i$-$C_4$ | 2.63 | 330 | 61.7 | 15 | 14.8 | 0.2 |
| $n$-$C_4$ | 2.01 | 66 | 12.3 | 25 | 25.1 | 1.9 |
| $i$-$C_5$ | 1.00 | 1.00 | 0.187 | 20 | 3.15 | 16.85 |
| $n$-$C_5$ | 0.843 | 0.36 | 0.0672 | 35 | 2.20 | 32.80 |
| | | | | 100 | 48.25 | 51.75 |

The end temperatures corresponding to these product compositions are 344 K (159°F) and 386 K (236°F). These temperatures plus the feed bubble point temperature of 358 K (185°F) provide a new set of $\alpha_i$'s that vary only slightly from those used earlier. Consequently, the $D = 48.25$ value is not expected to vary greatly, and it will be used to estimate a new $i$-$C_5$ split. The desired distillate composition for $i$-$C_5$ is 7 percent, so it will be assumed that $Dx_D = (0.07)(48.25) = 3.4$ for $i$-$C_5$ and that the split on that component will be 3.4/16.6. The results obtained with the new $\alpha_i$'s and the new $i$-$C_5$ split are as follows:

| Component | $\alpha_i^{6.0}$ | $0.2048\ \alpha_i^{6.0}$ | $Fx_{iF}$ | $Dx_{iD}$ | $Bx_{iB}$ | $x_{iD}$ | $x_{iB}$ |
|---|---|---|---|---|---|---|---|
| $C_3$ | | | 5 | 5.0 | 0.0 | 0.102 | 0.000 |
| $i$-$C_4$ | 322 | 65.9 | 15 | 14.8 | 0.2 | 0.301 | 0.004 |
| $n$-$C_4$ | 68 | 13.9 | 25 | 23.3 | 1.7 | 0.473 | 0.033 |
| $i$-$C_5$ | 1.00 | 0.205 | 20 | 3.4 | 16.6 | 0.069 | 0.327 |
| $n$-$C_5$ | 0.415 | 0.085 | 35 | 2.7 | 32.3 | 0.055 | 0.636 |
| | | | 100 | 49.2 | 50.8 | 1.000 | 1.000 |

The calculated $i$-$C_5$ composition in the overhead stream is 6.9 percent, which is close enough to the target value of 7.0 for now.

Table 13-2 shows subsequent calculations using the Underwood minimum reflux equations. The $\alpha$ and $x_D$ values in Table 13-2 are those from the Fenske total reflux calculation. As noted earlier, the $x_D$ values should be those at minimum reflux. This inconsistency may reduce the accuracy of the Underwood method, but to be useful, a shortcut method must be fast, and it has not been shown that a more rigorous estimation of $x_D$ values results in an overall improvement in accuracy. The calculated $R_{min}$ is 0.9426. The actual reflux assumed is obtained from the specified maximum top vapor rate of 0.022 kg·mol/s [175 lb·(mol/h)] and the calculated $D$ of 49.2 ( from the Fenske equation).

$$L_{N+1} = V_N - D$$

$$R = \frac{V_N}{D} - 1 = \frac{175}{49.2} - 1 = 2.557$$

The values of $R_{min} = 0.9426$, $R = 2.557$, and $N = 10$ are now used with the Gilliland correlation in Fig. 13-29 or Eq. (13-30) to check the initially assumed value of 6.0 for $N_{min}$. Equation (13-30) gives $N_{min} = 6.95$, which differs from the assumed value.

Repetition of the calculations with $N_{min} = 7$ gives $R = 2.519$, $R_{min} = 0.9782$, and a calculated check value of $N_{min} = 6.85$, which is close enough. The final product compositions and the $\alpha$ values used are as follows:

| Component | $\alpha_i$ | $Dx_{iD}$ | $Bx_{iB}$ | $x_{iD}$ | $x_{iB}$ |
|---|---|---|---|---|---|
| $C_3$ | 4.98 | 5.00 | 0 | 0.1004 | 0.0 |
| $i$-$C_4$ | 2.61 | 14.91 | 0.09 | 0.2996 | 0.0017 |
| $n$-$C_4$ | 2.02 | 24.16 | 0.84 | 0.4852 | 0.0168 |
| $i$-$C_5$ | 1.00 | 3.48 | 16.52 | 0.0700 | 0.3283 |
| $n$-$C_5$ | 0.851 | 2.23 | 32.87 | 0.0448 | 0.6532 |
| | | 49.78 | 50.32 | 1.0000 | 1.0000 |

These results indicate that the 7 percent composition of $i$-$C_5$ in $D$ and the 3 percent composition of $i$-$C_4$ in $B$ obtained in the original column can also be obtained with the smaller column. These results disagree somewhat with the answers obtained from a rigorous computer solution, as shown in the following comparison. However, given the approximations that went into the FUG method, the agreement is good.

| | $x_{iD}$ | | $x_{iB}$ | |
|---|---|---|---|---|
| Component | Rigorous | FUG | Rigorous | FUG |
| $C_3$ | 0.102 | 0.100 | 0.0 | 0.0 |
| $i$-$C_4$ | 0.299 | 0.300 | 0.006 | 0.002 |
| $n$-$C_4$ | 0.473 | 0.485 | 0.037 | 0.017 |
| $i$-$C_5$ | 0.073 | 0.070 | 0.322 | 0.328 |
| $n$-$C_5$ | 0.053 | 0.045 | 0.635 | 0.653 |
| | 1.000 | 1.000 | 1.000 | 1.000 |

**TABLE 13-2 Application of Underwood Equations**

| | | | | $\theta = 1.36$ | | $\theta = 1.365$ | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| Component | $x_F$ | $\alpha$ | $\alpha x_F$ | $\alpha - \theta$ | $\frac{\alpha x_F}{\alpha - \theta}$ | $\alpha - \theta$ | $\frac{\alpha x_F}{\alpha - \theta}$ | $x_D$ | $\alpha x_D$ | $\alpha - \theta$ | $\frac{\alpha x_D}{\alpha - \theta}$ |

| | 1.00 | | | | −0.0196 | | +0.0014 | 1.000 | | | $1.9426 = R_m + 1$ |

Interpolation gives $\theta = 1.3647$.

## KREMSER EQUATION

Starting with the classical method of Kremser [*Nat. Pet. News* **22**(21): 43 (1930)], approximate methods of increasing complexity have been developed to calculate the behavior of groups of equilibrium stages for a countercurrent cascade, such as those used in simple absorbers and strippers of the type shown in Fig. 13-2*b* and *d*. However, none of these methods can adequately account for stage temperatures that are considerably higher or lower than the two entering stream temperatures for absorption and stripping, respectively, when appreciable composition changes occur. Therefore, only the simplest form of the Kremser method is presented here. Fortunately, rigorous computer methods described later can be applied when accurate results are required. The Kremser method is most useful for making preliminary estimates of absorbent and stripping agent flow rates or equilibrium-stage requirements. The method can also be used to quickly extrapolate the results of a rigorous solution to a different number of equilibrium stages.

Consider the general adiabatic countercurrent cascade of Fig. 13-30 where $v$ and $\ell$ are molar component flow rates. Regardless of whether the cascade is an absorber or a stripper, components in the entering vapor will tend to be absorbed and components in the entering liquid will tend to be stripped. If more moles are stripped than absorbed, the cascade is a stripper; otherwise, the cascade is an absorber. The Kremser method is general and applies to either case. Application of component material balance and phase equilibrium equations successively to stages 1 through $N-1$, 1 through $N-2$, etc., as shown by Henley and Seader (1981), leads to the following equations originally derived by Kremser. For each component *i,*

$$(v_i)_N = (v_i)_0(\Phi_i)_A = (l_i)_{N+1}[1-(\Phi_i)_s] \tag{13-39}$$

where

$$(\Phi_i)_A = \frac{(A_i)_e - 1}{(A_i)_e^{N+1} - 1} \tag{13-40}$$

is the fraction of component $i$ in the entering vapor that is not absorbed,

$$(\Phi_i)_s = \frac{(S_i)_e - 1}{(S_i)_e^{N+1} - 1} \tag{13-41}$$

is the fraction of component $i$ in the entering liquid that is not stripped,

$$(A_i)_e = \left(\frac{L}{K_i V}\right)_e \tag{13-42}$$

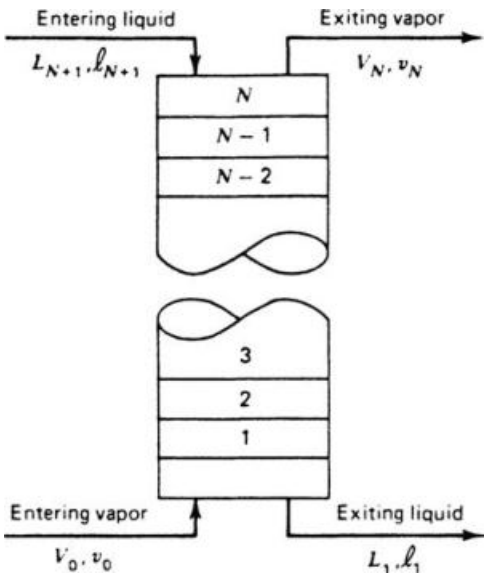

**FIG. 13-30** General adiabatic countercurrent cascade for simple absorption or stripping.

is the effective or average absorption factor for component *i,* and

$$(S_i)_e = \frac{1}{(A_i)_e} \tag{13-43}$$

is the effective or average stripping factor for component *i.* When the entering streams are at the same temperature and pressure and negligible absorption and stripping occur, effective component absorption and stripping factors are determined simply by entering stream conditions. Thus, if $K$ values are composition-independent, then

$$(A_i)_e = \frac{1}{(S_i)_e} = \frac{L_{N+1}}{K_i(T_{N+1}, P_{N+1})V_0} \tag{13-44}$$

When entering stream temperatures differ or moderate to appreciable absorption or stripping occurs, the values of $A_i$ and $S_i$ should be based on the effective average values of $L$, $V$, and $K_i$ in the cascade. However, even then, Eq. (13-44) with $T_{N+1}$ replaced by $(T_{N+1} + T_0)/2$ may be able to give a first-order approximation of $(A_i)_e$. In the case of an absorber, $L_{N+1} < L_e$ and $V_0 > V_e$ will be compensated to some extent by $K_i\{(T_{N+1} + T_0)/2, P\} < K_i\{T_e, P\}$. A similar compensation, but in opposite directions, will occur in the case of a stripper. Equations (13-40) and (13-41) are plotted in Fig. 13-31.

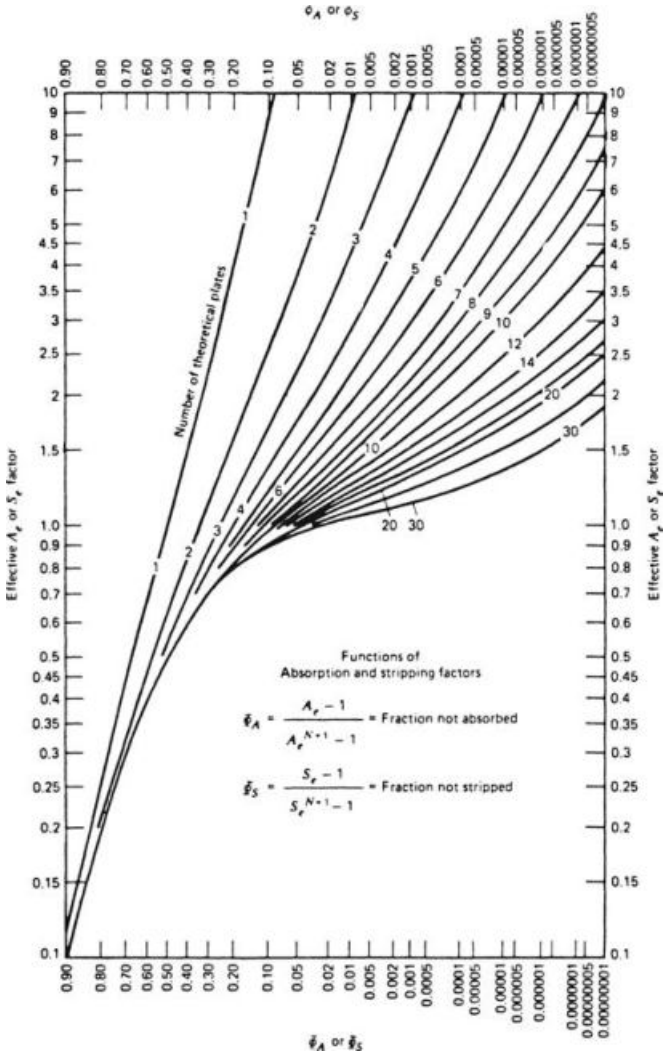

**FIG. 13-31** Absorption and stripping factors. [*W. C. Edmister,* AIChE J., ***3:*** *165–171 (1957).*]

Components having large values of $A_e$ or $S_e$ absorb or strip, respectively, to a large extent. Corresponding values of $\Phi_A$ and $\Phi_S$ approach a value of 1 and are almost independent of the number of equilibrium stages.

An estimate of the minimum absorbent flow rate for a specified amount of absorption from the entering gas of some key component $K$ for a cascade with an infinite number of equilibrium stages is obtained from Eq. (13-40) as

$$(L_{N+1})_{\min} = K_K V_0[1 - (\Phi_K)_A] \tag{13-45}$$

The corresponding estimate of minimum stripping agent flow rate for a stripper is obtained as

$$(V_0)_{\min} = \frac{L_{N+1}[1-(\Phi_K)_S]}{K_K} \tag{13-46}$$

***Example 13-2 Calculation of Kremser Method*** For the simple absorber specified in Fig. 13-32, a rigorous calculation procedure as described below gives the results in Table 13-3. Values of $\Phi$ were computed from component product flow rates, and corresponding effective absorption and stripping factors were obtained by iterative calculations in using Eqs. (13-40) and (13-41) with $N = 6$. Use the Kremser method to estimate component product rates if $N$ is doubled to a value of 12.

Assume that values of $A_e$ and $S_e$ will not change with a change in $N$. Application of Eqs. (13-40), (13-41), and (13-39) gives the results in the last four columns of Table 13-3. Because of its small value of $A_e$, the extent of absorption of $C_1$ is unchanged. For the other components, somewhat increased amounts of absorption occur. The degree of stripping of the absorber oil is essentially unchanged. Overall, only an additional 0.5 percent of absorption occurs. The greatest increase in absorption occurs for $n$-$C_4$, to the extent of about 4 percent.

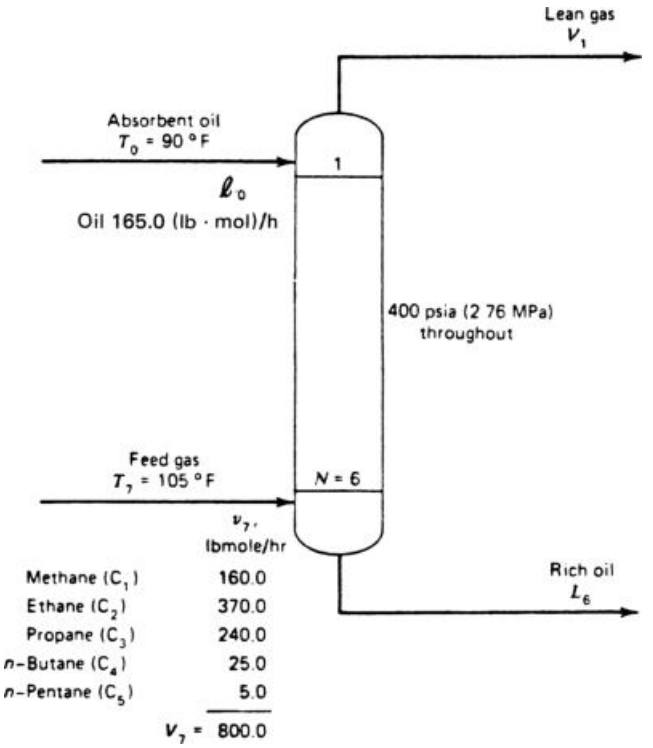

**FIG. 13-32** Specifications for the absorber example.

**TABLE 13-3 Results of Calculations for Simple Absorber of Fig. 13-32**

## SIMULATION OF DISTILLATION PROCESSES

Chemical engineers have been solving distillation problems by using the *equilibrium-stage model* since 1893 when Sorel outlined the concept to describe the distillation of alcohol. Since that time, it has been used to model a wide variety of distillation-like processes, including simple distillation (single-feed, two-product columns), complex distillation (multiple-feed, multiple-product columns), extractive and azeotropic distillation, petroleum distillation, absorption, liquid-liquid extraction, stripping, and supercritical extraction.

Real distillation processes, however, nearly always operate away from equilibrium. In recent years it has become possible to simulate distillation and absorption as the mass-transfer rate-based operations that they really are, using what have become known as *nonequilibrium* (NEQ) or *rate-based* models [Taylor et al., *CEP* (2003, July 28, pp. 28–39)].

### EQUILIBRIUM-STAGE MODELING

A schematic diagram of an equilibrium stage is shown in Fig. 13-33*a*. Vapor from the stage below and liquid from a stage above are brought into contact on the stage together with any fresh or recycle feeds. The vapor and liquid streams leaving the stage are assumed to be in equilibrium with each other. A complete separation process is modeled as a sequence of these *equilibrium stages,* as shown in Fig. 13-33*b*.

**The MESH Equations (the 2*c* + 3 Formulation)** The equations that model equilibrium stages often are referred to as the MESH equations. The M equations are the material balance equations, E stands for equilibrium equations, S stands for mole fraction summation equations, and H refers to the heat or enthalpy balance equations.

There are two types of material balance: the total material balance

$$V_{j+1} + L_{j-1} + F_j - (1 + r_j^v)V_j - (1 + r_j^L)L_j = 0 \tag{13-47}$$

and the component material balance

$$V_{j+1}y_{ij+1} + L_{j-1}x_{ij-1} + F_j z_{ij} - (1 + r_j^v)V_j y_{ij} - (1 + r_j^L)L_j x_{ij} = 0 \tag{13-48}$$

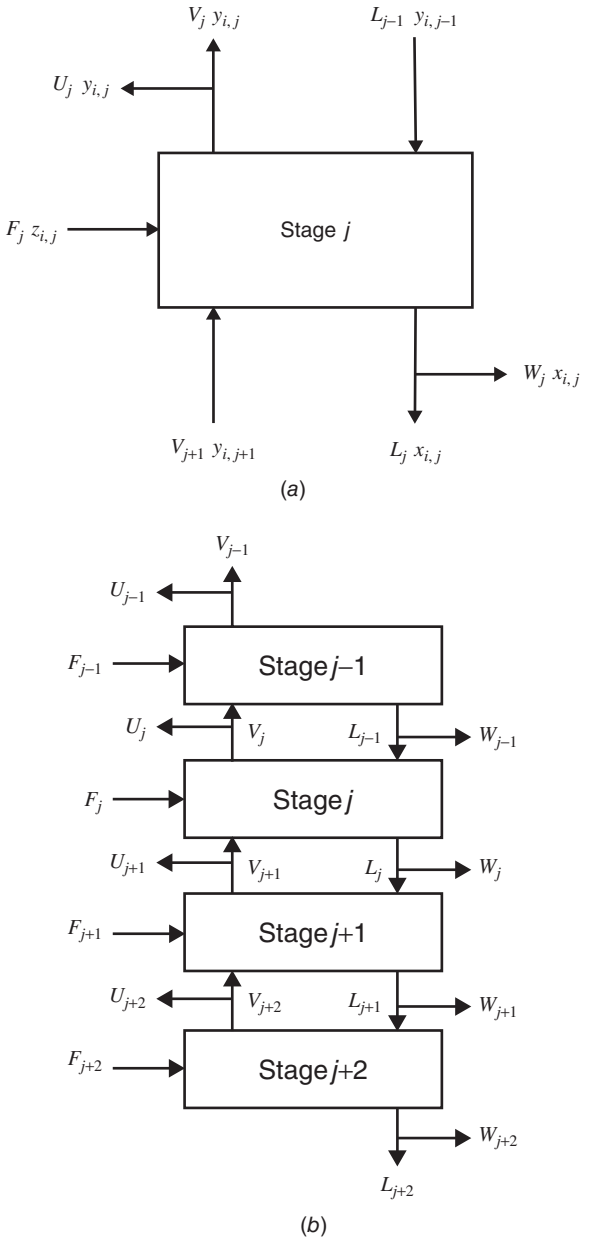

**FIG. 13-33** (*a*) The equilibrium stage. (*b*) Multistage column.

In these material balance equations, $r_j$ is the ratio of sidestream flow to interstage flow:

$$r_j^V = \frac{U_j}{V_j} \qquad r_j^L = \frac{W_j}{L_j} \tag{13-49}$$

Mole fractions must be forced to sum to unity, thus

$$\sum_{i=1}^{c} x_{i,j} = 1 \quad \sum_{i=1}^{c} y_{i,j} = 1 \quad \sum_{i=1}^{c} z_{i,j} = 1 \tag{13-50}$$

The enthalpy balance is given by

$$V_{j+1}H_{j+1}^V + L_{j-1}H_{j-1}^L + F_jH_j^F - (1+r_j^V)V_jH_j^V - (1+r_j^L)L_jH_j^L - Q_j = 0 \tag{13-51}$$

The superscripted $H'$s are the enthalpies of the appropriate phase.

**TABLE 13-4 Equations for an Equilibrium Stage**

| Equation | Equation no. | Number |
|---|---|---|
| Total mass balance | (13-47) | 1 |
| Component mass balances | (13-48) | $c$ |
| Total energy balance | (13-51) | 1 |
| Mole fraction summation equations | (13-50) | 2 |
| Equilibrium equations | (13-52) | $c$ |
| | | $2c+4$ |

To complete the model, it is usual to add equations that relate the compositions of the two streams leaving the stage. In the standard model of a distillation column, we assume that these two streams are in equilibrium with each other. Thus, the mole fractions in the exiting streams are related by the familiar equations of phase equilibrium:

$$y_{i,j} = K_{i,j}x_{i,j} \tag{13-52}$$

The $K_{i,j}$ are the equilibrium ratios or $K$ values for species $i$ on stage $j$.

**Degrees-of-Freedom Analysis and Problem Formulation** Table 13-4 summarizes the equations for a single equilibrium stage (in a sequence of stages). There are $2c + 4$ equations per stage, of which only $2c + 3$ are independent. Thus, one of these equations must be ignored in a (computer-based) method to solve the equations. In some methods we disregard the total material balance; an alternative is to combine the vapor and liquid mole fraction summation equations, as was done for flash calculations by Rachford and Rice [*J. Pet. Technol.* **4**(10): sec. 1, p. 19, and sec. 2, p. 3 (1952)]. The mole fraction summation equations for the feed are omitted here, as are the mole fraction summation equations for interstage vapor and liquid traffic; the latter "belong" to the equation set for adjacent stages (see, however, the subsection Degrees of Freedom, in which this topic is revisited in greater detail).

The quantities for stage $j$ that appear in these equations are summarized in Table 13-5. The total number of variables appearing in these equations is $3c + 10$. Note that the $K$ values and enthalpies that also appear in the MESH equations are not included in the table of variables, nor are equations for their estimation included in the list of equations. Thermodynamic properties are functions of temperature, pressure, and composition, quantities that do appear in the table of variables.

The $2c + 3$ unknown variables normally determined by solving the MESH equations are the $c$ vapor mole fractions $y_{i,j}$, the $c$ liquid mole fractions $x_{i,j}$, the stage temperature $T_j$, and the vapor and liquid flow $V_j$ and $L_j$. The remaining variables, $c + 7$ in number (the difference between the number of variables and the number of independent equations), that need to be specified are the stage pressure $P_j$, the feed flow rate, $c - 1$ mole fractions in the feed (the last is then computed directly from the feed mole fraction summation equation, which was not included in the equations for stage $j$ in Table 13-4), temperature and pressure of the feed, the stage heat duty $Q_j$, and the sidestream flows $U_j$ and $W_j$. It is important to recognize that the other flows and composition variables appearing in the MESH equations are associated with the equivalent equations for adjacent stages.

**TABLE 13-5 Variables for an Equilibrium Stage**

| Variable | Symbol | Number |
|---|---|---|
| Vapor flow rate | $V_j$ | 1 |
| Liquid flow rate | $L_j$ | 1 |
| Feed flow rate | $F_j$ | 1 |
| Vapor sidestream flow | $W_j$ | 1 |
| Liquid sidestream flow | $U_j$ | 1 |
| Vapor-phase mole fractions | $y_{i,j}$ | c |
| Liquid-phase mole fractions | $x_{i,j}$ | c |
| Feed composition | $z_{i,j}$ | c |
| Stage temperature | $T_j$ | 1 |
| Stage pressure | $P_j$ | 1 |
| Feed temperature | | 1 |
| Feed pressure | | 1 |
| Stage heat duty | $Q_j$ | 1 |
| | | $3c+10$ |

For a column of $N$ stages, we must solve $N(2c + 3)$ equations. The following table shows how we may need to solve hundreds or even thousands of equations.

| $c$ | $N$ | $N(2c+3)$ |
|---|---|---|
| 2 | 10 | 70 |
| 3 | 20 | 180 |
| 5 | 50 | 650 |
| 10 | 30 | 690 |
| 40 | 100 | 8300 |

**The $2c + 1$ Formulation** An alternative form of the MESH equations is used in many algorithms. In this variation, we make use of the component flow defined by

$$v_{ij} = V_j y_{ij} \qquad l_{ij} = L_j x_{ij} \qquad f_{ij} = F_j z_{ij} \tag{13-53}$$

In terms of the component flow, the component material balance becomes

$$v_{ij+1} + l_{ij-1} + f_{ij} - (1 + r_j^V)v_{ij} - (1 + r_j^L)l_{ij} = 0 \tag{13-54}$$

Since the total vapor and liquid flow rates are, by definition, the sum of the component flow rates of the respective phases, the summation equations and total mass balance equation are satisfied automatically. Thus, the number of equations and variables per stage have been reduced by 2 to $2c + 1$.

**Condenser and Reboiler** The MESH equations given above apply to all the interior stages of a column. In addition, any reboiler and condenser must be considered. On an actual plant, a total condenser may be followed by a reflux accumulator and a stream divider. The accumulator does not add any equations to a steady-state model (but it is important to consider in an un-steady-state model), but the stream splitter is a separate unit with its own temperature, pressure, and heat loss, and it is modeled by the appropriate balance equations (see the subsection on Degrees of Freedom, where we address this topic in greater detail). In practice the condenser and reflux splitter often are modeled as a single combined unit, and the MESH equations described previously may be used to model these stages with only some minor modifications. For example, for a total condenser *and* the reflux stream splitter at the top of a distillation column, the liquid distillate is $U_1$ and the reflux ratio $R = 1/r_1^L$. For a partial condenser (with no stream splitter needed), the vapor product is $V_1$ and the reflux ratio is $R = L_1/V_1$. A condenser/splitter device that provides both vapor and liquid products is given by a combination of these two units. Finally, for a partial reboiler at the base of a column, the bottoms flow rate is $L_N$. Note that an equilibrium stage with a sidestream is considered here to be a single unit in essentially the same way.

In computer-based methods for solving the MESH equations, it is common to replace the energy balance of the condenser (with or without the associated stream splitter) and reboiler with a specification equation. Possible specifications include

- The flow rate of the distillate/bottoms product stream
- The mole fraction of a component in either the distillate or bottoms product stream
- Component flow rate in either the distillate or bottoms product stream
- A reflux/reboil ratio or rate
- The temperature of the condenser or reboiler
- The heat duty to the condenser or reboiler

If the condenser and/or reboiler heat duties are not specified, it is possible to calculate them from the energy balances after all the other model equations have been solved.

For a total condenser, the vapor composition used in the equilibrium relations is that determined during a bubble point calculation based on the actual pressure and liquid compositions found in the condenser. These vapor mole fractions are not used in the component mass balances since there is no vapor stream from a total condenser. It often happens that the temperature of the reflux stream is below the bubble point temperature of the condensed liquid (subcooled condenser). In such cases it is necessary to specify either the actual temperature of the reflux stream or the difference in temperature between the reflux stream and the bubble point of the condensate.

**Solution of the MESH Equations** We may identify several classes of methods of solving the *equilibrium*-stage model equations:

- *Graphical methods.* These methods were developed before modern computer methods became widely adopted. Some graphical methods retain their value for a variety of reasons and were discussed at length earlier in this section.
- *Approximate methods.* In these, a great many simplifying assumptions are made to obtain solutions to the model equations. These methods were the subject of the immediately preceding subsection.
- *Computer-based methods.* From the late 1950s to the early 1990s, hardly a year passed without the publication of at least one (and usually many more than one) new algorithm for solving these equations [Seader, "The B. C. (Before Computers) and A. D. of Equilibrium-Stage Operations," *Chem. Eng. Educ.* **14**(2): 88–103 (1985)]. One could make the case that it was the equilibrium model that brought computing into chemical engineering in the first place! One of the incentives for this activity has always been a desire to solve problems with which existing methods have trouble. The evolution of algorithms for solving the stage model equations has been influenced by, among other things, the availability (or lack) of sufficient computer storage and speed, the development of mathematical techniques that can be exploited, the complexity of physical property ($K$ value and enthalpy) correlations, and the form of the model equations being solved. We continue with a brief discussion of computer-based methods. Many computer-based methods are discussed at length in a number of textbooks [see, e.g., Holland, *Fundamentals of Multicomponent Distillation,* McGraw-Hill, New York, 1981; King, *Separation Processes,* 2d ed., McGraw-Hill, New York, 1980; Seader and Henley, *Separation Process Principles*, Wiley, New York, 1998; Haas (in Kister 1992)]. Seader (1985) has written an interesting and elegant history of equilibrium-stage simulation. Other reviews of simulation methods can be found in this chapter in the 7th edition of this handbook.

**Examples** In what follows we illustrate possible column specifications by considering four examples from Seader (*Perry's Chemical Engineers' Handbook,* 7th ed., 1997, pp. 13-46–13-49). They are a simple distillation column, a more complicated distillation column, an absorber, and a reboiled stripper. A simultaneous convergence method was used for the calculations reported below. The computer program that was used for these exercises automatically generated initial estimates of all the unknown variables (flows, temperatures, and mole fractions). In most cases the results here differ only very slightly from those obtained by Seader (almost certainly due to small differences in physical property constants).

***Example 13-3 Simple Distillation Column*** Compute stage temperatures, interstage vapor and liquid flow rates and compositions, and reboiler and condenser duties for the butane-pentane splitter studied in Example 13-1. The specifications for this problem are summarized next and in Fig. 13-34.

The specifications made in this case are:

| Variable | Number | Value |
|---|---|---|
| Number of stages | 1 | 11 |
| Feed stage location | 1 | 6 |
| Component flows in feed | $c = 5$ | 5, 15, 25, 20, 35 lb·mol/h |
| Feed pressure | 1 | 120 psia |
| Feed vapor fraction | 1 | 0 |
| Pressure on each stage including condenser and reboiler | $N = 11$ | $P_j = 120$ psia |
| Heat duty on each stage except reboilers and condensers | $N - 2 = 9$ | $Q_j = 0$ |
| Vapor flow to condenser (replaces heat duty of reboiler) | 1 | $V_2 = 175$ lb·mol/h |
| Distillate flow rate (replaces heat duty of condenser) | 1 | $D = 48.9$ lb·mol/h |
| Total | 31 | |

In addition, we have assumed that the pressure of the reflux divider is the same as the pressure of the condenser, the heat loss from the reflux divider is zero, and the reflux temperature is the boiling point of the condensed overhead vapor.

The Peng-Robinson equation of state was used to estimate $K$ values and enthalpy departures [as opposed to the De Priester charts used in Example 13-1 and by Seader (1977)].

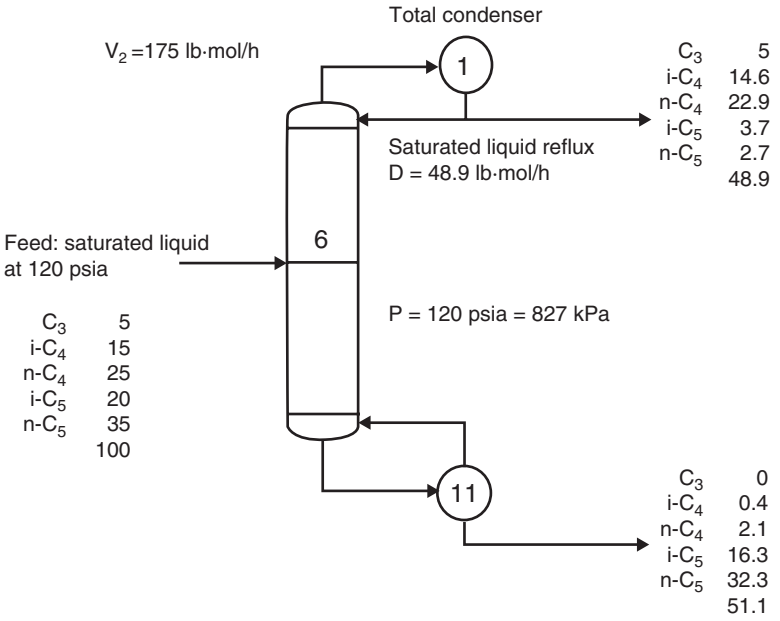

**FIG. 13-34** Specifications and calculated product stream flows for butane-pentane splitter. Flows are in pound-moles per hour.

With 11 stages and 5 components, the equilibrium-stage model has 143 equations to be solved for 143 variables (the unknown flow rates, temperatures, and mole fractions). Convergence of the computer algorithm was obtained in just four iterations. Computed product flows are shown in Fig. 13-34.

A pseudobinary McCabe-Thiele diagram for this multicomponent system is shown in Fig. 13-35. For systems with more than two components, these diagrams can only be computed from the results of a computer simulation. The axes are defined by the relative mole fractions:

$$X = \frac{x_{lk}}{x_{lk} + x_{hk}} \qquad Y = \frac{y_{lk}}{y_{lk} + y_{hk}}$$

where the subscripts *lk* and *hk* refer to light and heavy key, respectively. The lines in the diagram have similar significance as would be expected from our knowledge of McCabe-Thiele diagrams for binary systems discussed earlier in this section; the triangles correspond to equilibrium stages. The operating lines are not straight because of heat effects and because the feed is not in the best location.

The fact that the staircase of triangles visible in Fig. 13-35 fails to come close to the corners of the diagram where $X = Y = 1$ and $X = Y = 0$ shows that the separation is not especially sharp. It is worth asking what can be done to improve the separation obtained with this column. The parameters that have a significant effect on the separation are the numbers of stages in the sections above and below the feed, the reflux ratio, and a product flow rate (or reflux flow). Figure 13-36 shows how the mole fraction of *i*-pentane in the overhead and of *n*-butane in the bottom product changes with the reflux ratio. For the base case considered above, the reflux ratio is 2.58 (calculated from the results of the simulation). It is clear that increasing the reflux ratio has the desired effect of improving product purity. This improvement in purity is, however, accompanied by an increase in both the operating cost, indicated in Fig. 13-36 by the increase in reboiler duty, and capital cost, because a larger column would be needed to accommodate the increased internal flow. Note, however, that the curves that represent the mole fractions of the keys in the overhead and bottoms appear to flatten, showing that product purity will not increase indefinitely

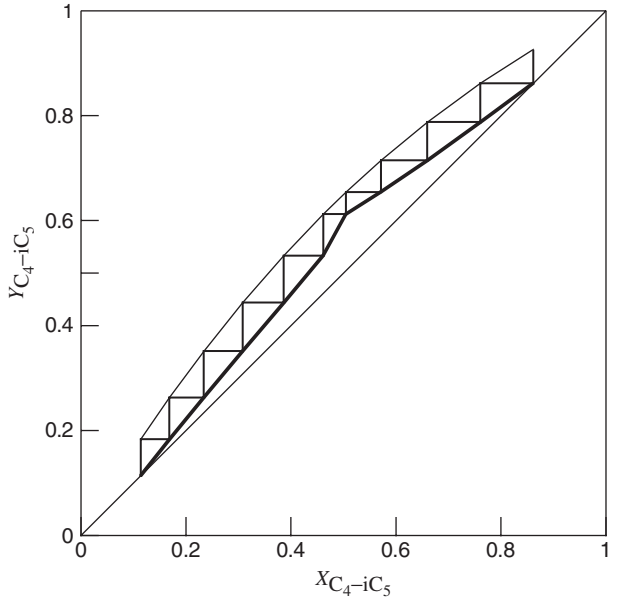

**FIG. 13-35** Multicomponent McCabe-Thiele diagram for butane-pentane splitter in Fig. 13-34.

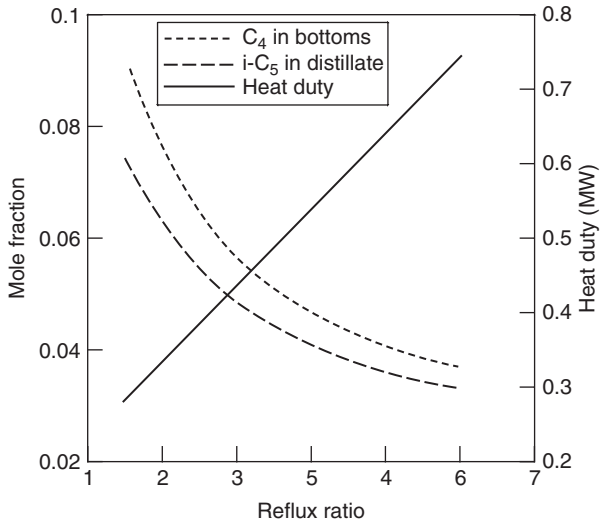

**FIG. 13-36** Product mole fractions and reboiler heat duty as a function of the reflux ratio for butane-pentane splitter in Fig. 13-34.

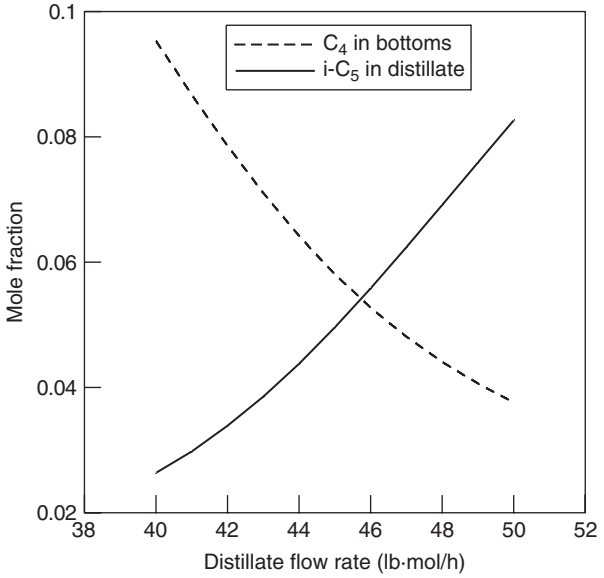

**FIG. 13-37** Product mole fraction duty as a function of the distillate rate for butane-pentane splitter in Fig. 13-34.

as the reflux ratio increases. Further improvement in product purity can best be made by changing a different specification.

Figure 13-37 shows the tradeoff in product purities when we change the specified distillate flow rate, maintaining all other specifications at the values specified in the base case. At lower distillate flow rates, the mole fraction of heavy key ($i$-$C_5$) in the distillate is small, and at higher distillate flow rates the mole fraction of light key ($n$-$C_4$) in the bottoms is small. Both cannot be small simultaneously. From this result we see that the "best" overall product purities are obtained when the distillate rate is in the vicinity of 45 lb · mol/h. On reflection, this should not come as a surprise; the flow rate of the light key ($n$-butane) and all components with a higher volatility is 45 lb · mol/h. However, even with the distillate flow rate set to 45 lb · mol/h there remains room for improvement in the separation.

The other key design specifications here are the total number of stages and the location of the feed stage. In most cases, increasing the number of stages will improve the separation. On increasing the number of stages to 26, with the feed to stage 12, increasing the overhead vapor flow to 195 lb · mol/h, and decreasing the distillate rate to 45 lb · mol/h, we obtain the following products:

| Mole flows, lb · mol/h | Feed | Top | Bottom |
|---|---|---|---|
| Propane | 5.00 | 5.00 | 0.00 |
| Isobutane | 15.00 | 15.00 | 0.00 |
| $n$-Butane | 25.00 | 24.81 | 0.19 |
| Isopentane | 20.00 | 0.16 | 19.84 |
| $n$-Pentane | 35.00 | 0.03 | 34.97 |
| Total | 100.00 | 45.00 | 55.00 |

The McCabe-Thiele diagram for this configuration, shown in Fig. 13-38, shows that the product purities have improved significantly.

The temperature and liquid phase composition profiles for this final case are shown in Fig. 13-39. The temperature increases from top to bottom in the column. This is normally the case in distillation columns (exceptions may occur with cold feeds or feeds with boiling points significantly lower than that of the mixture on stages above the feed stage). The composition profiles also are as expected. The components more volatile than the light key ($n$-butane) are concentrated above the feed; those compounds less volatile than the heavy key ($i$-pentane) are concentrated below the feed. The mole fractions of the two keys exhibit maxima, the light key above the feed stage and the heavy key below the feed stage. The decrease in the mole fraction of light key over the top few stages is necessary to accommodate the increase in the composition of the lighter compounds. Similar arguments pertain to the decrease in the mole fraction of the heavy key over the stages toward the bottom of the column.

Flow profiles are shown in Fig. 13-39*c*. Note the step change in the liquid flow rate around the feed stage. Had the feed been partially vaporized, we would have observed changes in both vapor and liquid flows around the feed stage, and a saturated vapor feed would significantly change only the vapor flow profile. The slight (in this case) curvature in the flow profiles is due to enthalpy changes.

***Example 13-4 Light Hydrocarbon Distillation*** Compute stage temperatures, interstage vapor and liquid flow rates and compositions, and reboiler and condenser duties for the light hydrocarbon distillation column shown in Fig. 13-40. How might the separation be improved?

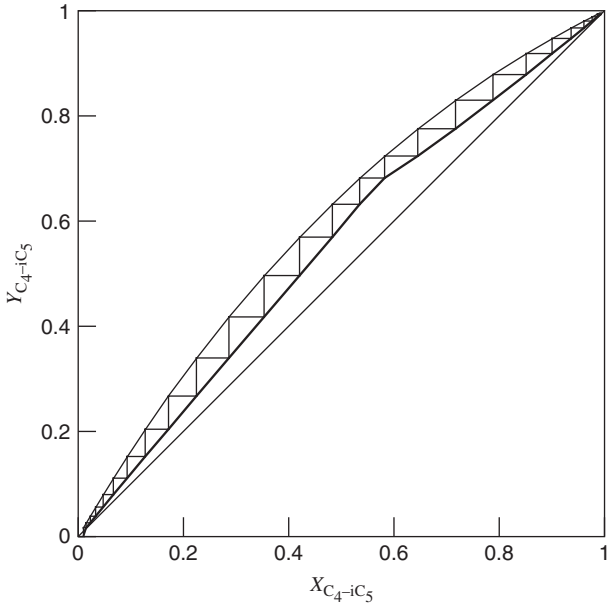

**FIG. 13-38** Multicomponent McCabe-Thiele diagram for butane-pentane splitter after optimization to improve product purities.

This more complicated example features a partial condenser (with vapor product) and a vapor sidestream withdrawn from the 13th stage. The SRK equation of state may be used for estimating the $K$ values and enthalpy departures for thermodynamic properties.

The specifications made in this case are summarized as follows:

| Variable | Number | Value |
|---|---|---|
| Number of stages | 1 | 17 |
| Feed stage location | 1 | 9 |
| Component flows in feed | $c = 5$ | 3, 20, 37, 35, 5 lb · mol/h |
| Feed pressure | 1 | 260 psia |
| Feed vapor fraction | 1 | 0 |
| Pressure on each stage including condenser and reboiler | $N = 17$ | $P_j = 250$ psia |
| Heat duty on each stage except reboilers and condensers | $N - 2 = 15$ | $Q_j = 0$ |
| Reflux rate (replaces heat duty of reboiler) | 1 | $L_1 = 150$ lb · mol/h |
| Distillate flow rate (replaces heat duty of condenser) | 1 | $D = 23$ lb · mol/h |
| Sidestream stage | 1 | 13 |
| Sidestream flow rate and phase | 2 | 37 lb · mol/h vapor |
| Total | 46 | |

As in Example 13-3, we have assumed that the pressure of the reflux divider is the same as the pressure of the condenser, the heat loss from the reflux divider is zero, and the reflux temperature is the boiling point of the condensed overhead vapor.

The specifications were selected to obtain three products: a vapor distillate rich in $C_2$ and $C_3$, a vapor sidestream rich in $n$-$C_4$, and a bottoms rich in $n$-$C_5$ and $n$-$C_6$, as summarized in the following table:

| Mole flows, lb · mol/h | Feed | Top | Bottom | Sidestream |
|---|---|---|---|---|
| Ethane | 3.00 | 3.00 | 0.0 | 0.0 |
| Propane | 20.00 | 18.3 | 0.0 | 1.6 |
| $n$-Butane | 37.00 | 1.7 | 9.6 | 25.7 |
| $n$-Pentane | 35.00 | 0.0 | 25.8 | 9.2 |
| $n$-Hexane | 5.00 | 0.0 | 4.5 | 0.5 |
| Total molar flow | 100.00 | 23.0 | 40.0 | 37.0 |

Convergence of the simultaneous convergence method was obtained in five iterations.

Further improvement in the purity of the sidestream as well as of the other two products could be obtained by increasing the reflux flow rate (or reflux ratio) and the number of stages in each section of the column. If, for example, we increase the number

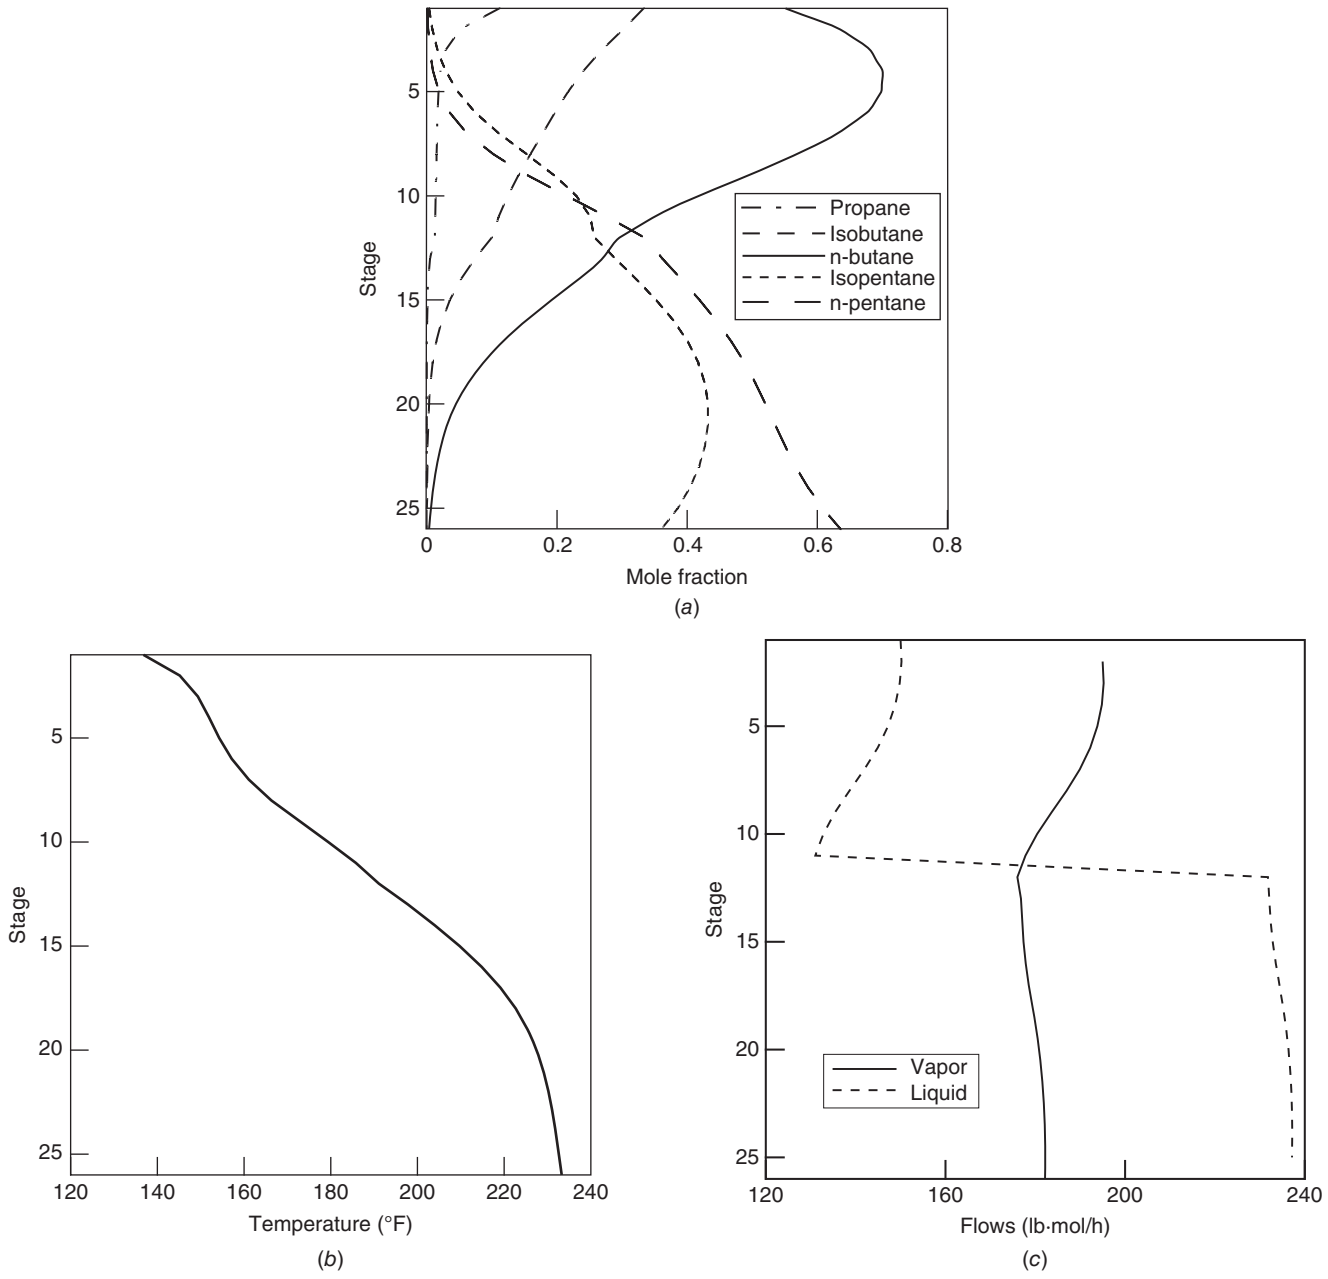

**FIG. 13-39** (*a*) Composition, (*b*) temperature, and (*c*) flow profiles in butane-pentane splitter.

of stages to 25 (including condenser and reboiler in this total), with the feed to stage 7 and the sidestream removed from stage 17, we obtain the following:

| Mole flows, lb · mol/h | Feed | Top | Bottom | Sidestream |
|---|---|---|---|---|
| Ethane | 3.00 | 3.00 | 0.00 | 0.00 |
| Propane | 20.00 | 19.46 | 0.00 | 0.54 |
| *n*-Butane | 37.00 | 0.54 | 7.46 | 29.00 |
| *n*-Pentane | 35.00 | 0.00 | 27.93 | 7.07 |
| *n*-Hexane | 5.00 | 0.00 | 4.61 | 0.39 |
| Total | 100.0 | 23.0 | 40.0 | 37.00 |

The McCabe-Thiele diagram for this design, showing that the feed is to the optimum stage, is shown in Fig. 13-41. The flow profiles are shown in Fig. 13-42; note the step changes due to both the feed and the sidestream. As was the case in Example 13-3, the curvature in the flow profiles is due to enthalpy changes.

***Example 13-5 Absorber*** Compute stage temperatures and interstage vapor and liquid flow rates and compositions for the absorber specifications shown in Fig. 13-43. Note that a second absorber oil feed is used in addition to the main absorber oil and that heat is withdrawn from the seventh theoretical stage. The oil may be taken to be *n*-dodecane.

The specifications made in this case are summarized as follows:

| Variable | Number | Value(s) |
|---|---|---|
| Number of stages | 1 | 8 |
| Location of feed 1 | 1 | 1 |
| Component flows in feed 1 | $c = 6$ | 0, 0, 0, 0, 0, 250 lb · mol/h |
| Pressure of feed 1 | 1 | 400 psia |
| Temperature of feed 1 | 1 | 80°F |
| Location of feed 2 | 1 | 4 |
| Component flows in feed 2 | $c = 6$ | 13, 3, 4, 5, 5, 135 lb · mol/h |
| Pressure of feed 2 | 1 | 400 psia |
| Temperature of feed 2 | 1 | 80°F |
| Location of feed 3 | 1 | 8 |
| Component flows in feed 3 | $c = 6$ | 360, 40, 25, 15, 15, 10 lb · mol/h |
| Pressure of feed 3 | 1 | 400 psia |
| Temperature of feed 3 | 1 | 80°F |
| Pressure on each stage | $N = 8$ | $P_j = 400$ psia; $j = 1, 2, \ldots, 8$ |
| Heat duty on each stage | $N = 8$ | $Q_j = 0, j = 1, 2, \ldots, 6, 8$; $Q_7 = 150{,}000$ Btu/h |
| Total | 44 | |

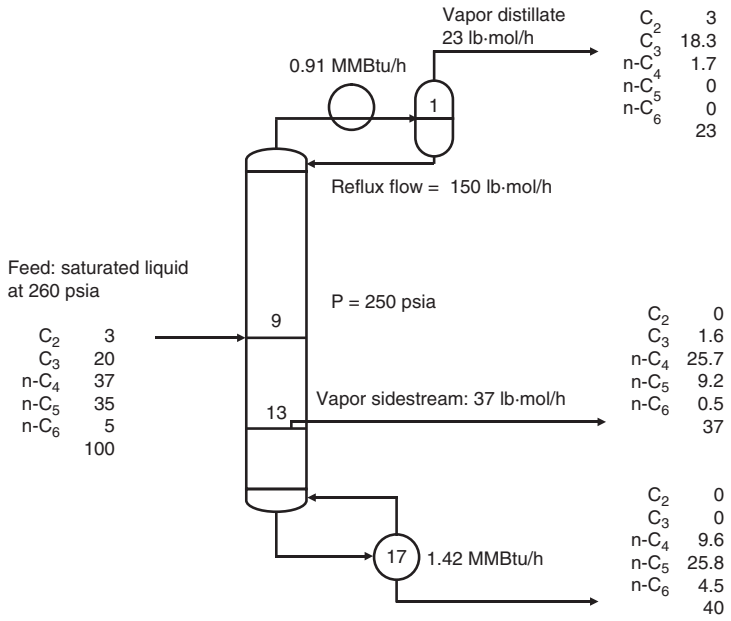

**FIG. 13-40** Specifications and calculated product stream flows and heat duties for light hydrocarbon still. Flows are in pound-moles per hour.

The simultaneous solution method solved this example in four iterations. The Peng-Robinson equation of state was used to estimate $K$ values and enthalpy departures and by Seader (*Perry's Chemical Engineers' Handbook,* 7th ed. p. 13-47), who solved this problem by using the SR method.

The computed product flows are summarized as follows:

| Mole flows, lb · mol/h | Lean oil | Secondary oil | Rich gas | Lean gas | Rich oil |
|---|---|---|---|---|---|
| Methane | 0.0 | 13.0 | 360.0 | 303.7 | 69.3 |
| Ethane | 0.0 | 3.0 | 40.0 | 10.7 | 32.3 |
| Propane | 0.0 | 4.0 | 25.0 | 0.2 | 28.8 |
| *n*-Butane | 0.0 | 4.0 | 15.0 | 0.0 | 19.0 |
| *n*-Pentane | 0.0 | 5.0 | 10.0 | 0.0 | 15.0 |
| *n*-Dodecane | 250.0 | 135.0 | 0.0 | 0.0 | 385.0 |
| Total molar flow | 250.0 | 164.0 | 450.0 | 314.6 | 549.4 |

The energy withdrawn from stage 7 has the effect of slightly increasing the absorption of the more volatile species in the rich oil leaving the bottom of the column. Temperature and flow profiles are shown in Fig. 13-44. The temperature profile shows the rise in temperature toward the bottom of the column that is typical of gas absorption processes. The bottom of the column is where the bulk of the absorption takes place, and the temperature rise is a measure of the heat of absorption. The liquid flow profile exhibits a step change due to the secondary oil feed at the midpoint of the column.

***Example 13-6 Reboiled Stripper*** Compute the stage temperatures and interstage vapor and liquid flow rates and compositions and reboiler heat duty for the reboiled stripper shown in Fig. 13-45. Thermodynamic properties may be estimated by using the Peng-Robinson equation of state.

The specifications made in this case are summarized in Fig. 13-45 and in the following table. The specified bottoms rate is equivalent to removing most of the $n$-$C_5$ and $n$-$C_6$ in the bottoms.

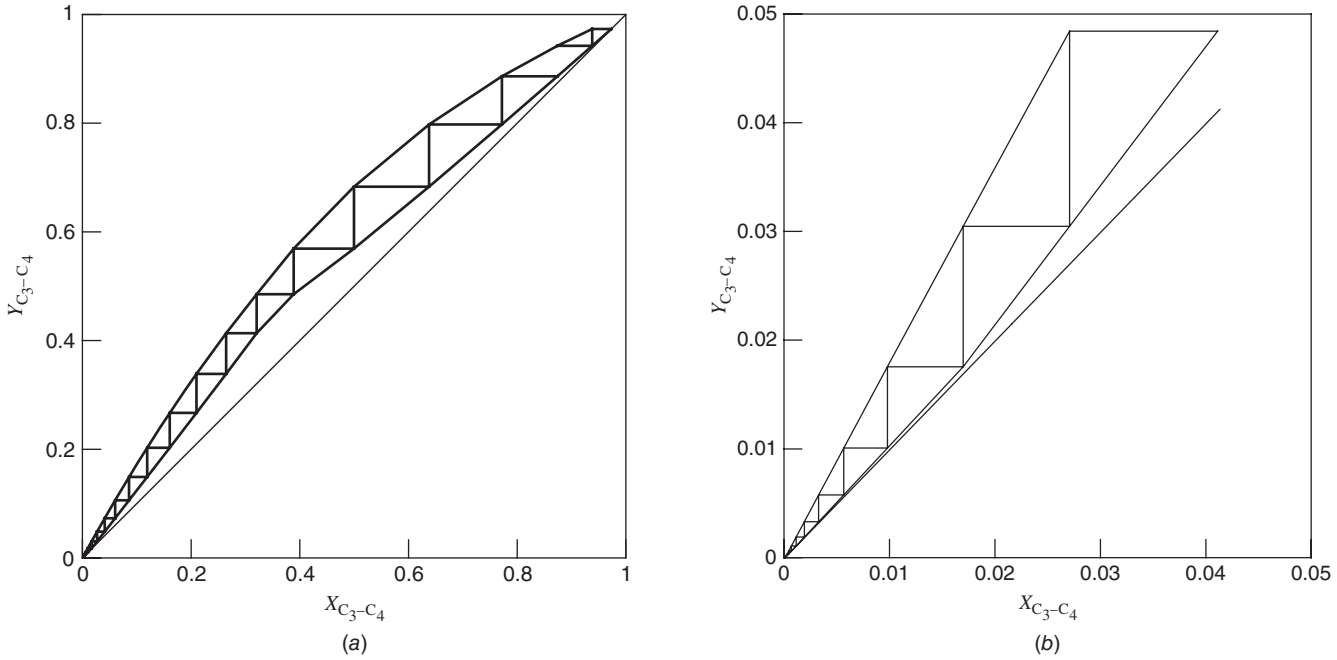

**FIG. 13-41** Multicomponent McCabe-Thiele diagram for the hydrocarbon distillation in Fig. 13-40.

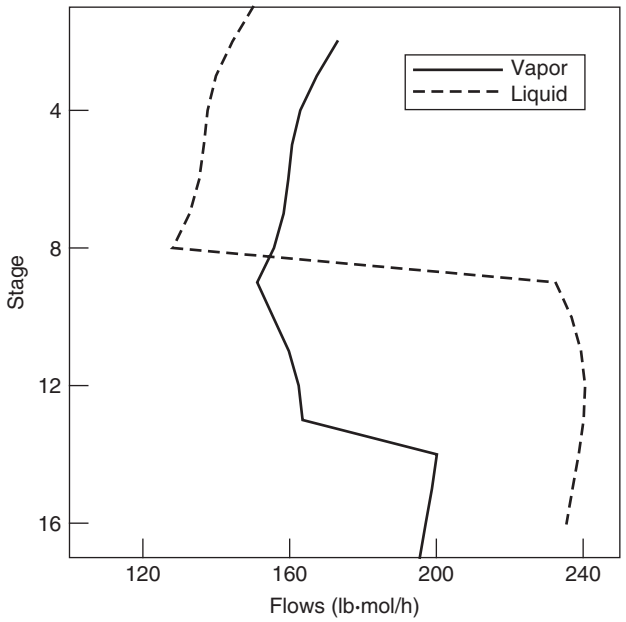

**FIG. 13-42** Flow profiles in hydrocarbon distillation in Fig. 13-40.

| Variable | Number | Value(s) |
|---|---|---|
| Number of stages | 1 | 8 |
| Component flows in feed | $c = 7$ | 0.22, 59.51, 73.57, 153.2, 173.2, 58.22, 33.63 lb · mol/h |
| Pressure of feed | 1 | 150 psia |
| Temperature of feed | 1 | 40.8°F |
| Pressure on each stage | $N = 8$ | $P_j = 150$ psia; $j = 1, \ldots, 8$ |
| Heat duty on each stage (except reboiler) | $N - 1 = 7$ | $Q_j = 0, j = 1, \ldots, 7$ |
| Bottom product flow rate | 1 | 99.33 lb · mol/h |
| Total | 26 | |

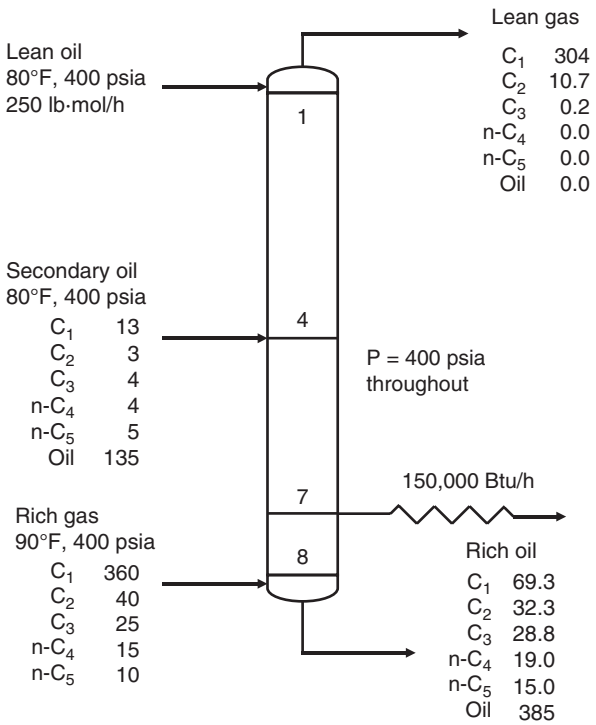

**FIG. 13-43** Specifications and calculated product stream flows and heat duties for absorber. Flows are in pound-moles per hour.

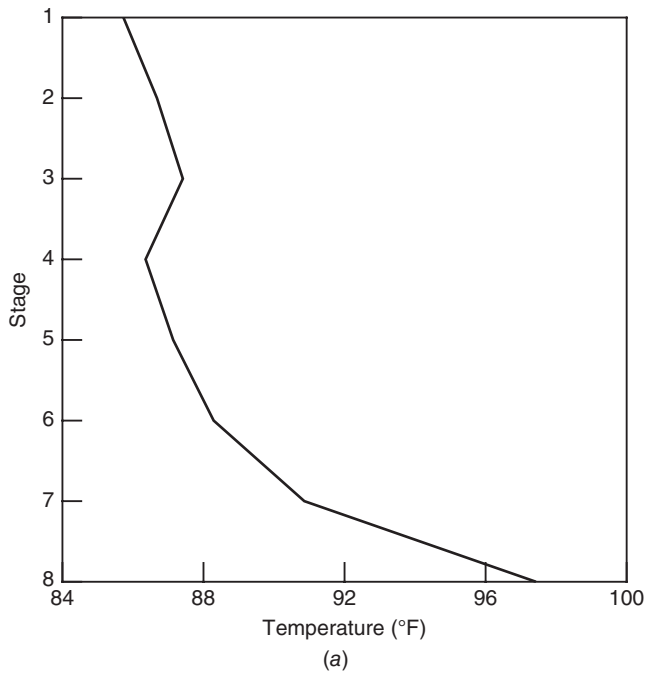

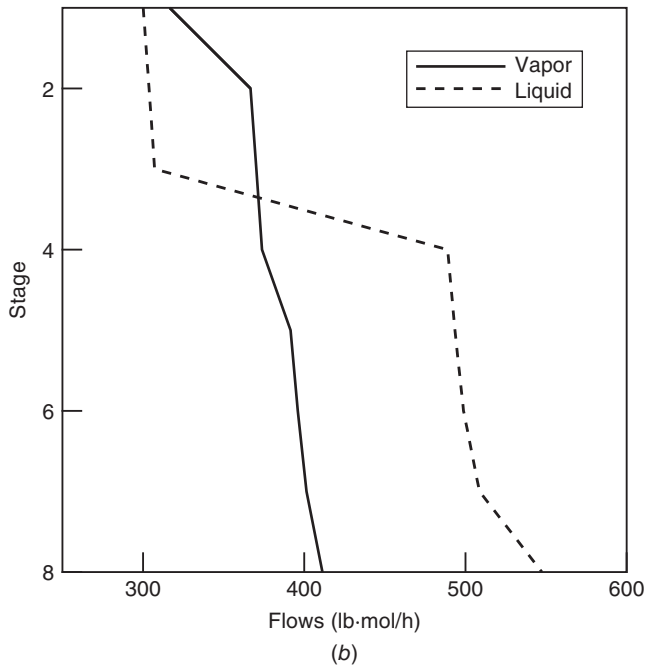

**FIG. 13-44** (*a*) Temperature and (*b*) flow profiles in absorber in Fig. 13-43.

The computed product flows and reboiler duty are shown alongside the specifications in Fig. 13-45 and in the following table:

| Mole flows, lb · mol/h | Feed | Overhead | Bottoms |
|---|---|---|---|
| Nitrogen | 0.22 | 0.22 | 0.0 |
| Methane | 59.51 | 59.51 | 0.0 |
| Ethane | 73.57 | 73.57 | 0.0 |
| Propane | 153.22 | 153.17 | 0.05 |
| *n*-Butane | 173.22 | 148.10 | 25.12 |
| *n*-Pentane | 58.22 | 15.08 | 43.14 |
| *n*-Hexane | 33.63 | 2.61 | 31.02 |
| Total | 551.59 | 452.26 | 99.33 |

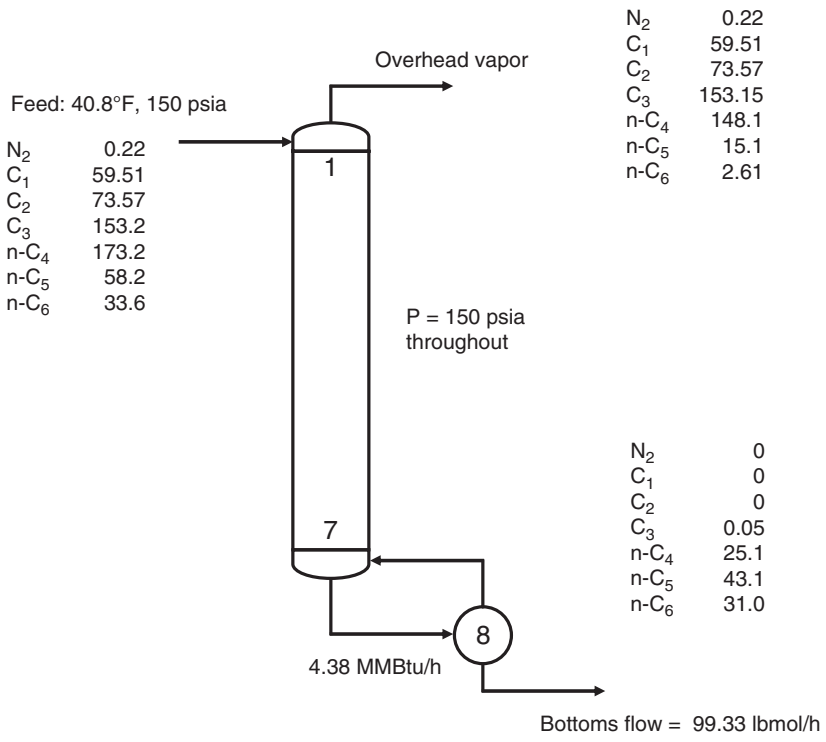

**FIG. 13-45** Specifications and calculated product stream flows and reboiler heat duty for a reboiled stripper. Flows are in pound-moles per hour.

Computed temperature, flow rates, and vapor-phase mole fraction profiles, shown in Fig. 13-46, are not of the shapes that might have been expected. Vapor and liquid flow rates for *n*-$C_4$ change dramatically from stage to stage.

***Example 13-7 An Industrial i-Butane/n-Butane Fractionator*** Klemola and Ilme [*Ind. Eng. Chem.* **35:** 4579 (1996)] and Ilme (Ph.D. thesis, University of Lapeenranta, Finland, 1997) report data from an industrial *i*-butane/*n*-butane fractionator that is used here as the basis for this example.

The column has 74 valve trays, the design details of which can be found in Example 13-11. The feed was introduced onto tray 37.

To properly model an existing column, it is necessary to know all feed and product conditions (flow rate, temperature, pressure, and composition). Flows, temperatures, and pressures often are available from standard instrumentation. It may be necessary to obtain additional samples of these streams to determine their composition. Such sampling should be scheduled as part of a plant trial to ensure that measured data are consistent. Ideally, multiple sets of plant measurements should be obtained at different operating conditions, and care should be taken to ensure that operating data are obtained at steady state since a steady-state model can only be used to describe a column at steady state. Measurements should be taken over a time interval longer than the residence time in the column and time-averaged to avoid a possible mismatch between feed and product data. Condenser and reboiler heat duties should be known (or available from the appropriate energy balance) whenever possible.

The measured compositions and flow rates of the feed and products for the $C_4$ splitter are summarized in the following table:

Measured Feed and Product Flows and Compositions (Mass %) for *i*-Butane/*n*-Butane Fractionator (Ilme 1997)

| Species | Feed | Top | Bottom |
|---|---|---|---|
| Propane | 1.50 | 5.30 | 0.00 |
| Isobutane | 29.4 | 93.5 | 0.30 |
| *n*-Butane | 67.7 | 0.20 | 98.1 |
| $C_4$ olefins | 0.50 | 1.00 | 0.20 |
| Neopentane | 0.10 | 0.00 | 0.20 |
| Isopentane | 0.80 | 0.00 | 1.10 |
| *n*-Pentane | 0.10 | 0.00 | 0.10 |
| Total flow, kg/h | 26,234 | 8011 | 17,887 |

Other measured parameters are as follows:

Other Details of the *i*-Butane/*n*-Butane Fractionator

| | |
|---|---|
| Reflux flow rate, kg/h | 92,838 |
| Reflux temperature, °C | 18.5 |
| Column top pressure, kPa | 658.6 |
| Pressure drop per tray, kPa | 0.47 |
| Feed pressure, kPa | 892.67 |
| Boiler duty, MW | 10.24 |

Rarely, and this is a case in point, are plant data in exact material balance, and it will be necessary to reconcile errors in such measurements before continuing. The feed and product compositions, as adjusted by Ilme so that they satisfy material balance constraints, are provided next. Note how the $C_4$ olefins are assigned to isobutene and 1-butene.

Adjusted Feed and Product Compositions (Mass %) and Flows for *i*-Butane/*n*-Butane Fractionator (Ilme 1997)

| Species | Feed | Top | Bottom |
|---|---|---|---|
| Propane | 1.54 | 4.94 | 0.00 |
| Isobutane | 29.5 | 94.2 | 0.3 |
| *n*-Butane | 67.7 | 0.20 | 98.1 |
| Isobutene | 0.13 | 0.23 | 0.08 |
| 1-Butene | 0.20 | 0.41 | 0.10 |
| Neopentane | 0.11 | 0.00 | 0.17 |
| Isopentane | 0.77 | 0.00 | 1.12 |
| *n*-Pentane | 0.08 | 0.00 | 0.11 |
| Total flow, kg/h | 26,122 | 8123 | 17,999 |

To proceed with building a model of this column, we specify the number of stages equal to the number of trays plus condenser and reboiler ($N = 76$). The common arrangement of locating the actual feed between stages may require modeling as two separate feeds, the liquid portion to the stage below and the vapor portion to the stage above. In this illustration, the feed is (assumed to be) saturated liquid, and we provide just a single feed to stage 38.

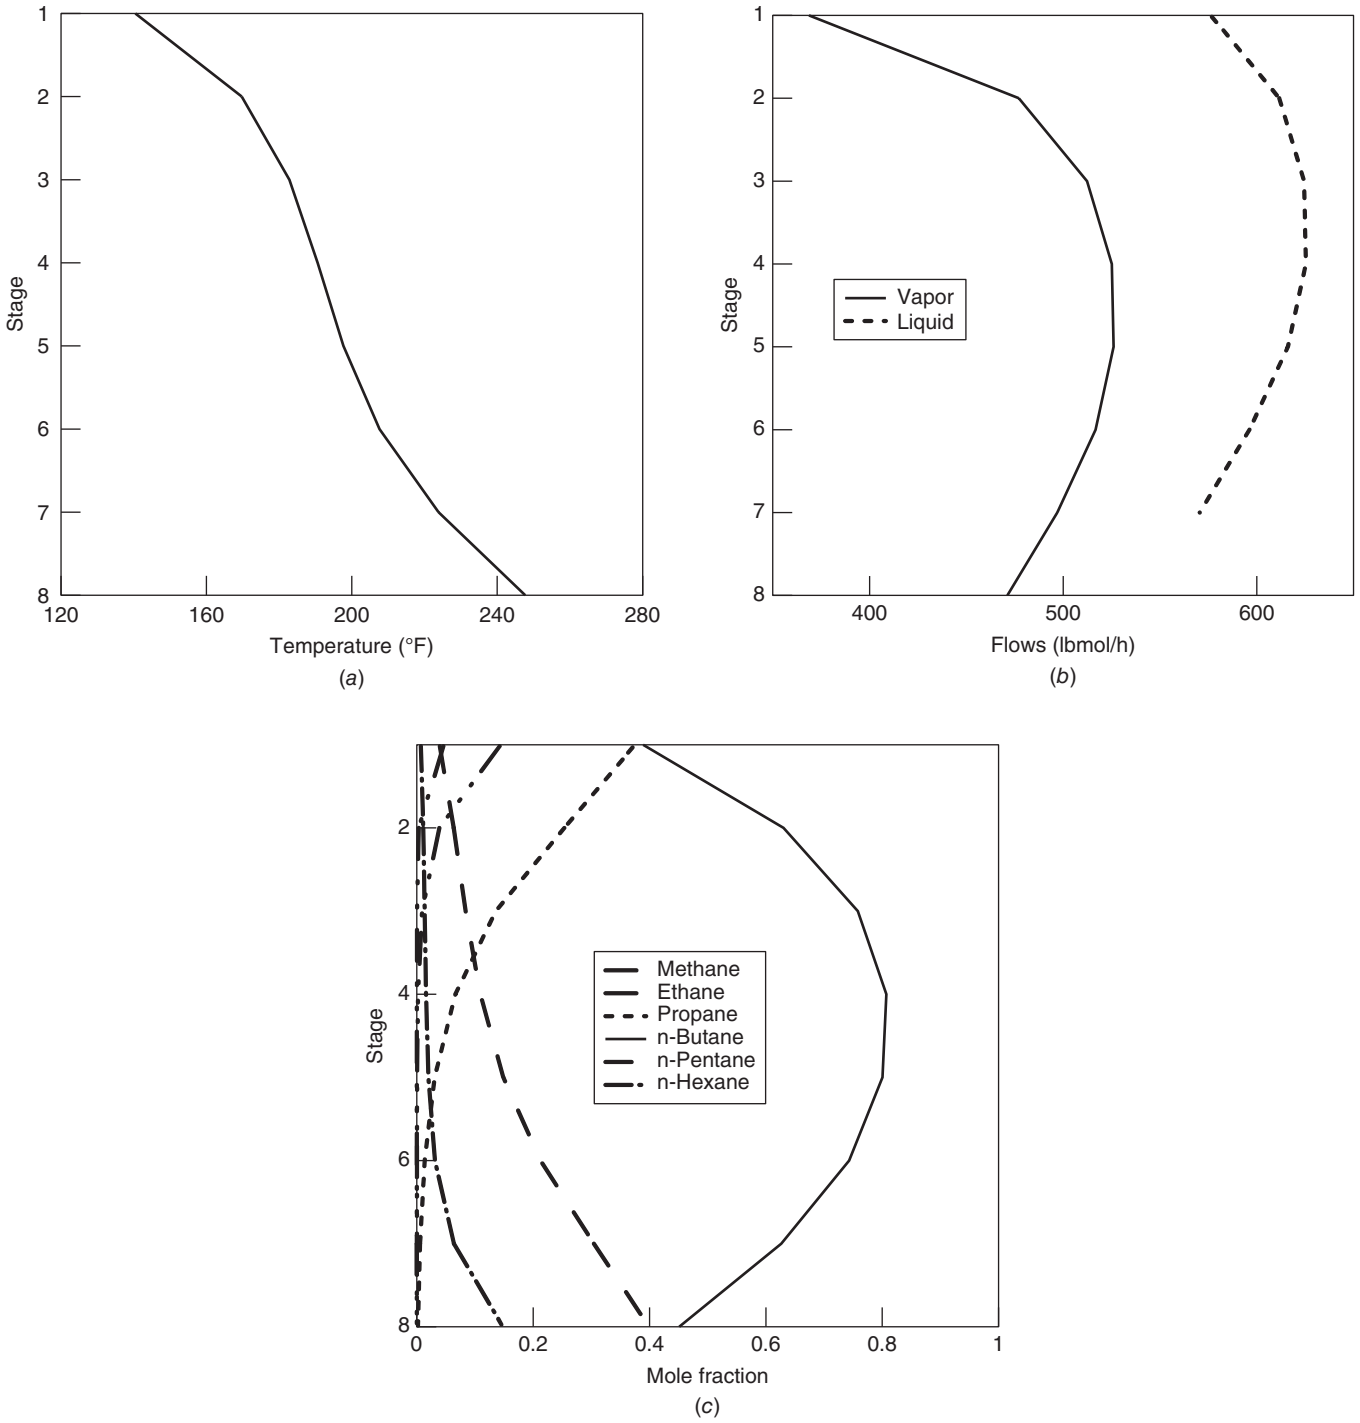

**FIG. 13-46** (*a*) Temperature, (*b*) flow, and (*c*) vapor mole fraction profiles in reboiled stripper in Fig. 13-45.

Upon computing the bubble point of the overhead product, we find that the measured reflux temperature is well below the estimated boiling point. Thus, we choose the subcooled condenser model. The steady-state concept of the "subcooled" condenser often does not exist in practice. Instead, the condenser is in vapor-liquid equilibrium, with the vapor augmented by a blanket of noncondensable gas (which has the effect of lowering the dew point of the overhead vapor). The subcooled condenser is a convenient work-around for steady-state models (as is needed here), but not for dynamic models. We assume a partial reboiler.

The pressure of the top stage is specified (at 658.6 kPa). The pressures of all trays below the top tray can then be fixed from the knowledge of the per-tray pressure drop (0.47 kPa). The pressure of the condenser is not known here. Thus, in the absence of further information, we make the condenser pressure equal to the top tray pressure (knowing that in practice it will be lower).

It is advisable to use the plant set points in building a model. For example, it is possible that a column simulation might involve the specification of the reflux ratio and bottoms flow rate because such specifications are (relatively) easy to converge. It is quite likely that the column may be controlled by using the temperature at some specific location (e.g., the temperature of tray 48). This specification should be used in building the model. In this case, we do not know the set points used for controlling the column, but we do have enough information to allow us to compute the reflux ratio from plant flow data ($R = 11.6$). Finally, the bottom product flow is specified as equal to the adjusted value reported above (17,999 kg/h).

The specifications made to model this column are summarized as follows:

| Variable | Number | Value |
|---|---|---|
| Number of stages | 1 | $N = 76$ |
| Feed stage location | 1 | 39 |
| Component flows in feed | $c = 8$ | See previous table |
| Feed pressure | 1 | 120 psia |
| Feed vapor fraction | 1 | 0 |
| Pressure at the top of the column | 1 | 658.6 kPa |
| Pressure drop per stage | $N - 1 = 75$ | 0.47 kPa |
| Heat duty on each stage except reboilers and condensers | $N - 2 = 74$ | $Q_j = 0$ |
| Reflux ratio (replaces heat duty of condenser) | 1 | $R = 11.588$ |
| Bottoms flow rate (replaces heat duty of reboiler) | 1 | $B = 17{,}999$ kg/h |
| Temperature of reflux | 1 | 291.65 K |
| Total | 165 | |

Finally, we must select appropriate methods of estimating thermodynamic properties. Ilme (1997) used the SRK equation of state to model this column, whereas Klemola and Ilme [*Ind. Eng. Chem.* **35:** 4579 (1996)] had earlier used the UNIFAC model for liquid-phase activity coefficients, the Antoine equation for vapor pressures, and the SRK equation for vapor-phase fugacities only. For this exercise we used the Peng-Robinson equation of state. Computed product compositions and flow rates are shown in the following table:

Specified Feed and Computed Product Compositions (Mass %) and Flows for *i*-Butane/*n*-Butane Fractionator (Ilme 1997)

| Compound | Feed | Top | Bottom |
|---|---|---|---|
| Propane | 1.54 | 4.95 | 0.00 |
| Isobutane | 29.49 | 93.67 | 0.53 |
| *n*-Butane | 67.68 | 0.73 | 97.89 |

The agreement with the adjusted material balance (tabulated previously) appears to be quite good, and to a first approximation it seems that we have a good model of the column.

Note that although this column is distilling a mixture containing at least eight identifiable compounds, only two are present in significant amounts, and therefore this is essentially a binary separation. It is usually relatively straightforward to match product compositions in processes involving only two different species simply by adjusting the number of equilibrium stages. We return to this point later.

**Efficiencies** In actual operation, the trays of a distillation column rarely, if ever, operate at equilibrium despite attempts to approach this condition by proper design and choice of operating conditions. The usual way of dealing with departures from equilibrium in multistage towers is through the use of stage and/or overall efficiencies.

The overall column efficiency is defined by

$$E_o = \frac{N_{\text{EQ}}}{N_{\text{actual}}} \tag{13-55}$$

where $N_{\text{EQ}}$ is the number of equilibrium stages.

There are many different definitions of stage (or tray) efficiency, with that of Murphree [*Ind. Eng. Chem.* **17:** 747–750, 960–964 (1925)] being by far the most widely used in separation process calculations:

$$E_{i,J}^{MV} = \frac{y_{i,j} - y_{i,j+1}}{y_{i,j}^{*} - y_{i,j+1}} \tag{13-56}$$

Here $E_{i,J}^{MV}$ is the Murphree vapor efficiency for component *i* on stage *j,* and $y_{i,j}^{*}$ is the composition of the vapor in equilibrium with the liquid. Other types of efficiency include that of Hausen [*Chemie Ingr. Tech.* **25:** 595 (1953)], vaporization (see Holland, 1975), and generalized Hausen [Standart, *Chem. Eng. Sci.* **20:** 611 (1965)]. There is by no means a consensus on which is best. Arguments for and against various types are presented by, among others, Standart [*Chem. Eng. Sci.* **20:** 611 (1965); **26:** 985 (1971)], Holland and McMahon [*Chem. Eng. Sci.* **25:** 431 (1972)], and Medina et al. [*Chem. Eng. Sci.* **33:** 331 (1978); **34:** 1105 (1979)]. Possibly the most soundly based definition, the generalized Hausen efficiency of Standart (1965), is never used in industrial practice. Seader [*Chem. Eng. Progress* **85**(10): 41 (1989)] summarizes the shortcomings of efficiencies.

The Murphree (and Hausen) efficiencies of both components in a binary mixture are equal; although they cannot be less than 0, they may be greater than 1. A table of typical values of Murphree tray efficiency can be found in Sec. 14. Also described in Sec. 14 are methods for estimating Murphree efficiencies when they are not known.

For multicomponent systems (those with more than two components), there are $c - 1$ independent component efficiencies, and there are sound theoretical reasons as well as experimental evidence for not assuming the individual component efficiencies to be alike; indeed, they may take values between plus and minus infinity. Component efficiencies are more likely to differ for strongly nonideal mixtures. While models exist for estimating efficiencies in multicomponent systems [see chapter 13 in Taylor and Krishna (*Multicomponent Mass Transfer,* Wiley, New York, 1993) for a review of the literature], they are not widely used and have not (yet) been included in any of the more widely used commercial simulation programs.

The fact that component efficiencies in multicomponent systems are unbounded means that the arithmetic average of the component Murphree efficiencies is useless as a measure of the performance of a multicomponent distillation process. Taylor, Baur, and Krishna [*AIChE J.* **50:** 3134 (2004)] proposed the following efficiency for multicomponent systems:

$$\varepsilon_j = \frac{\sqrt{\sum_{i=1}^{c} (\Delta y_{i,j})^2}}{\sqrt{\sum_{i=1}^{c} (\Delta y_{i,j}^{*})^2}} \tag{13-57}$$

This efficiency has a simple and appealing physical significance; it is the ratio of the length of the actual composition profile (in mole fraction space) to the length of the composition profile given by the equilibrium-stage model. The Taylor-Baur-Krishna (TBK) efficiency has just one value per stage regardless of the number of components in the mixture; it can never be negative. For binary systems in tray columns, the TBK average efficiency simplifies to the Murphree efficiency [Taylor, Baur, and Krishna (2004)].

Murphree efficiencies are easily incorporated within simultaneous convergence algorithms (something that is not always easy, or even possible, with some tearing methods). As an aside, note that vaporization efficiencies are very easily incorporated in all computer algorithms, a fact that has helped to prolong the use of these quantities in industrial practice despite the lack of any convenient way to relate them to the fundamental processes of heat and mass transfer. Unfortunately, it is not at all easy to include the more fundamentally sound TBK efficiencies in a computer method for equilibrium-stage simulations.

Efficiencies are often used to fit actual operating data, along with the number of equilibrium stages in each section of the column (between feed and product takeoff points). The maximum number of these efficiencies is the number of independent efficiencies per stage ($c - 1$) times the number of stages—potentially a very large number, indeed. This many adjustable parameters may lead to a model that fits the data very well, but has no predictive ability (i.e., cannot describe how the column will behave when something changes). At the other extreme, the overall efficiency defined by Eq. (13-55) is just a single parameter that can improve the robustness of the model and speed of convergence, but it may be difficult to match actual temperature or composition profiles because there is unlikely to be a one-to-one correspondence between the model stages and actual trays. A compromise often used in practice is to use just one value for all components and all stages in a single section of a column. Efficiencies should not be used to model condensers and reboilers; it is usually safe to assume that they are equilibrium devices. It is also unwise to employ Murphree efficiencies for trays with a vapor product since any Murphree efficiency less than 1 will necessarily lead to the prediction of a subcooled vapor.

***Example 13-8 The Industrial i-Butane/n-Butane Fractionator (Again)*** With the material on efficiencies in mind, we return to the model of the $C_4$ splitter that we developed in Example 13-7.

It is possible to estimate the overall efficiency for a column such as this one simply by adjusting the number of equilibrium stages in each section of the column that is needed to match the mass fractions of *i*-butane in the distillate and *n*-butane in the bottoms. Using the SRK equation of state for estimating thermodynamic properties, Ilme (1997) found that 82 equilibrium stages (plus condenser and reboiler) and the feed to stage 38 were required. This corresponds to an overall column efficiency of 82/74 = 111 percent. Klemola and Ilme (1996) used the UNIFAC model for liquid-phase activity coefficients, the Antoine equation for vapor pressures, and the SRK equation for vapor-phase fugacities only and found that 88 ideal stages were needed; this corresponded to an overall efficiency of

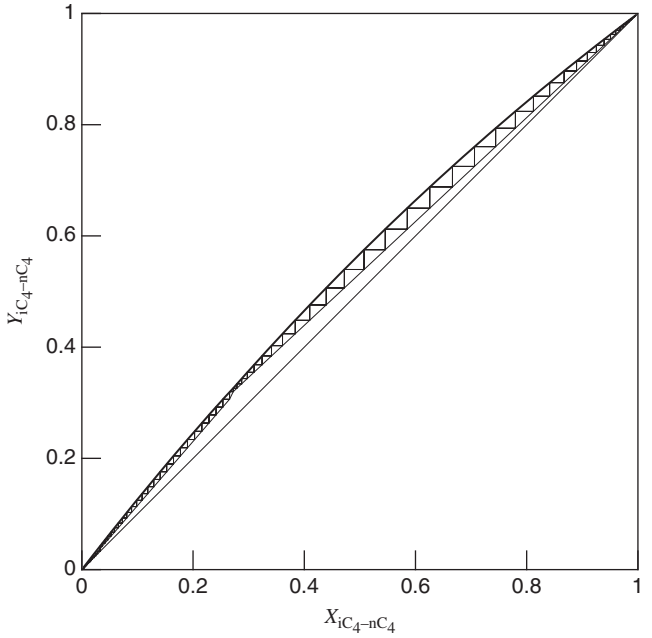

**FIG. 13-47** McCabe-Thiele diagram for $C_4$ splitter.

119 percent. With the Peng-Robinson equation of state for the estimation of thermodynamic properties, we find that 84 stages are needed (while maintaining the feed to the center stage as is the case here); the overall column efficiency for this model is 114 percent. The differences between these efficiencies are not large in this case, but the important point here is that efficiencies—all types—depend on the choice of model used to estimate the thermodynamic properties. Caution must therefore be exercised when one is using efficiencies determined in this way to predict column performance.

As an alternative to varying the number of stages, we may prefer to maintain a one-to-one correspondence between the number of stages and the number of actual trays, 74 in this case (plus condenser and reboiler), with the feed to tray 38. Using the Peng-Robinson equation of state and a Murphree stage efficiency of 116 percent, we find the product mass fractions that are in excellent agreement with the plant data. The McCabe-Thiele (Hengstebeck) diagram for this case, assembled from the results of the simulation, is shown in Fig. 13-47. Composition profiles computed from this model are shown in Fig. 13-48. Note that the mole fractions are shown on a logarithmic axis so that all the composition profiles can easily be seen.

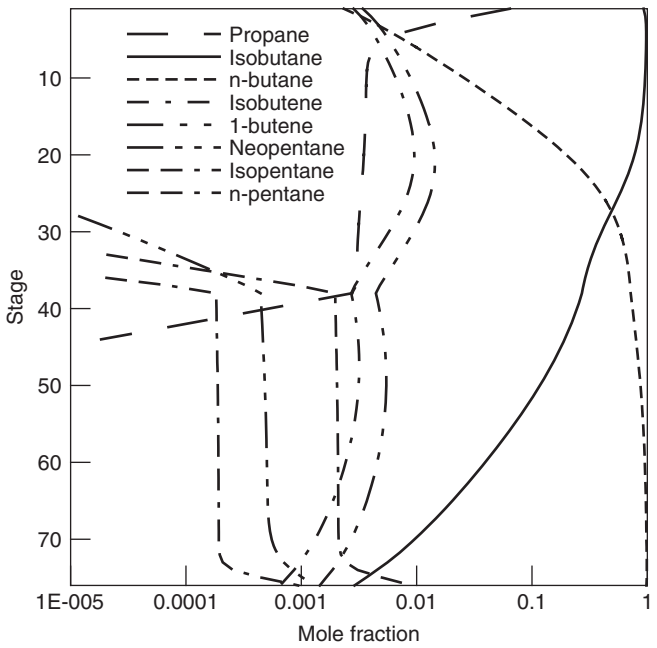

**FIG. 13-48** Liquid-phase mole fraction profiles for *i*-butane/*n*-butane fractionator.

It must be remembered that this is essentially a binary separation and that it is usually relatively straightforward to match product compositions in processes involving only two different species. In other cases involving a greater number of species with significant concentrations, it will likely be necessary to vary both the number of stages and the component efficiencies to match plant data. We do not recommend adjusting thermodynamic model parameters to fit plant data since this can have unfortunate consequences on the prediction of product distributions, process temperatures, and pressures.

The performance of a packed column often is expressed in terms of the height equivalent to a theoretical plate (HETP) for packed columns. The HETP is related to the height of packing $H$ by

$$\text{HETP} = \frac{H}{N_{EQ}} \tag{13-58}$$

In this case $N_{EQ}$ is the number of equilibrium stages (theoretical plates) needed to accomplish the separation that is possible in a real packed column of height $H$.

***Example 13-9 HETP of a Packed Absorber*** McDaniel, Bassyoni, and Holland [*Chem. Eng. Sci.* **25:** 633 (1970)] presented the results of field tests on a packed absorber in a gas plant. The packed section was 23 ft in height, and the column was 3 ft in diameter and filled with 2-in metallic Pall rings. The measured feeds are summarized in the following table.

| Stream | Lean oil | Rich gas |
|---|---|---|
| Pressure, psia | 807 | 807 |
| Temperature, °F | 2.9 | 0 |
| Mole flows, lb · mol/h | | |
| Carbon dioxide | 0.0 | 14.1 |
| Nitrogen | 0.0 | 5.5 |
| Methane | 0.0 | 2655.8 |
| Ethane | 0.0 | 199.9 |
| Propane | 0.0 | 83.2 |
| Isobutane | 0.0 | 19.1 |
| *n*-Butane | 0.0 | 10.9 |
| Isopentane | 0.2 | 3.5 |
| *n*-Pentane | 0.2 | 1.5 |
| *n*-Hexane | 4.5 | 0.4 |
| *n*-Heptane | 17.2 | 0.2 |
| *n*-Octane | 54.5 | 0.1 |
| *n*-Nonane | 50.5 | 0.0 |
| *n*-Decane | 61.7 | 0.0 |
| Total molar flow | 188.9 | 2994.2 |

Determine the number of equilibrium stages needed to match the lean gas product flow for this column (2721.1 lb · mol/h, 93.6 percent methane).

As a first step, we choose an appropriate thermodynamic model that will be used to estimate $K$ values and enthalpies. Either the Chao-Seader method or the Peng-Robinson equation of state could be considered for this system. It turns out not to be possible to match the plant data with the Chao-Seader method since even one equilibrium stage overpredicts the separation by a very significant amount. It is not even possible to match the exit flows by using the Chao-Seader model combined with a stage efficiency as low as 0.00001. With the Peng-Robinson equation of state, however, it is possible to obtain reasonable agreement with the measured overall product flows by using precisely one equilibrium stage! This suggests that the HETP for this column is 23 ft, a value much higher than any HETP ever published by a packing vendor. In this case the reason for the unrealistic estimate of the HETP has nothing to do with the packing; it is the extreme sensitivity of the simulation to the thermodynamic model, emphasizing the need for caution when one is using efficiencies and HETPs to model some absorption (and distillation) processes.

**Using a Simulator to Solve Distillation Problems** Computer-based methods for solving distillation (and related) column simulation problems now are reasonably reliable. Nevertheless, at times such methods fail to converge. The principal cause of convergence failures is generally a poor initial estimate of the variables being computed. In the discussion that follows, we identify some of the reasons that a simulation might be difficult to converge, along with suggestions on what might make the problem more amenable to solution. The key idea is to modify the problem that is difficult to solve as posed into one that is easy to solve—essentially to provide an improved initial estimate that is more likely to lead to convergence. Note that most simulators allow a calculation to be restarted from an older converged solution. The solution to the "easy" problem may then be used as a starting point for the more difficult problem. By doing this we are using a form of continuation (albeit executed manually, at least in part) to solve those problems with which the algorithm at hand may have trouble.

As a rule, the degree of difficulty increases with increasing nonideality. Simultaneous convergence methods are often recommended for simulating strongly nonideal systems (as opposed to tearing or inside-out methods),

but even SC methods can experience difficulties with strongly nonideal systems. A possible remedy is to make the system "less nonideal." It is likely that an activity coefficient model is part of the model used to describe the thermodynamics of these systems, and the source of the convergence difficulties often encountered with such systems. First solving an equivalent ideal system that entirely omits the activity coefficient model (i.e., using Raoult's law) may provide a converged solution that may be an adequate starting point for the nonideal system of interest. However, since many simulators use ideal solution thermodynamic models in any self-initialization method, this technique may not provide enough help.

A measure of the nonideality of the system is given by the magnitude of the interaction parameters for the activity coefficient model. It is possible, therefore, to lessen the degree of nonideality by reducing the interaction parameters enough to make the problem easy to solve. The parameters may then be increased in size in a series of steps until the desired values are reached, each time using the solution converged by using the previous set of parameter values as the starting point. It is essential that the parameters return to their correct values in the final step because intermediate solutions have no meaning, serving merely as an aid to convergence. Using the stage efficiency as a continuation parameter also is useful for such cases, provided that the simulation uses standard specifications (more on this topic below).

The most strongly nonideal systems are those that may exhibit two liquid phases. We have avoided a detailed discussion of such systems in this section because special algorithms are needed for these cases; see, however, the section on azeotropic distillation and, for example, chapter 8 of Doherty and Malone (*Conceptual Design of Distillation Systems*, McGraw-Hill, New York, 2001) for entry points to the literature.

Large heat effects can lead to convergence difficulties. For such systems it is the enthalpies that are the source of the nonlinearity that leads to convergence failures. It is generally not straightforward to modify enthalpies in a simulator because no adjustable parameters exert their influence over the enthalpy in a way comparable to that of the interaction parameters in the activity coefficient model. The use of a constant-enthalpy model in distillation calculations, if available, will lead to constant molar flows from stage to stage (within each separate section of the column), a condition often approached in many real distillation (but not absorption) columns. Thus, if the simulator includes a constant-enthalpy model, then this can be used to obtain a converged solution that may provide a good starting point for the problem with a more realistic enthalpy model.

High pressure adds to the difficulties of converging simulation models. It is likely that an equation of state will be used to estimate fugacity coefficients and enthalpy departures in such systems. Mixtures become increasingly nonideal as the pressure is raised. In some cases the column may operate close to the critical point at which the densities of both phases approach each other. In other cases the iterations may take the estimates of temperature and composition into regions where the equation of state can provide only one mathematically real root for density or compressibility. Occurrences of this behavior often are a source of convergence difficulties. For such systems we suggest reducing the pressure until the problem becomes easy to solve. A converged solution obtained in this way may be used as the starting point for subsequent calculations at increasingly higher pressures (up to that desired).

Very large numbers of stages can pose their own kind of convergence difficulty. A possible remedy is to reduce the number of stages until a converged solution can be obtained. This solution can then be used as the starting point for a problem with more stages. Interpolation will have to be used to estimate the values of the flows, temperatures, and mole fractions for any added stages, something not available in all programs.

Nonstandard specifications are very likely to be the source of convergence difficulties. It is all too easy to specify a desired product purity or component flow rate that simply cannot be attained with the specified column configuration. There is always (at least) one solution if the reflux ratio and bottoms flow rate are specified (the so-called standard specifications), which is likely to converge easily. Other specifications that can cause difficulties for similar reasons include specifying temperatures and compositions anywhere in the column and specifying condenser or reboiler heat duties. A way to circumvent this kind of difficulty is first to obtain a converged solution for a case involving standard specifications. Once the behavior of the column is understood, it will be possible to make sensible nonstandard specifications, again using an old converged result as a starting point.

Columns in which temperature and/or compositions change over a wide range in a limited number of stages pose their own difficulties. Some highly nonideal systems exhibit this kind of behavior (see Example 13-11). For cases such as this, it is wise to limit per-iteration changes to temperature and composition. Most modern computer methods will do this as a matter or course, and problems with this cause are not the source of convergence difficulties that they once were.

This is by no means an exhaustive list of the reasons that computer-based simulations fail. Indeed, in many cases it is a combination of more than one of the factors that leads to difficulty. In those cases it may be necessary to combine several of the strategies we have outlined to solve the simulation problem. Often, however, there is no substitute for trial and error. Haas (chap. 4 in Kister 1992) offers some additional insight on using simulators to solve distillation column models.

***Example 13-10 Multiple Steady States in Distillation*** This example is one of the most famous in the literature on distillation column modeling, having been studied, in one form or another, by many investigators, including Shewchuk [Ph.D. thesis in *Chem. Eng.* Appendix A1, University of Cambridge (1974)], Magnussen et al. [*I. Chem. E. Symp. Series* **56** (1979)], Prokopakis and Seider [*AIChE J.* **29:** 49 (1983)], Venkataraman and Lucia [*Comput. Chem. Eng.* **12:** 55 (1988)], and Rovaglio and Doherty [*AIChE J.* **36:** 39 (1990)]. The column simulated here is adapted from the work of Prokopakis and Seider and shown in Fig. 13-49. The ethanol-benzene-water ternary

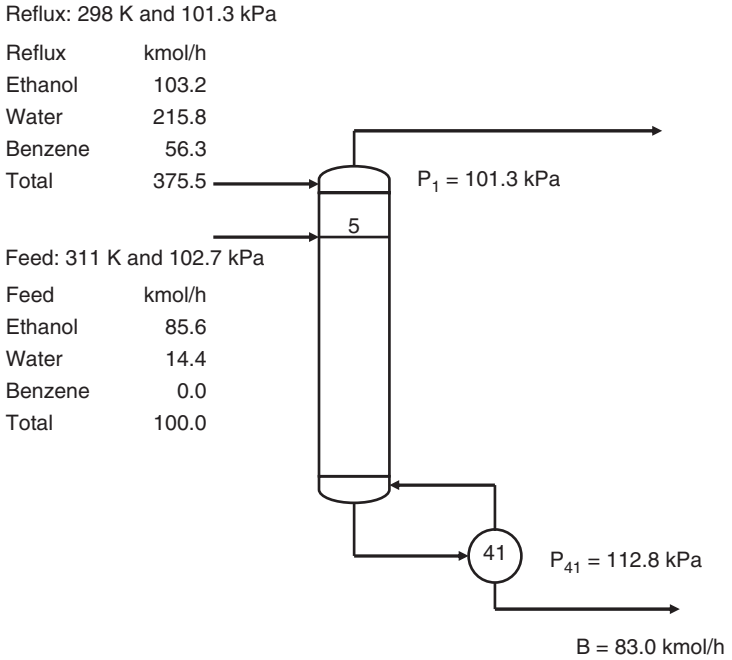

**FIG. 13-49** Azeotropic distillation tower for distillation of an ethanol-water mixture using benzene as a mass separating agent. [*After Prokopakis and Seider,* AIChE J. ***29:*** *49 (1983).*]

system actually splits into two liquid phases when the overhead vapor is condensed and cooled below its bubble point. One liquid phase is sent to a second column, and the other is returned to the main column as (cold) reflux. Here, in common with others, this column is modeled by ignoring the condenser and decanter. Reflux is simulated by a feed of appropriate composition, temperature, and pressure to the top of the column. The UNIQUAC method was used for estimating the activity coefficients, with parameters given by Prokopakis and Seider. The numerical results are very sensitive to the choice of activity coefficient model and associated parameters; qualitatively, however, the behavior illustrated here is typical of many systems.

This system is considered difficult because convergence of the MESH equations can be difficult to obtain with any algorithm. In fact, for the specifications considered here, there are no less than three solutions; the composition profiles are shown in Fig. 13-50. The goal of the distillation is to recover high-purity ethanol in the bottom stream from the column by using benzene as a mass separating agent. The low-purity profile in Fig. 13-50*a*, containing a large amount of water in the bottom product, is easily obtained from an ideal solution starting point (but with severe restrictions on the maximum allowed temperature change per iteration). The intermediate profile in Fig. 13-50*b* is rather more difficult to obtain. We were able to find it by using, as a starting point, a profile that had been converged at a stage efficiency of 0.7. The high-purity solution in Fig. 13-50*c*, containing very little water in the bottom product, is also easily obtained from an initial profile calculated by assuming that the stage efficiency is quite low (0.3). Multiple solutions for this column have been reported by many authors. In fact, with the parameters used here, the three solutions exist over a narrow range of ethanol feed flows. Taylor, Achuthan, and Lucia [*Comput. Chem. Eng.* **20:** 93 (1996)] found complex-valued solutions to the MESH equations for values outside this range.

Multiple steady-state solutions of the MESH equations have been found for many systems, and the literature on this topic is quite extensive. An introduction to the literature is provided by Bekiaris, Guttinger, and Morari [*AIChE J.* **46:** 955 (2000)]. Chavez, Seader, and Wayburn [*Ind. Eng. Chem. Fundam.* **25:** 566 (1986)] used homotopy methods to find multiple solutions for some systems of interlinked columns. Parametric continuation has been used to detect multiple solutions of the MESH

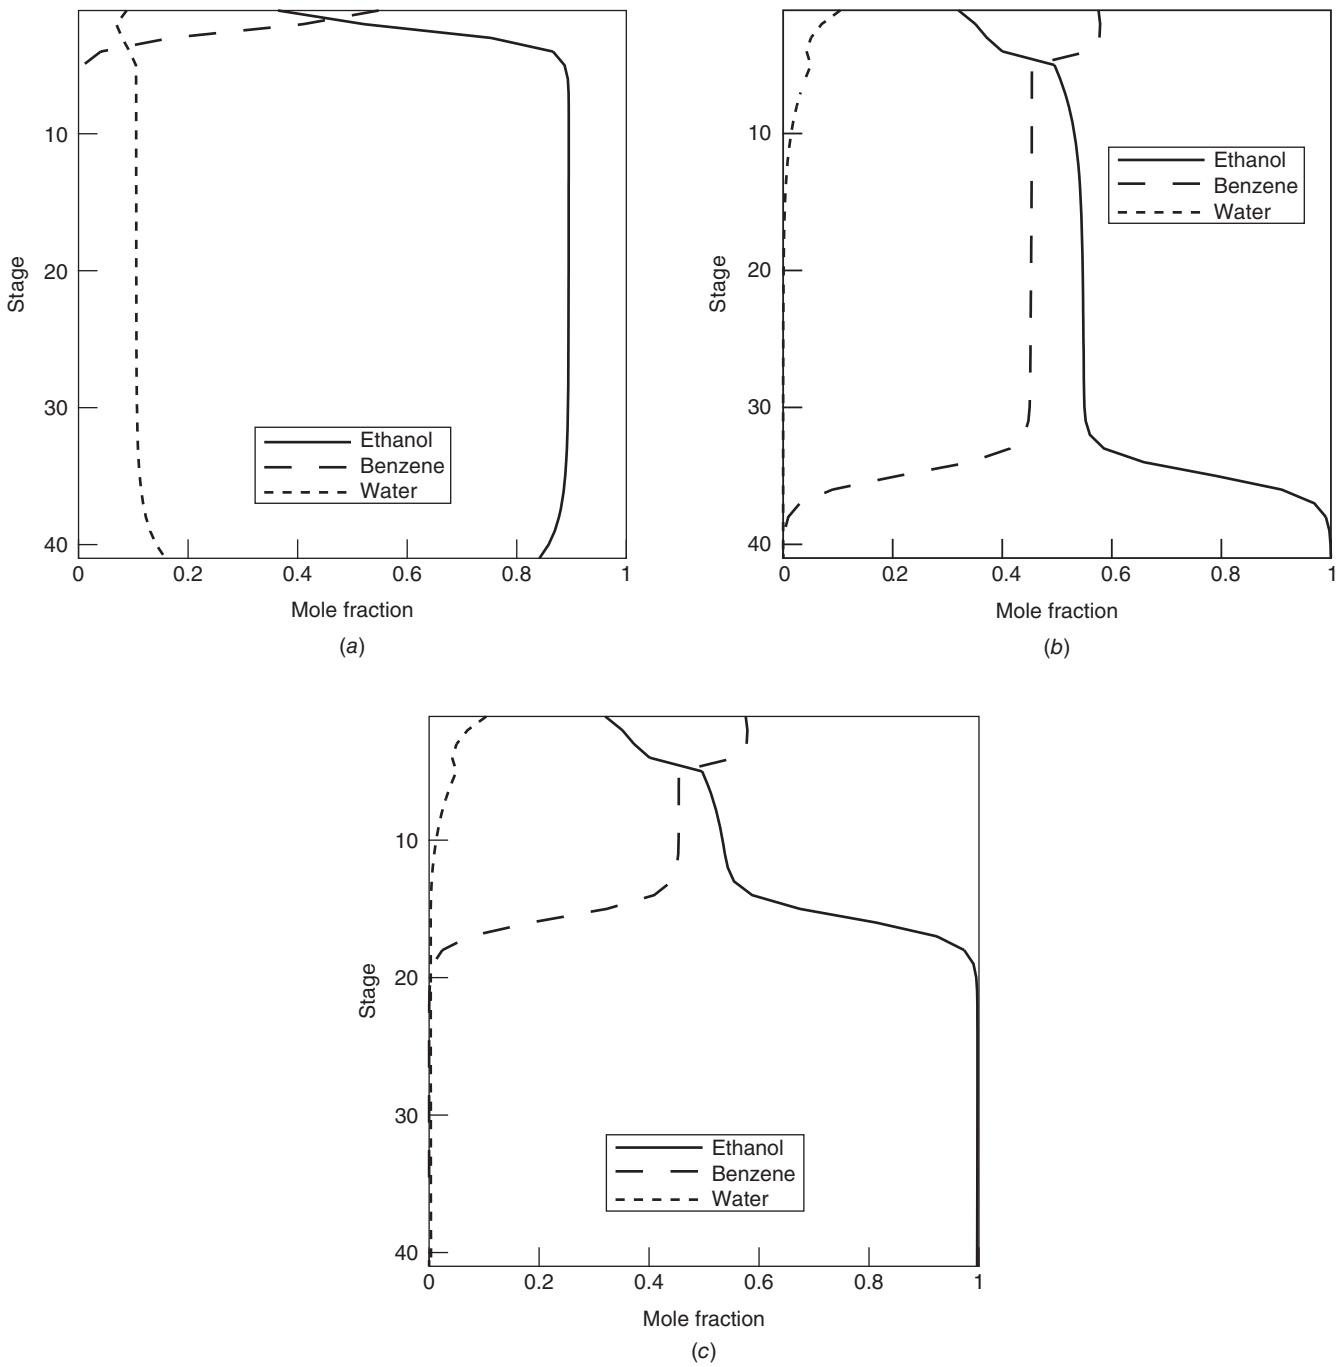

**FIG. 13-50** Liquid-phase mole fraction profiles for ethanol-benzene-water distillation. (*a*) Low-purity profile. (*b*) Intermediate-purity profile. (*c*) High-purity profile.

equations [Ellis et al., *Comput. Chem. Eng.* **10:** 433 (1986); Kovach and Seider, *Comput. Chem. Eng.* **11:** 593 (1987); Burton, Ph.D. thesis in Chem. Eng., Cambridge University, 1986]. That real distillation columns can possess multiple steady states has been confirmed by the experimental work of Kienle et al. [*Chem. Eng. Sci.* **50:** 2691 (1995)], Køggersbol et al. [*Comput. Chem. Eng.* **20:** S835 (1996)], Gaubert et al. [*Ind. Eng. Chem. Res.* **40:** 2914 (2001)], and others.

## NONEQUILIBRIUM MODELING

Although the widely used equilibrium-stage models for distillation, described previously, have proved to be adequate for binary and close-boiling, ideal and near-ideal multicomponent vapor/liquid mixtures, their deficiencies for general multicomponent mixtures have long been recognized. Even Murphree [*Ind. Eng. Chem.* **17:** 747–750, 960–964 (1925)], who formulated the widely used plate efficiencies that carry his name, pointed out clearly their deficiencies for multicomponent mixtures and when efficiencies are small. Walter and Sherwood [*Ind. Eng. Chem.* **33:** 493 (1941)] showed that experimentally measured efficiencies could cover an enormous range, with some values less than 10 percent. Toor [*AIChE J.* **3:** 198 (1957)] predicted that the Murphree vapor efficiencies in some multicomponent systems could cover the entire range of values from minus infinity to plus infinity, a result that was verified experimentally by others.

In recent years, a new approach to the modeling of distillation and absorption processes has become available: the *nonequilibrium* or *rate-based* models. These models treat these classical separation processes as the mass-transfer-rate–governed processes that they really are, and they avoid entirely the (a priori) use of concepts such as efficiency and HETP [Krishnamurthy and Taylor, *AIChE J.* **31:** 449–465 (1985); Taylor, Kooijman, and Hung, *Comput. Chem. Eng.* **18:** 205–217 (1994)].

A schematic diagram of a nonequilibrium (NEQ) stage is given in Fig. 13-51. This NEQ stage may represent (part of) the two phases on a tray or within a section of a packed column. The wavy line in the middle of the box represents the phase interface. This illustration is intended only to aid in understanding the basic principles of nonequilibrium modeling; the actual flow patterns and the shape of the phase boundary are very complicated and depend on, among other things, the equipment design, the column operation, and the physical properties of the system.

In a nonequilibrium model, separate balance equations are written for each distinct phase. The material balances for each species in the vapor and liquid phases on an arbitrary stage $j$ are

$$(1+r_j^V)V_j y_{i,j} - V_{j+1} y_{i,j+1} - f_{j+1}^V + \mathcal{N}_{i,j}^V = 0 \tag{13-59}$$

$$(1+r_j^L)L_j x_{i,j} - L_{j-1} x_{i,j+1} - f_{j+1}^L + \mathcal{N}_{i,j}^L = 0 \tag{13-60}$$

where $r_j^V$ and $r_j^L$ are the ratios of sidestream to interstage flows and are defined by Eqs. (13-49); $f_{i,j}^p$ is the external feed flow rate of species $i$ in phase $p$ to stage $j$; and $\mathcal{N}_{i,j}$ is the rate of mass transfer across the phase interface (with units of moles per second or equivalent). Formally, we may write

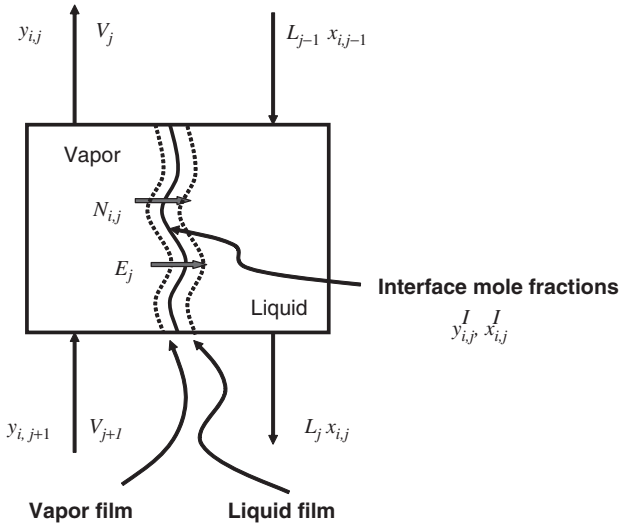

**FIG. 13-51** Schematic diagram of a nonequilibrium stage.

$$\mathcal{N}_{i,j}^p = \int N_{i,j}^p \, da_j \tag{13-61}$$

where $N_{i,j}^p$ is the molar flux in phase $p$ [with units of mol/(m$^2$ · s) or equivalent] at a particular point in the two-phase dispersion, and $da_j$ is the portion of interfacial area through which that flux passes. A material balance around the interface yields

$$\mathcal{N}_{i,j}^V = \mathcal{N}_{i,j}^L \tag{13-62}$$

The sum of the phase and interface balances yields the component material balance for the stage as a whole, the equation used in the equilibrium-stage model.

The energy balance is treated in a similar way, split into two parts—one for each phase, each part containing a term for the rate of energy transfer across the phase interface.

$$(1+r_j^V)V_j H_j^V - V_{j+1} H_{j+1}^V - F_j^V H_j^{VF} + \mathcal{E}_j^V + Q_j^V = 0 \tag{13-63}$$

$$(1+r_j^L)L_j H_j^L - L_{j-1} H_{j-1}^L - F_j^L H_j^{LF} + \mathcal{E}_j^L + Q_j^L = 0 \tag{13-64}$$

where $\mathcal{E}_j^p$ is the rate of energy transfer across the phase interface in phase $p$ and is defined by

$$\mathcal{E}_j^p = \int_a E_j^p \, da \tag{13-65}$$

where $a$ is the interfacial area and $E_j^p$ is the energy flux across the interface from/to phase $p$. An energy balance at the phase interface yields

$$\mathcal{E}_j^V = \mathcal{E}_j^L \tag{13-66}$$

In addition, we need summation equations for the mole fractions in the vapor and liquid phases.

A review of early applications of NEQ models is available in chapter 14 of Taylor and Krishna (*Multicomponent Mass Transfer*, Wiley, New York, 1993).

It is worth emphasizing that Eqs. (13-59) to (13-66) hold regardless of the models used to calculate the interphase transport rates $\mathcal{N}_{i,j}$ and $\mathcal{E}_j^p$. With a mechanistic model of sufficient complexity it is possible, at least in principle, to account for mass transfer from bubbles in the froth on a tray as well as to entrained droplets in a spray, as well as transport between the phases flowing over and through the elements of packing in a packed column. However, a completely comprehensive model for estimating mass-transfer rates in all the possible flow regimes does not exist at present, and simpler approaches are used.

The simplest approach is to say that the molar fluxes at a vapor-liquid interface may be expressed as

$$N_i^V = c_t^V k_i^V (y_i^V - y_i^I) + y_i^V N_t^V \tag{13-67}$$

with a similar expression for the liquid phase.

$$N_i^L = c_t^L k_i^L (x_i^I - x_i^L) + x_i^L N_t^L \tag{13-68}$$

In these equations, $c_t^V$ and $c_t^L$ are the molar densities of the superscripted phases, $y_i^V$ is the mole fraction in the bulk vapor phase, $x_i^L$ is the mole fraction in the bulk liquid phase, and $x_i^I$ and $y_i^I$ are the mole fractions of species $i$ at the phase interface. Also $N_t^p$ is the total molar flux in phase $p$, and $k_i^V$ and $k_i^L$ are the mass-transfer coefficients for the vapor and liquid phases (with units of velocity), respectively. Methods for estimating mass-transfer coefficients in distillation processes are discussed briefly below and at greater length in Sec. 5 of this handbook.

The second term on the right-hand sides of Eqs. (13-67) and (13-68) is not often important in distillation (its neglect is equivalent to the assumption of equimolar counterflows in the column), but it can be quite significant in gas absorption.

The energy fluxes are related by

$$E^V = q^V + \sum_{i=1}^{c} N_t^V \bar{H}_i^V = E = q^L + \sum_{i=1}^{c} N_i^L \bar{H}_i^L = E^L \tag{13-69}$$

with

$$q^V = h^V(T^V - T^I) \qquad q^L = h^L(T^I - T^L) \tag{13-70}$$

where $h^V$ and $h^L$ are the heat-transfer coefficients in the vapor and liquid phases, respectively.

The inclusion in the model of the mass and energy transport equations introduces the mole fractions and temperature at the interface. It is common in almost all treatments of mass transfer across a phase boundary to assume that the mole fractions in the vapor and liquid phases at the interface are in equilibrium with each other. We may, therefore, use the very familiar equations from phase equilibrium thermodynamics to relate the interface mole fractions

$$y_i^I = K_i x_i^I \tag{13-71}$$

where the superscript $I$ denotes the interface compositions and $K_i$ is the vapor-liquid equilibrium ratio (or $K$ value) for component $i$. In equilibrium-stage calculations, the equilibrium equations are used to relate the composition of the streams leaving the stage, and the $K$ values are evaluated at the composition of the two exiting streams and the stage temperature (usually assumed to be the same for both phases). In nonequilibrium models, the $K$ values are evaluated at the interface composition and temperature by using exactly the same thermodynamic property models as those used in equilibrium-stage simulations. The interface composition and temperature must, therefore, be computed during a nonequilibrium column simulation. Strictly speaking, the composition and temperature at the interface vary with position in two-phase dispersion that exists on a tray or within the confines of a packed bed. In most NEQ models, the interface state is assumed to be uniform on the stage; thus, the model of a single stage includes one set of mass-transfer, heat-transfer, and phase equilibrium equations.

In equilibrium-stage models, the compositions of the leaving streams are related through the assumption that they are in equilibrium (or by the use of an efficiency equation). It is important to recognize that efficiencies are not used in a nonequilibrium model; they may, however, be calculated from the results obtained by solving the model equations.

**Degrees of Freedom** Table 13-6 summarizes the equations for a single nonequilibrium stage. There are $6c + 5$ independent equations per stage. As with the equilibrium-stage model discussed previously, we have not included the feed mole fraction summation equation, or those for the vapor and liquid streams coming from adjacent stages.

The variables appearing in these equations are summarized in Table 13-7.

It is important to recognize that we have not included mass- and heat-transfer coefficients in the table of variables. These quantities are considered analogous to the thermodynamic properties of the equilibrium-stage model and are functions of other variables (as discussed in greater detail below).

The $6c + 5$ variables for each stage determined during the solution of the nonequilibrium model equations are the vapor and liquid flow $V_j$ and $L_j$, respectively; the bulk vapor mole fractions, $y_{i,j}$ ($c$ in number); the bulk liquid mole fractions $x_{i,j}$ ($c$); the vapor and liquid temperatures $T_j^V$ and, $T_j^L$, respectively; the interface mole fractions and temperature $y_{i,j}^I$ ($c$), $x_{i,j}^I$ ($c$), and $T_j^I$; and the mass-transfer rates $\mathcal{N}_{i,j}^V$ ($c$) and $\mathcal{N}_{i,j}^L$ ($c$). Note that the interface material balance, Eq. (13-62), means that only one set of mass-transfer rates really needs to be counted in the set of variables for this stage, say, $\mathcal{N}_{i,j}$ (this reduces the number of variables being computed). The remaining variables, $2c + 7$ in number, that need to be specified, are identified in Table 13-7. It is important to recognize that the other flows and composition variables appearing in the nonequilibrium-stage model equations are associated with the equivalent equations for adjacent stages. Although it appears that the number of degrees of freedom is higher for this more complicated model, this is misleading. The additional variables that are specified here take into account that there is one additional heat duty (one per phase) and that the feed is split into vapor and liquid fractions. In practice, the overall feed flow, pressure, temperature (or vapor fraction), and composition would be specified, and the vapor and liquid component flows in the feed determined from an adiabatic flash.

**TABLE 13-6 Equations for a Nonequilibrium Stage**

| Equation | Reference | Number |
|---|---|---|
| Vapor phase component balance | (13-59) | $c$ |
| Liquid phase component balance | (13-60) | $c$ |
| Interface material balance | (13-62) | $c$ |
| Vapor bulk mole fraction summation equation | | 1 |
| Liquid bulk mole fraction summation equation | | 1 |
| Vapor phase energy balance | (13-63) | 1 |
| Liquid phase energy balance | (13-64) | 1 |
| Equilibrium at the interface | (13-71) | $c$ |
| Mass transfer in the vapor phase | (13-67) | $c - 1$ |
| Mass transfer in the liquid phase | (13-68) | $c - 1$ |
| Energy balance at phase interface | (13-69) | 1 |
| Summation equation for vapor mole fractions at phase interface | | 1 |
| Summation equation for liquid mole fractions at phase interface | | 1 |
| Summation equations for bulk vapor and liquid mole fractions | | 2 |
| | Total | $6c + 7$ |

**TABLE 13-7 Variables for a Nonequilibrium Stage**

| Variable | Symbol | Number | Specified |
|---|---|---|---|
| Vapor and liquid flow rates | $V_j, L_j$ | 2 | |
| Sidestream flow rates | $U_j, W_j$ | 2 | Yes |
| Vapor-phase bulk composition | $y_{i,j}$ | $c$ | |
| Liquid-phase bulk composition | $x_{ij}$ | $c$ | |
| Vapor interface composition | $y_{ij}^I$ | $c$ | |
| Liquid interface composition | $x_{ij}^I$ | $c$ | |
| Component feed flow rates | $f_{i,j}^V, f_{i,j}^L$ | $2c$ | Yes |
| Feed pressure and temperature | | 2 | Yes |
| Vapor-phase temperature | $T_j^V$ | 1 | |
| Liquid-phase temperature | $T_j^L$ | 1 | |
| Interface temperature | $T_j^I$ | 1 | |
| Stage pressure | $P_j$ | 1 | Yes |
| Heat loss from vapor phase | $Q_j^V$ | 1 | Yes |
| Heat loss from liquid phase | $Q_j^L$ | 1 | Yes |
| Mass-transfer rates in the vapor phase | $\mathcal{N}V_{i,j}$ | $c$ | |
| Mass-transfer rates in the liquid phase | $\mathcal{N}L_{i,j}$ | $c$ | |
| | Total | $8c + 12$ | $2c + 7$ |

**Physical Properties** The only physical properties needed for an equilibrium-stage simulation are those needed to estimate $K$ values and enthalpies; these same properties are needed for nonequilibrium models as well. Enthalpies are required for the energy balance equations; vapor-liquid equilibrium ratios are needed for the calculation of driving forces for mass and heat transfer. The need for mass- (and heat-) transfer coefficients means that nonequilibrium models are rather more demanding of physical property data than are equilibrium-stage models. These coefficients may depend on a number of other physical properties, as summarized in Table 13-8.

Methods for estimating physical and transport properties are described in Secs. 4 and 5 of this handbook (see also Poling et al., *The Properties of Gases and Liquids*, McGraw-Hill, 5th ed., 2001).

**Flow Models** In a real column the composition of the vapor and liquid phases changes due to flow across a tray or over and around packing. Thus, the bulk phase mole fractions that appear in the rate equations (13-67) and (13-68) vary with position and should not automatically be assumed to be equal to the average exit mole fractions that appear in the material balance equations. In practice, we assume a flow pattern for the vapor and

**TABLE 13-8 Physical Property Needs of Equilibrium and Nonequilibrium Models**

| Property | EQ model | NEQ model | Used for |
|---|---|---|---|
| $K$ values | Yes | Yes | Driving forces |
| Enthalpy | Yes | Yes | Energy balances |
| Activity coefficient | Yes | Yes | $K$ values, enthalpies |
| Fugacity coefficients | Yes | Yes | $K$ values, enthalpies |
| Vapor pressure | Yes | Yes | $K$ values |
| Heat capacity | Yes | Yes | Enthalpies, heat-transfer coefficient |
| Mass-transfer coefficients | | Yes | Mass-transfer rate equations |
| Heat-transfer coefficients | | Yes | Energy-transfer rate equation |
| Density | | Yes | Mass-transfer coefficients |
| Diffusion coefficients | | Yes | Mass-transfer coefficients |
| Viscosity | | Yes | Mass-transfer coefficients |
| Surface tension | | Yes | Mass-transfer coefficients |
| Thermal conductivity | | Yes | Heat-transfer coefficients |

liquid phases, and this allows us to determine appropriate average mole fractions for use in the rate equations. There are three flow models in general use: mixed flow, plug flow, and dispersion flow (Lockett, *Distillation Tray Fundamentals*, Cambridge University Press, Cambridge, England, 1986). A flow model needs to be identified for each phase. If both phases are assumed to be well mixed, then the average mole fractions are indeed equal to the mole fractions in the exit streams. This is the simplest (and an often used) approach that leads to the most conservative simulation (lowest mass-transfer rates, tallest column); at the opposite extreme is plug flow. The most realistic model is dispersion flow (see Lockett, *Distillation Tray Fundamentals*, Cambridge University Press, Cambridge, England, 1986), but this model is not included in most computer implementations of NEQ models because it is quite complicated. For further discussion of the importance of flow models and the equations used to estimate average compositions, see Taylor and Krishna (1993) and Kooijman and Taylor [*Chem. Eng. J.* **57:** 177 (1995)].

**Mass-Transfer Coefficients** Mass-transfer coefficients (and the equally important interfacial area, a parameter with which they often are combined) may be computed from empirical correlations or theoretical models.

The mass-transfer performance of trays often is expressed by way of a dimensionless group called the number of transfer units [see Lockett (1986), Kister (1992), and Sec. 14 for additional background]. These dimensionless numbers are defined by

$$\mathbb{N}^V = k^V a' t_V = \frac{k^V a h_f}{u_s^V} \tag{13-72}$$

$$\mathbb{N}^L = k^L \bar{a} t_L = \frac{k^L a h_f Z}{Q_L / W} \tag{13-73}$$

where $h_f$ = froth height, m
$Z$ = liquid flow path length, m
$W$ = weir length, m
$Q_L = \dfrac{L}{c_t^L}$ = volumetric liquid flow rate, $m^3/s$
$u_s = \dfrac{V}{c_t^V A_{bub}}$ = superficial vapor velocity, m/s
$A_{bub}$ = bubbling area of tray, $m^2$
$h_L$ = clear liquid height on tray, m
$a'$ = interfacial area per unit volume of vapor, $m^2/m^3$
$\bar{a}$ = interfacial area per unit volume of liquid, $m^2/m^3$

These areas are related to the interfacial area per unit volume of froth $a$ by

$$a' = \frac{1}{1-a} \qquad \bar{a} = \frac{a}{\alpha} \tag{13-74}$$

where $\alpha = h_L/h_f$ is the relative froth density. Also $t_V$ and $t_L$ are the vapor- and liquid-phase residence times, defined by

$$t_V = (1-\alpha) h_f u_s \tag{13-75}$$

$$t_L = \frac{Z}{u_L} = \frac{h_L Z W}{Q_L} \tag{13-76}$$

The *AIChE Bubble Tray Design Manual,* published in 1958 (see also Gerster et al., *Tray Efficiencies in Distillation Columns*, AIChE, New York, 1958), presented the first comprehensive procedure for estimating the numbers of transfer units in distillation. For many years this work represented the only such procedure available in the open literature; the work of organizations such as Fractionation Research Incorporated (FRI) was available only to member companies. Other comprehensive procedures for trays appeared in the 1980s [Zuiderweg, *Chem. Eng. Sci.* **37:** 1441 (1982); Chan and Fair, *Ind. Eng. Chem. Proc. Des. Dev.* **23:** 814, 820 (1984)]. Readers are referred to Kister (1992), Lockett (1986), Klemola and Ilme (1996), and Sec. 14 of this handbook for summaries and references to what is available in the open literature.

***Example 13-11 Mass-Transfer Coefficient in a Tray Column*** Consider again the $C_4$ splitter that formed the basis of Examples 7 and 8. The key design parameters for the valve trays are given in the following table ( from Klemola and Ilme 1996):

| | | | |
|---|---|---|---|
| Column height | 51.8 m | Downcomer area center | 0.86 $m^2$ |
| Column diameter | 2.9 m | Tray spacing | 0.6 m |
| Number of trays | 74 | Hole diameter | 39 mm |
| Weir length, side | 1.859 m | Total hole area | 0.922 $m^2$ |
| Weir length, center | 2.885 m | Outlet weir height | 51 mm |
| Liquid flow path length | 0.967 m per pass | Tray thickness | 2 mm |
| Active area | 4.9 $m^2$ | Number of valves per tray | 772 |
| Downcomer area, side | 0.86 $m^2$ | Free fractional hole area | 18.82% |

Estimate the mass-transfer coefficients for tray 7, where the flow and physical properties are estimated to be summarized as:

| | Gas/vapor | Liquid |
|---|---|---|
| Flow, mol/s | 590 | 550 |
| Density, $kg/m^3$ | 16.8 | 520 |
| Viscosity, $N/m^2$ | $8.6 \times 10^{-6}$ | $1.35 \times 10^{-4}$ |
| Molecular weight, kmol/kg | 58.0 | 58.0 |
| Diffusivity, $m^2/s$ | $800 \times 10^{-9}$ | $1.0 \times 10^{-9}$ |
| Surface tension, N/m | 0.014 | |

We use the AIChE correlation to illustrate the general approach, noting that the correlation was not developed specifically for valve trays ( few methods were). In this model, the number of transfer units is given by

$$\mathbb{N}^V = \frac{0.776 + 4.57 h_w - 0.238 F_s + 104.8 Q_L/W}{\sqrt{\mathrm{Sc}^V}} \tag{13-77}$$

$$\mathbb{N}^L = 19{,}700 \sqrt{D^L}\,(0.4 F_s + 0.17) t_L \tag{13-78}$$

In the preceding expressions, $h_w$ is the weir height (m). The vapor-phase Schmidt number $\mathrm{Sc}^V$ is defined by $\mathrm{Sc}^V = \mu^V/(\rho^V D^V)$, which here takes the value $\mathrm{Sc}^V = 0.640$.

The superficial velocity is computed next from $u_s^V = V/(c_t^V A_{bub}) = 0.42$ m/s. Here $F_s$ is the so-called $F$ factor and is $F_s = u_s^V \sqrt{\rho^V} = 1.7$ $(kg/ms)^{1/2}$. The volumetric liquid flow is $Q_L = L/c_t^L = 0.061$ $m^3/s$.

The froth height on the tray is estimated (by using the methods in Sec. 14 of this handbook—see also Lockett, *Distillation Tray Fundamentals,* Cambridge University Press, Cambridge, UK, 1986; Kister 1992) to be $h_f = 0.143$ m. The liquid-phase residence time is $t_L = h_L Z W_l / Q_L = 4.67$ s.

The number of transfer units follows for the vapor phase from Eq. (13-77) as $\mathbb{N}^V = 2.45$ and for the liquid phase from Eq. (13-78) as $\mathbb{N}^L = 2.33$. The products of the vapor- and liquid-phase mass-transfer coefficients and the interfacial area follow directly from the second parts of the same equations. Note that it is not possible with these correlations to separate the mass-transfer coefficient from the interfacial area. In practice this is not a concern because it is the mass-transfer rates that are needed rather than the fluxes, and the product suffices for NEQ model computations.

The diffusivities used in this example were for the light key–heavy key pair of components. For systems similar to this one, the diffusion coefficients of all binary pairs in the mixture would be expected to have similar values. This will not be the case for mixtures of components that differ sharply in their fundamental properties (e.g., size, polarity). For these more highly nonideal mixtures, it is necessary to estimate the mass-transfer coefficients for each of the binary pairs.

The number of transfer units for packed columns is defined by

$$\mathbb{N}^V = \frac{k^V a' H}{u_V} \tag{13-79}$$

$$\mathbb{N}^L = \frac{k^L a' H}{u_L} \tag{13-80}$$

where $u_V = V/(c_t^V A_c)$ and $u_L = \mathrm{L}/(c_t^L A_c)$ are the superficial vapor and liquid velocities, with $A_c$ the cross-sectional area of the column; $a'$ is the interfacial area per unit volume. The height of a transfer unit (HTU) is defined as

$$\mathbb{H}^V = \frac{H}{\mathbb{N}^V} = \frac{u_V}{k^V a'} \tag{13-81}$$

$$\mathbb{H}^L = \frac{H}{\mathbb{N}^L} = \frac{u_L}{k^L a'} \tag{13-82}$$

Methods of estimating numbers and heights of transfer units and mass-transfer coefficients and interfacial areas in packed columns are reviewed by Ponter and Au Yeung (in *Handbook of Heat and Mass Transfer*, Gulf Pub., Houston, 1986), by Wang et al. [*Ind. Eng. Chem. Res.* **44:** 8715 (2005)], and in Sec. 5 of this handbook; one such method is illustrated next.

***Example 13-12 Mass-Transfer Coefficients in a Packed Column*** Estimate the mass-transfer coefficients at the top of the packed gas absorber in Example 13-9. The column has 23 ft of 2-in metallic Pall rings and is 3 ft in diameter. The specific surface area of this packing is 112 $m^2/m^3$. The flows and physical properties are estimated to be as follows:

| | Gas/vapor | Liquid |
|---|---|---|
| Flow, mol/s | 332 | 37 |
| Temperature, K | 267 | 266 |
| Density, kg/$m^3$ | 51.2 | 705 |
| Viscosity, N/$m^2$ | $1.17 \times 10^{-5}$ | $2.43 \times 10^{-4}$ |
| Molecular weight, kmol/kg | 16.8 | 87.9 |
| Diffusivity, $m^2/s$ | $100 \times 10^{-9}$ | $4.6 \times 10^{-9}$ |
| Surface tension, N/m | 0.0085 | |

We will use the well-known correlation of Onda et al. (see Sec. 14) to estimate the mass-transfer coefficients. The vapor-phase coefficient is given by

$$\frac{k^V}{a_p D^V} = A\left(\frac{\rho^V u^V}{\mu^V a_p}\right)^{0.7}\left(\frac{\mu^V}{\rho^V D^V}\right)^{0.33}(a_p d_p)^{-2} \tag{13-83}$$

where $d_p$ is the nominal packing size (2 in = 0.0508 m), and $a_p$ is the specific surface area of the packing. Also, $A$ is a constant that has the value 2 if nominal packing size is less than 0.012 m, otherwise, $A = 5.23$.

The liquid-phase mass-transfer coefficient is given by

$$k^L = 0.0051\left(\frac{\rho^L}{\mu^L g}\right)^{-1/3}\left(\frac{u_L}{a'\mu^L}\right)^{2/3}\left(\frac{\mu^L}{\rho^L D^L}\right)^{1/2}(a_p d_p)^{0.4} \tag{13-84}$$

Finally, the interfacial area per unit volume is given by

$$a' = a_p\left\{1-\exp\left[-1.45\left(\frac{\sigma_c}{\sigma^L}\right)^{0.75}\left(\frac{\rho^L u_L}{a_p\mu_L}\right)^{0.1}\left(\frac{a_p u_L^2}{g}\right)^{0.05}\left(\frac{u^2{}_L\rho^L}{a_p\sigma^L}\right)^{0.2}\right]\right\} \tag{13-85}$$

The vapor and liquid velocities are calculated to be $u_V = V/(c_t^V A_t) = 0.42$ m/s and $u_L = L/(c_t^L A_t) = 0.0017$ m/s. Substituting these values into Eqs. (13-83) to (13-85) gives $k^V = 0.0021$ m/s, $a' = 96.2$ $m^2/m^3$, and $k^L = 3.17 \times 10^{-4}$ m/s.

**Solving the NEQ Model Equations** In general, a nonequilibrium model of a column has many more equations than does an equivalent equilibrium-stage model. Nevertheless, we use essentially the same computational approaches to solve the nonequilibrium model equations: simultaneous convergence [Krishnamurthy and Taylor, *AIChE J.* **31:** 449–465 (1985)] and continuation methods [Powers et al., *Comput. Chem. Eng.* **12:** 1229 (1988)]. Convergence of a nonequilibrium model is likely to be slower than that of the equilibrium model because of the greater number of model equations and the associated overhead in evaluating a greater number of physical properties. Finally, we note that the strategies we have outlined for helping to converge equilibrium-stage simulation may prove equally useful when simulating distillation operations using the nonequilibrium models described here.

**Equipment Design** As we have already seen, the estimation of mass-transfer coefficients and interfacial areas from empirical correlations nearly always requires us to know something about the column design. At the very least we need to know the diameter and type of column internals (although usually we need to know more than that since most empirical correlations for mass-transfer coefficients have some dependency on equipment design parameters, such as the weir height of trays). This need for more or less complete equipment design details suggests that nonequilibrium models cannot be used in preliminary process design (before any actual equipment design has been carried out). This is not true, however. Column design methods are available in the literature as well in most process simulation programs, and it is straightforward to carry out equipment sizing calculations at the same time as the stage equations are being solved (Taylor et al., 1994). This does not add significantly to the difficulty of the calculation, while providing the very significant advantage of allowing nonequilibrium or rate-based models to be used at all stages of process simulation.

***Example 13-13 A Nonequilibrium Model of a C4 Splitter*** Consider again the $C_4$ splitter that formed the basis of Examples 7, 8, and 11.

In this example we do not need to guess how many stages to use in each section of the column. The real column had 74 valve trays; the model column includes 74 model trays with the feed to tray 38 [plus a (subcooled) condenser and a reboiler, both of which are modeled as equilibrium stages, as described previously]. All operating specifications are the same as for the corresponding equilibrium-stage model and are given in Examples 7 and 8. It is necessary to choose models that allow for the estimation of the rates of interphase mass transfer; that means selecting vapor and liquid flow models and correlations to estimate the mass-transfer coefficients in each phase. In this case, the AIChE correlations were used. It is known that this method is more conservative than others (i.e., the predicted efficiencies are lower). The importance of the flow model is clear from the simulation results tabulated below. The predicted component Murphree efficiencies computed with Eq. (13-56) vary more widely from stage to stage and from component to component than might be expected for a system such as this. The TBK efficiency, on the other hand, does not change by more than a few percentage points over the height of the column; the value in the following table is an average of that computed for each tray from the simulation results using Eq. (13-57).

| Vapor flow model | Liquid flow model | *i*-$C_4$ in distillate, % | *n*-$C_4$ in bottoms, % | TBK efficiency, % |
|---|---|---|---|---|
| Mixed | Mixed | 90.2 | 96.3 | 63 |
| Plug | Mixed | 92.2 | 97.2 | 78 |
| Plug | Dispersion | 93.9 | 98.0 | 106 |

Internal vapor and liquid composition data rarely are available, but such data are the best possible for model discrimination and validation. It is often relatively easy to match even a simple model only to product compositions. In the absence of composition profiles, the internal temperature profile can often be as useful, provided that it is known to which phase a measured temperature pertains. The following table compares the few available measured tray temperatures with those computed during the simulation. The agreement is quite good.

| | Temperature, °C | |
|---|---|---|
| Tray | Measured | Predicted |
| 9 | 47.5 | 48.6 |
| 65 | 62.2 | 62.5 |
| 74 | 63.2 | 63.1 |

A portion of the McCabe-Thiele diagram for the simulation involving plug flow of vapor and dispersion flow of the liquid is shown in Fig. 13-52. For a nonequilibrium column, these diagrams can only be constructed from the results of a computer simulation. Note that the triangles that represent the stages extend beyond the curve that represents the equilibrium line; this is so because the efficiencies are greater than 100 percent.

In this case, the converged composition and temperature profiles have the same shape as those obtained with the equilibrium-stage model (with specified efficiency), and therefore they are not shown. The reason for the similarity is that this is basically a binary separation of very similar compounds. The important point here is that, unlike the equilibrium-stage model simulations, the nonequilibrium model predicted how the column would perform; *no parameters were adjusted to provide a better fit to the plant data.* That is not to say, of course, that NEQ models cannot be used to fit plant data. In principle, the mass-transfer coefficients and interfacial area (or parameters in the equations used to estimate them) can be tuned to help the model better fit plant data.

## MAXWELL-STEFAN APPROACH

Strictly speaking, Eqs. (13-67) and (13-68) are valid only for describing mass transfer in binary systems under conditions where the rates of mass transfer are low. Most industrial distillation and absorption processes, however, involve more than two different chemical species. The most fundamentally sound way to model mass transfer in multicomponent systems is to use the Maxwell-Stefan (MS) approach (Taylor and Krishna, *Multicomponent Mass Transfer,* Wiley, New York, 1993).

The MS equation for diffusion in a mixture with any number of different species can be written as

$$d_i = -\sum_{k=1}^{c}\frac{x_i x_k (u_i - u_k)}{\mathcal{D}_{ik}} \tag{13-86}$$

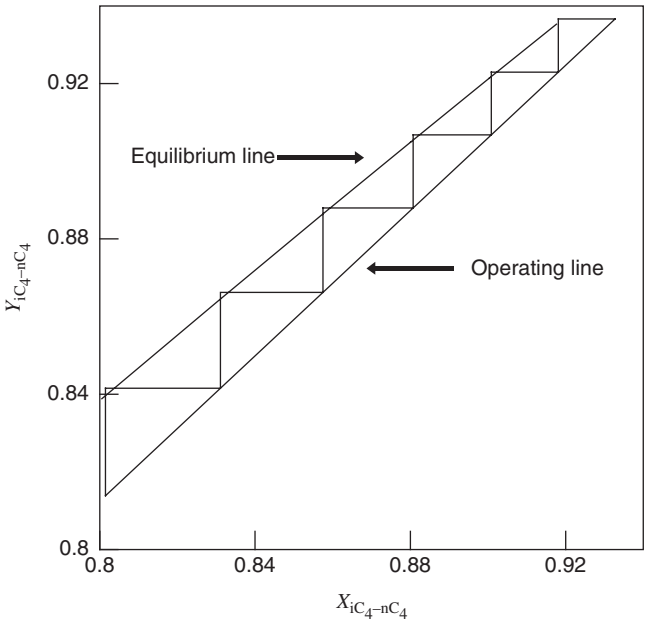

**FIG. 13-52** Expanded view near upper right corner of McCabe-Thiele diagram for $C_4$ splitter.

where $Đ_{ik}$ is the Maxwell-Stefan diffusion coefficient for the binary *i-k* pair of components. Methods for estimating these coefficients are discussed by Taylor and Krishna (1993) (see also Sec. 5 of this handbook and Poling et al., *The Properties of Gases and Liquids*, McGraw-Hill, 5th ed., 2001).

In Eq. (13-86), $d_i$ is termed the generalized driving force. For an ideal gas mixture, the driving force is related to the partial pressure gradient and the mole fraction gradient as follows:

$$d_i = \frac{1}{P}\frac{dp_i}{dz} = \frac{dx_i}{dz} \tag{13-87}$$

For a nonideal fluid, the driving force is related to the chemical potential gradient

$$d_i = \frac{x_i}{RT}\frac{d\mu_i}{dz} \tag{13-88}$$

Equation (13-86) for ideal gas mixtures may be derived by using nothing more complicated than Newton's second law: *The sum of the forces acting on the molecules of a particular species is directly proportional to the rate of change of momentum*. The rate of change of momentum between different species is proportional to the concentrations (mole fractions) of the different species and to their relative velocity (see also Taylor and Krishna 1993 for a more complete derivation). Equation (13-86) is more familiar in the form

$$d_i = -\sum_{k=1}^{c}\frac{x_i N_k - x_k N_i}{c_t Đ_{ik}} \tag{13-89}$$

where we have replaced the velocities with the molar fluxes $N_i = c_i u_i$ (see Sec. 5). Only $c - 1$ of Eq. (13-89) are independent; the mole fraction of the last component is obtained by the mole fraction summation equations for both phases.

Solving the MS equations can be quite involved (see Taylor and Krishna 1993). Most often, a simple film model solution of Eq. (13-89) is used, leading to a simple difference approximation to the MS equations

$$\Delta x_i = -\sum_{k=1}^{c}\frac{\bar{x}_i N_k - \bar{x}_k N_i}{c_t \kappa_{i,k}} \tag{13-90}$$

where $\kappa_{i,k}$ is the mass-transfer coefficient for the binary *i-k* pair of components. The Maxwell-Stefan mass-transfer coefficients can be estimated from existing correlations for mass-transfer coefficients using the binary MS diffusion coefficients.

For a nonideal fluid, the driving force is related to the chemical potential gradient

$$d_i = \frac{x_i}{RT}\frac{d\mu_i}{dz} \tag{13-91}$$

The difference approximation of this expression is somewhat more involved because we have to include the derivative of the activity (or fugacity) coefficient in the approximation. If, as we often assume (not always with justification), the resistance to mass transfer in the liquid phase is negligible, then the MS equations for the liquid phase can safely be replaced by

$$\Delta x_i = x_i^I - x_i^L = 0 \tag{13-92}$$

The use of the MS equations in place of the simpler Eqs. (13-67) and (13-68) does not change the number of independent model equations or the number of degrees of freedom.

***Example 13-14 The Need for Rigorous Maxwell-Stefan-Based NEQ Models*** Design a distillation column to separate a feed of 20 mol/s methanol, 10 mol/s isopropanol, and 20 mol/s water. The bottom product is to contain no more than 0.5 mol% methanol, and the distillate is to contain at least 99 mol% methanol but no more than 50 ppm water.

As a first step, we try to design the column by using the equilibrium-stage model. Following Doherty and Malone (2001), the NRTL model was used for the activity coefficients and the Antoine equation for the vapor pressures. Doherty and Malone estimate the minimum reflux as 5; we used a value 50 percent higher in this example and specified the bottoms product rate at 30 mol/s; this choice provides a consistent basis for the comparison of different models. The number of stages and the location of the feed were varied until a column configuration was obtained that met the desired product purity: 80 total stages (including total condenser and partial reboiler) with the feed to stage 16.

Efficiencies of alcohol-water and alcohol-alcohol systems obtained experimentally in sieve tray columns varied from 60 to 100 percent (Sec. 14 in the seventh edition of this handbook). After specifying an average efficiency of 80 percent, we find that 99 total stages with the feed to stage 21 were needed to get the distillate product below 50 ppm water.

If we use the nonequilibrium model to design a sieve tray column, we find that a column with 84 trays (plus condenser and reboiler) and with the feed to tray 21 (stage 22) will produce an overhead product of the desired purity. The reflux ratio and bottoms flows were maintained at the values employed for the equilibrium-stage design. The AIChE method was used for estimating the mass-transfer coefficient–interfacial area products, and the vapor and liquid phases were assumed to be in plug flow. The pressure was assumed to be constant in the column (an assumption that would need to be relaxed at a later stage of the design exercise). The computer simulation also provided a preliminary tray design; that for the trays above the feed is summarized in the following table:

| | |
|---|---|
| Column diameter, m | 1.76 |
| Total tray area, $m^2$ | 2.43 |
| Number of flow passes | 2 |
| Tray spacing, m | 0.6 |
| Liquid flow path length, m | 0.75 |
| Active area, % total | 91.4 |
| Total hole area, % active | 14 |
| Downcomer area, % total | 4.3 |
| Hole diameter, mm | 5 |
| Hole pitch, mm | 12 |
| Weir type | Segmental |
| Combined weir length, m | 1.55 |
| Weir height, mm | 50 |

To converge the nonequilibrium model at the specified reflux ratio, it was necessary first to solve the problem at a much lower reflux ratio $R = 2$ and then increase $R$ in steps until the desired value of 7.5 was reached.

The liquid composition, flow, and temperature profiles are shown in Fig. 13-53. In this system, the vapor and liquid temperatures estimated by the rate-based model are quite close (as often is the case in distillation operations).

The McCabe-Thiele diagram for this column is shown in Fig. 13-54. Note that in this case the triangles that represent the stages do not touch the equilibrium line. The length of the vertical section of each step in Fig. 13-54 is a measure of the efficiency of that tray. The component Murphree efficiencies calculated from the simulation results and Eq. (13-56), as well as the TBK average efficiency defined by Eq. (13-57), are shown in Fig. 13-55. The efficiency of methanol in the stripping section is seen to be around 80 percent, that of isopropanol is approximately 75 percent, while that of water is close to 90 percent in the bulk of the column before falling off on the bottom few trays. All

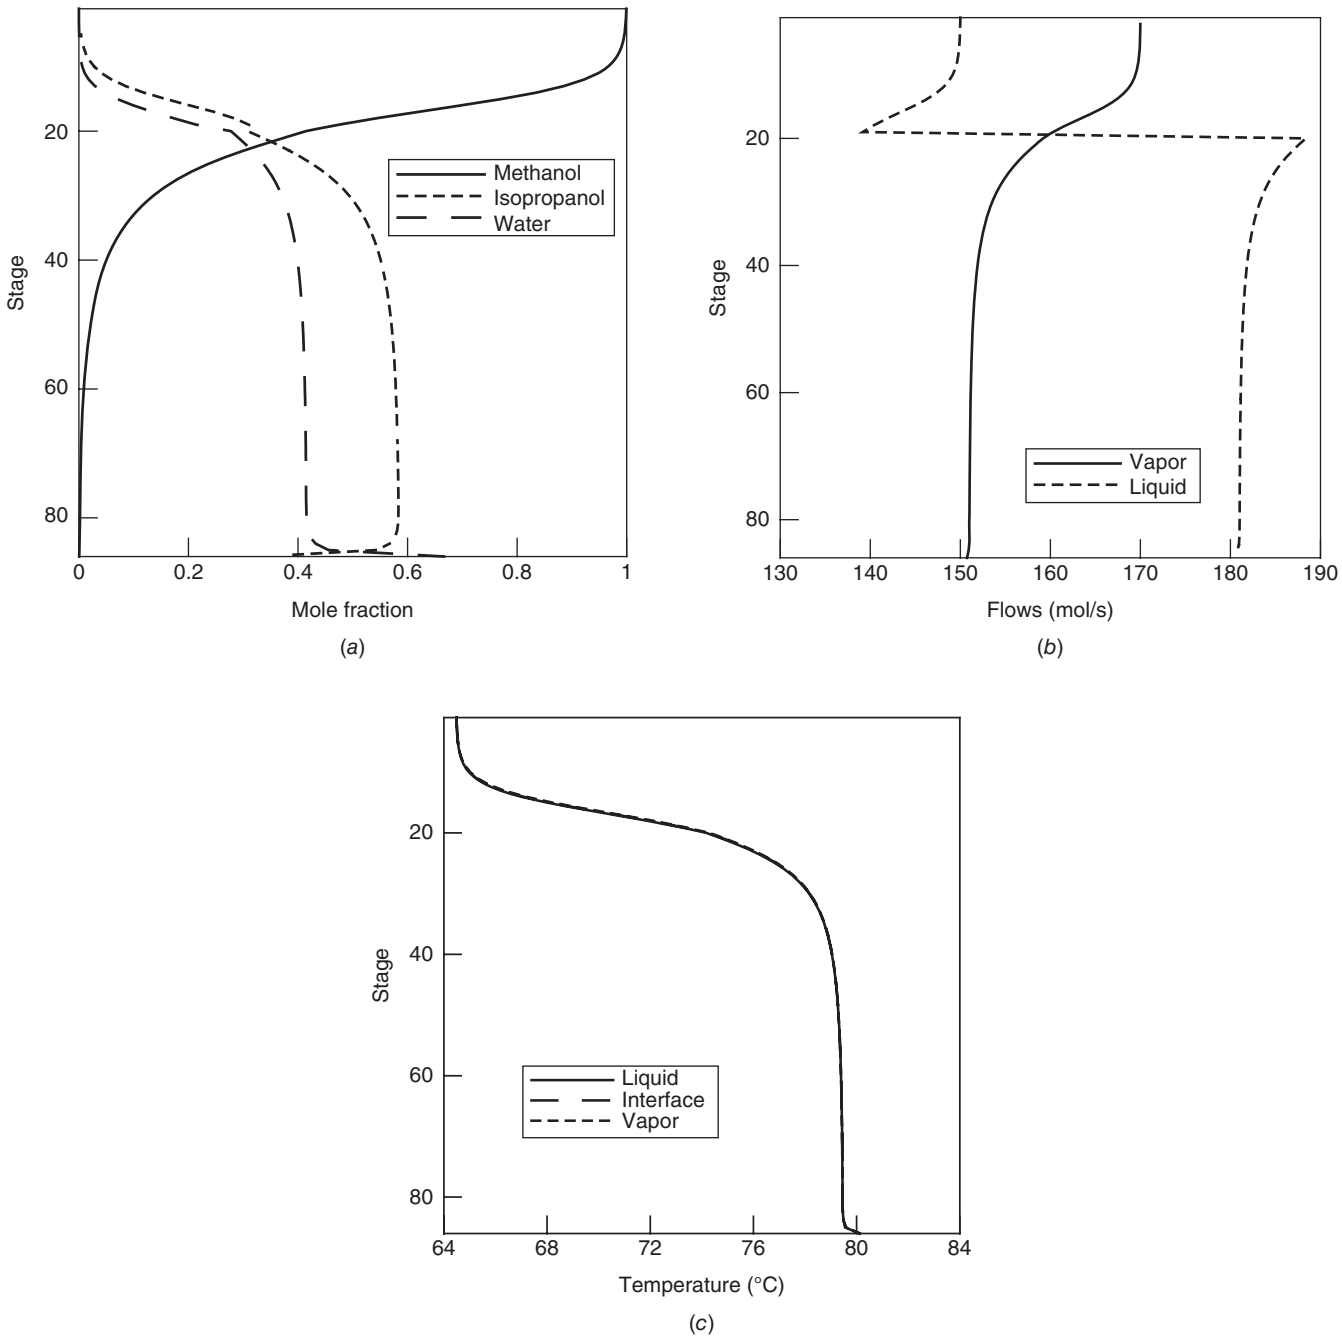

**FIG. 13-53** Composition, flow, and temperature profiles in nonideal distillation process.

component efficiencies are found to be lower in the rectifying section. The TBK average efficiency, also shown in Fig. 13-55, is close to the Murphree efficiency of methanol and varies from 60 percent in the top of the column to 78 percent. Thus, the constant value of 80 percent used above appears to be appropriate, and yet the column designed with the constant-efficiency model required no less than 99 stages (97 trays)!

With 84 trays as opposed to 78 equilibrium stages (not counting condenser and reboiler in either case), we find an overall efficiency of 93 percent, a figure that is quite at odds with the values of the individual component efficiencies seen in Fig. 13-55. How, then, is it possible that the nonequilibrium model suggests that the column needs only six trays more than the number of equilibrium stages? It is because the efficiency of water is so much higher than that of the alcohols that a column design can produce high-purity methanol while producing the 50-ppm methanol bottom product in so few extra stages. Note that nonequilibrium models will not always lead to a design with fewer trays than might be suggested by a constant-efficiency model; it is just as likely for the mass-transfer-rate–based model to predict that more stages will be needed. It all depends on the differences between the component efficiencies.

Individual component efficiencies can vary as much as they do in this example only when the diffusion coefficients of the three binary pairs that exist in this system differ significantly. For ideal or nearly ideal systems, all models lead to essentially the same results. This example demonstrates the importance of mass-transfer models for nonideal systems, especially when trace components are a concern. For further discussion of this example, see Doherty and Malone (2001) and Baur et al. [*AIChE J.* **51:** 854 (2005)]. It is worth noting that there is extensive experimental evidence for mass-transfer effects for this system, and it is known that nonequilibrium models accurately describe the behavior of this system, whereas equilibrium models (and equal-efficiency models) sometimes predict completely erroneous product compositions [Pelkonen et al., *Ind. Eng. Chem. Res.* **36:** 5392 (1997) and *Chem. Eng. Process* **40:** 235 (2001); Baur et al., *Trans. I. Chem. E.* **77:** 561 (1999)].

Nonequilibrium models should be preferred to equilibrium models when efficiencies are unknown, cannot be reliably predicted, and are low or highly variable in nonideal systems and in processes where trace components are a concern.

There is a rapidly growing body of literature on nonequilibrium modeling of distillation and absorption processes. An extended bibliography is available at www.chemsep.org/publications. A brief review of other applications follows.

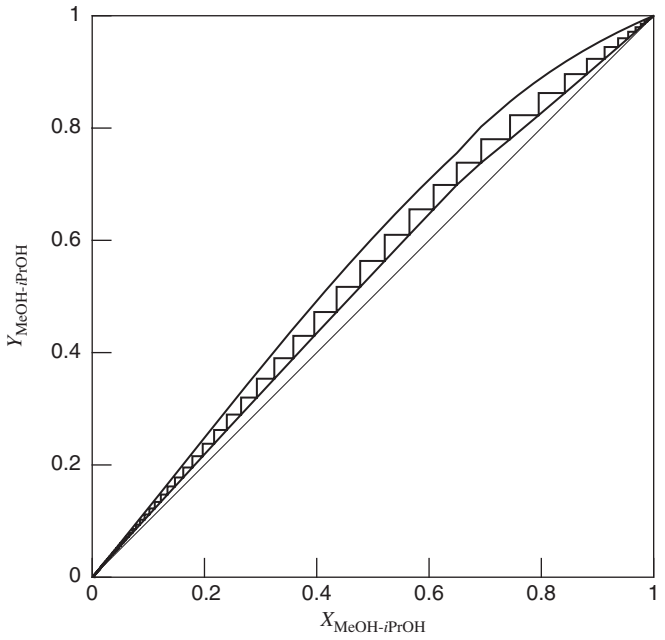

**FIG. 13-54** McCabe-Thiele diagram for nonideal distillation column.

Simulation methods currently in use for three-phase systems and systems involving chemical reaction use the equilibrium-stage model (Doherty and Malone, 2001). Three-phase distillation remains rather poorly understood compared to conventional distillation operations that involve just a single liquid phase. It is important to be able to correctly predict the location of the stages where a second liquid phase can form (e.g., to determine the appropriate location for a sidestream decanter). The limited experimental data available suggest that efficiencies are low and highly variable, commonly between 25 and 50 percent. Clearly, a model based on the assumption of equilibrium on every stage cannot hope to be able to *predict* column performance. Cairns and Furzer [*Ind. Eng. Chem. Res.* **29:** 5392 (1997)] explicitly warn against incorporating Murphree efficiencies into the equlilibrium-stage model for three-phase systems, although Müller and Marquardt [*Ind. Eng. Chem. Res.* **36:** 5410 (1997)] find that an efficiency modified EQ stage model is perfectly adequate for their column for the dehydration of ethanol using cyclohexane.

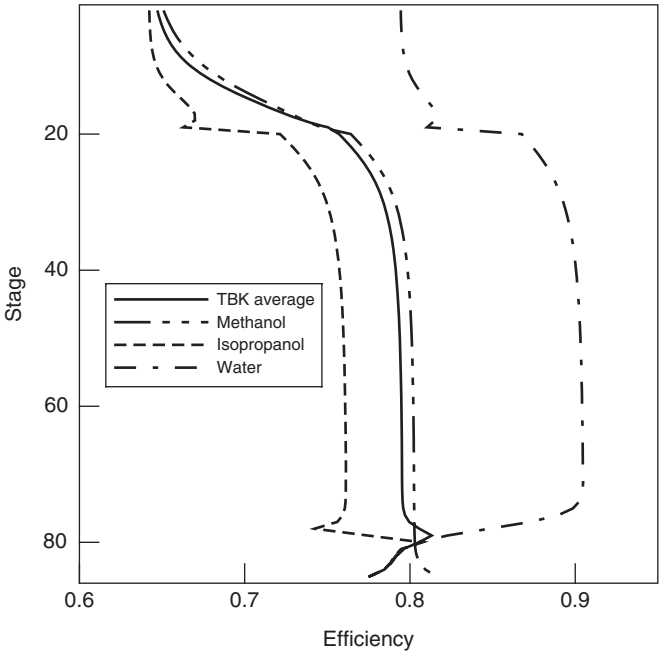

**FIG. 13-55** Component Murphree efficiencies and TBK average efficiency [defined by Eq. (13-57)] for nonideal distillation.

It is possible to develop nonequilibrium models for systems with more than two phases, as shown by Lao and Taylor [*Ind. Eng. Chem. Res.* **33:** 2367 (1994)], Eckert and Vanēk [*Comput. Chem. Eng.* **25:** 603 (2001)], and Higler et al. [*Comput. Chem. Eng.* **28:** 2021 (2004)]. Experimental work that can be used to evaluate these models is scarce; see, however, Cairns and Furzer (1997) and Springer et al. [*Chem. Eng. Res. Design* **81:** 413 (2003)].

There is now an extensive literature on using nonequilibrium models for reactive distillation; see, for example, Taylor and Krishna [*Chem. Eng. Sci.* **55:** 6139 (2000)], Sundmacher and Kienle (*Reactive Distillation: Status and Future Directions*, Wiley-VCH, New York, 2003), Noeres et al. [*Chem. Eng. Processing* **42:** 157 (2003)], and Klöcker et al. [*Chem. Eng. Processing* **44:** 617 (2005)]. Gas absorption accompanied by chemical reaction for a long time has been modeled by using mass-transfer rate-based concepts; see, for example, Cornelisse et al. [*Chem. Eng. Sci.* **35:** 1245 (1980)], Pacheco and Rochelle [*Ind. Eng. Chem. Res.* **37:** 4107 (1998)], and a review by Kenig et al. [*Chem. Eng. Technol.* **26:** 631 (2003)]. For such systems, the chemical reaction influences the efficiencies to such an extent that the concept loses its meaning.

Even at steady state, efficiencies vary from component to component and with position in a column. Thus, if the column is not at steady state, efficiencies also must vary with time as a result of changes to flow rates and composition inside the column. Thus, equilibrium-stage models with efficiencies should not be used to model the dynamic behavior of distillation and absorption columns. Nonequilibrium models for studying column dynamics are described by Kooijman and Taylor [*AIChE J.* **41:** 1852 (1995)], Baur et al. [*Chem. Eng. Sci.* **56:** 2085 (2001)], Gunaseelan and Wankat [*Ind. Eng. Chem. Res.* **41:** 5775 (2002)], Peng et al. [*Chem. Eng. Sci.* **58:** 2671 (2003)], and Kenig et al. [*Chem. Eng. Sci.* **54:** 5195 (1999)].

## SOFTWARE FOR DISTILLATION COLUMN SIMULATIONS

Computer software for equilibrium-stage and nonequilibrium column models is available from a number of suppliers. Many other models have been implemented primarily for research purposes and are not available commercially.

In Table 13-9 we list several suppliers of column simulation models that are available commercially, without in any way claiming that this list is exhaustive or providing an endorsement of any particular package. We recommend that users interested in any of these (or other) packages carry out an independent evaluation that focuses on the ability of the package to tackle the simulation problems of direct interest. The simulations described in this subsection were carried out with *ChemSep*.

# DEGREES OF FREEDOM AND DESIGN VARIABLES

## DEFINITIONS

In the models described in previous subsections, we have determined the degrees of freedom on a case-by-case basis. We now develop a general approach to the topic.

For separation processes, a design solution is possible if the number of independent equations equals the number of unknowns

$$N_i = N_v - N_c \tag{13-93}$$

where $N_v$ is the total number of variables (unknowns) involved in the process under consideration, $N_c$ is the number of restricting relationships among the unknowns (independent equations), and $N_i$ is the degrees of freedom that must be specified for there to be exactly the same number of unknowns as there are independent equations in the model. The concept of degrees of freedom in this context is similar to the same concept that appears in the Gibbs phase rule. The degrees of freedom is the number of design variables that must be specified to define one unique operation (solution) of the process.

The variables $N_i$ with which the designer of a separation process must be concerned are

1. Stream concentrations (e.g., mole fractions)
2. Temperatures
3. Pressures
4. Stream flow rates
5. Repetition variables $N_r$

The first three are intensive variables. The fourth is an extensive variable that is not considered in the usual phase rule analysis. The fifth is neither an intensive nor an extensive variable but is a single degree of freedom that the designer uses in specifying how often a particular element is repeated in a unit. For example, a distillation column section is composed of a series of equilibrium stages, and when the designer specifies the number of stages that the section contains, he or she uses the single degree of freedom represented by the repetition variable ($N_r = 1.0$). If the distillation column contains more than one section (such as above and below a feed stage), the number of stages in each section must be specified, and as many repetition variables exist as there are sections, that is, $N_r = 2$.

The various restricting relationships $N_c$ can be classified as

1. Inherent
2. Mass balance
3. Energy balance
4. Phase distribution
5. Chemical equilibrium

The inherent restrictions are usually the result of definitions and take the form of identities. For example, the concept of the equilibrium stage involves the inherent restrictions that $T^V = T^L$ and $P^V = P^L$ where the superscripts $V$ and $L$ refer to the equilibrium exit streams.

The mass balance restrictions are the $C$ balances written for the $C$ components present in the system. (Since we will deal with only nonreactive mixtures, each chemical compound present is a phase rule component.) An alternative is to write $C - 1$ component balances and one overall mass balance.

The phase distribution restrictions reflect the requirement that $f_i^V = f_i^L$ at equilibrium where $f$ is the fugacity. This may be expressed by Eq. (13-1). In vapor-liquid systems, it should always be recognized that all components appear in both phases to some extent, and there will be such a restriction for each component in the system. In vapor-liquid-liquid systems, each component will have three such restrictions, but only two are independent. In general, when all components exist in all phases, the number of restricting relationships due to the distribution phenomenon will be $C(N_p - 1)$, where $N_p$ is the number of phases present.

For the analysis here, the forms in which the restricting relationships are expressed are unimportant. Only the number of such restrictions is important.

## ANALYSIS OF ELEMENTS

An *element* is defined as part of a more complex *unit.* The unit may be all or only part of an operation or the entire *process.* Our strategy will be to analyze all elements that appear in a separation process and to determine the number of design variables associated with each. The appropriate elements can then be quickly combined to form the desired units, and the various units can be combined to form the entire process. Of course, allowance must be made for the connecting streams (*interstreams*) whose variables are counted twice when elements or units are joined.

The simplest element is a *single homogeneous stream.* The variables necessary to define it are

| | $N_v^e$ |
|---|---|
| Compositions | $C-1$ |
| Temperature | 1 |
| Pressure | 1 |
| Flow rate | 1 |
| | $C+2$ |

There are no restricting relationships when the stream is considered only at a point. Henley and Seader (*Equilibrium-Stage Separation Operations in Chemical Engineering,* Wiley, New York, 1981) count all $C$ compositions as variables, but then have to include as a restriction

$$\sum_i x_i = 1 \text{ or } \sum_i y_i = 1 \tag{13-94}$$

A stream divider simply splits a stream into two or more streams of the same composition. Consider Fig. 13-56, which shows the division of the condensed overhead liquid $L_c$ into distillate $D$ and reflux $L_{N+1}$. The divider is permitted to operate nonadiabatically if desired.

Three mass streams and one possible "energy stream" are involved, so

$$N_v^e = 3(C+2)+1 = 3C+7 \tag{13-95}$$

Each mass stream contributes $C+2$ variables, but an energy stream has only its rate $q$ as a variable. The independent restrictions are as follows:

| | $N_c^e$ |
|---|---|
| $T$ and $P$ identities between $L_{N+1}$ and $D$ | 2 |
| Composition identities between $L_{N+1}$ and $D$ | $C-1$ |
| Mass balances | $C$ |
| Energy balance | 1 |
| | $2C+2$ |

The number of design variables for the element is given by

$$N_i^e = N_v^e - N_c^e$$
$$= (3C+7) - (2C+2) = C+5 \tag{13-96}$$

Specification of the feed stream $L_c$ ($C + 2$ variables), the ratio $L_{N+1}/D$, the "heat leak" $q$, and the pressure of either stream leaving the divider uses these design variables and defines one unique operation of the divider.

A simple equilibrium stage (no feed or sidestreams) is depicted in Fig. 13-57. Four mass streams and a heat leak (or heat addition) stream provide the following number of variables:

$$N_v^e = 4(C+2)+1 = 4C+9 \tag{13-97}$$

Vapor and liquid streams $V_n$ and $L_n$, respectively, are in equilibrium with each other by definition and therefore are at the same $T$ and $P$. These two inherent identities when added to $C$-component balances, one energy balance, and the $C$ phase distribution relationships give

$$N_v^e = 2C+3 \tag{13-98}$$

Then

$$N_i^e = N_v^e - N_c^e \tag{13-99}$$
$$= (4C+9) - (2C+3) = 2C+6 \tag{13-100}$$

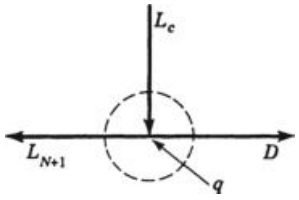

**FIG. 13-56** Stream divider.

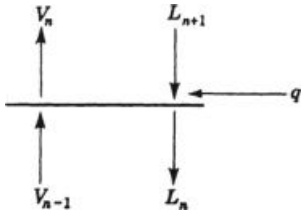

**FIG. 13-57** Simple equilibrium stage.

These design variables can be used as follows:

| Specifications | $N_i^e$ |
|---|---|
| Specification of $L_{n+1}$ stream | $C+2$ |
| Specification of $V_{n-1}$ stream | $C+2$ |
| Pressure of either leaving stream | 1 |
| Heat leak $q$ | 1 |
| | $2C+6$ |

The results of the analyses for all the various elements commonly encountered in distillation processes are summarized in Table 13-10. Details of the analyses are given by Smith (*Design of Equilibrium Stage Processes,* McGraw-Hill, New York, 1967) and in a somewhat different form by Henley and Seader (1981).

## ANALYSIS OF UNITS

A *unit* is defined as a combination of elements and may or may not constitute the entire process. By definition,

$$N_v^u = N_r + \sum_i N_i^e \tag{13-101}$$

and

$$N_i^u = N_v^u - N_c^u \tag{13-102}$$

where $N_c^u$ refers to *new* restricting relationships (identities) that may arise when elements are combined. Here $N_c^u$ does not include any of the restrictions considered in calculating the $N_i^e$'s for the various elements. It includes only the stream identities that exist in each interstream between two elements. The interstream variables $(C + 2)$ were counted in each of the two elements when their respective $N_i^e$'s were calculated. Therefore, $C + 2$ new restricting relationships must be counted for each interstream in the combination of elements to prevent redundancy.

The simple absorber column shown in Fig. 13-58 is analyzed here to illustrate the procedure. This unit consists of a series of simple equilibrium stages of the type in Fig. 13-57. Specification of the number of stages $N$ uses the single repetition variable and

$$N_c^u = N_r + \sum_i N_i^e = 1 + N(2C+6) \tag{13-103}$$

since $N_i^e = 2C + 6$ for a simple equilibrium stage in Table 13-10. There are $2(N - 1)$ interstreams, and therefore $2(N - 1)(C + 2)$ new identities (not previously counted) come into existence when elements are combined.

**TABLE 13-10 Design Variables $N_i^e$ for Various Elements**

| Element | $N_e^v$ | $N_e^c$ | $N_e^f$ |
|---|---|---|---|
| Homogeneous stream | $C+2$ | 0 | $C+2$ |
| Stream divider | $3C+7$ | $2C+2$ | $C+5$ |
| Stream mixer | $3C+7$ | $C+1$ | $2C+6$ |
| Pump | $2C+5$ | $C+1$ | $C+4$ |
| Heater | $2C+5$ | $C+1$ | $C+4$ |
| Cooler | $2C+5$ | $C+1$ | $C+4$ |
| Total condenser | $2C+5$ | $C+1$ | $C+4$ |
| Total reboiler | $2C+5$ | $C+1$ | $C+4$ |
| Partial condenser | $3C+7$ | $2C+3$ | $C+4$ |
| Partial reboiler | $3C+7$ | $2C+3$ | $C+4$ |
| Simple equilibrium stage | $4C+9$ | $2C+3$ | $2C+6$ |
| Feed stage | $5C+11$ | $2C+3$ | $3C+8$ |
| Sidestream stage | $5C+11$ | $3C+4$ | $2C+7$ |
| Adiabatic equilibrium flash | $3C+6$ | $2C+3$ | $C+3$ |
| Nonadiabatic equilibrium flash | $3C+7$ | $2C+3$ | $C+4$ |

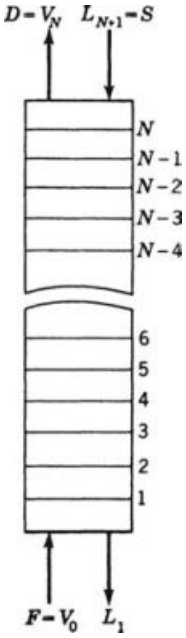

**FIG. 13-58** Simple absorption column.

Subtraction of these restrictions from $N_v^u$ gives $N_i^u$, the design variables that must be specified.

$$N_i^u = N_v^u - N_c^u = N_r + \sum_i N_i^e - N_c^u \tag{13-104}$$

$$= [1 + N(2C+6)] - 2[(N-1)(C+2)] \tag{13-105}$$

$$= 2C + 2N + 5 \tag{13-106}$$

These might be used as follows:

| Specifications | $N_i^u$ |
|---|---|
| Two feed streams | $2C+4$ |
| Number of stages $N$ | 1 |
| Pressure of either stream leaving each stage | $N$ |
| Heat leak for each stage | $N$ |
| | $2C+2N+5$ |

A more complex unit is shown in Fig. 13-59, which is a schematic diagram of a distillation column with one feed, a total condenser, and a partial reboiler. Dotted lines encircle the six connected elements (or units) that constitute the distillation operation. The variables $N_v^u$ that must be considered in the analysis of the entire process are just the sum of the $N_i^e$'s for these six elements since here $N_r = 0$. Using Table 13-10, we get the following:

| Element (or unit) | $N_v^u = \sum_i N_i^e$ |
|---|---|
| Total condenser | $C+4$ |
| Reflux divider | $C+5$ |
| $N-(M+1)$ equilibrium stages | $2C+2(N-M-1)+5$ |
| Feed stage | $3C+8$ |
| $M-1$ equilibrium stages | $2C+2(M-1)+5$ |
| Partial reboiler | $C+4$ |
| | $10C+2N+27$ |

Here, the two units of $N-(M+1)$ and $M-1$ stages are treated just as elements. Nine interstreams are created by the combination of elements, so

$$N_c^u = 9(C+2) = 9C + 18 \tag{13-107}$$

The number of design variables is

$$N_i^u = C + 2N + 9 \; N_v^u = (10C + 2N + 27) - (9C + 18) \tag{13-108}$$

$$= C + 2N + 9 \tag{13-109}$$

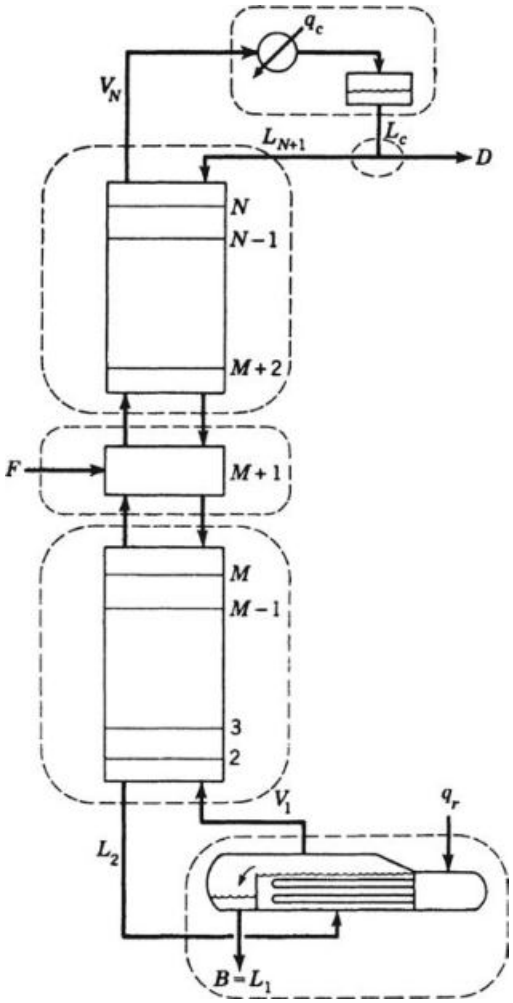

**FIG. 13-59** Distillation column with one feed, a total condenser, and a partial reboiler.

One set of specifications that is particularly convenient for computer solutions is the following:

| Specifications | $N_i^u$ |
|---|---|
| Pressure of either stream leaving each stage (including reboiler) | $N$ |
| Pressure of stream leaving condenser | 1 |
| Pressure of either stream leaving reflux divider | 1 |
| Heat leak for each stage (excluding reboiler) | $N-1$ |
| Heat leak for reflux divider | 1 |
| Feed stream | $C+2$ |
| Reflux temperature | 1 |
| Total number of stages $N$ | 1 |
| Number of stages below feed $M$ | 1 |
| Distillate rate $D/F$ | 1 |
| Reflux ratio $L_{N+1}/D$ | 1 |
| | $C+2N+9$ |

Other specifications often used in place of one or more of the last four listed are the fractional recovery of one component in either $D$ or $B$ and/or the composition of one component in either $D$ or $B$.

## OTHER UNITS AND COMPLEX PROCESSES

In Table 13-11, the number of design variables is summarized for several distillation-type separation operations, most of which are shown in Fig. 13-2. For columns not shown in Figs. 13-1 or 13-2 that involve additional feeds or sidestreams, add $C+3$ degrees of freedom for each additional feed ($C+2$ to define the feed and 1 to designate the feed stage) and 2 degrees of freedom for each sidestream (1 for the sidestream flow rate and 1 to designate the sidestream-stage location). Any number of elements or units can be combined to form complex processes. No new rules beyond those developed earlier are necessary for the analysis. Further examples are given in Henley and Seader (1981). An alternative method for determining the degrees of freedom for equipment and processes is given by Pham [*Chem. Eng. Sci.* **49:** 2507 (1994)].

**TABLE 13-11 Design Variables $N_i^u$ for Separation Units**

| Unit | $N_i^{u*}$ |
|---|---|
| Distillation (partial reboiler-total condenser) | $C+2N+9$ |
| Distillation (partial reboiler-partial condenser) | $C+2N+6$ |
| Absorption | $2C+2N+5$ |
| Rectification (partial condenser) | $C+2N+3$ |
| Stripping | $2C+2N+5$ |
| Reboiled stripping (partial reboiler) | $C+2N+3$ |
| Reboiled absorption (partial reboiler) | $2C+2N+6$ |
| Refluxed stripping (total condenser) | $2C+2N+9$ |
| Extractive distillation (partial reboiler–total condenser) | $2C+2N+12$ |

*$N$ includes reboiler, but not condenser.

# DISTILLATION SYSTEMS

Distillation systems for the separation of nonazeotropic mixtures are discussed in this subsection. Many of the results extend also to azeotropic mixtures when the desired splits do not try to break azeotropes or cross a distillation boundary.

Whenever we wish to separate a mixture into multiple products, various combinatorial possibilities of column arrangements are feasible, and the optimal (usually the least expensive) column configurations are sought. For example, there are at least two possible ways of separating a ternary mixture of components A, B, and C into pure-product streams (where A is the most volatile and C the least volatile component):

1. *Direct split*, where component A is separated from BC first (A/BC split) and then mixture BC is distilled to separate B from C
2. *Indirect split,* where C is removed first (AB/C) and then mixture AB is distilled

The difference in energy required for these splits can be assessed by simply comparing the total minimum vapor flows (summed over all the columns) for each column sequence. Example calculations were performed for a mixture with relative volatilities $\alpha_A = 4$, $\alpha_B = 2$, and $\alpha_C = 1$ containing 90 percent of A, 5 percent of B, and 5 percent of C in the feed stream. The indirect split requires 58 percent more energy than the direct split, assuming that columns are connected by a liquid stream in both cases. Moreover, the system using more energy requires bigger heat exchangers and larger column diameters, which increase the capital investment costs. Therefore, the direct split configuration would clearly be a better choice in this case.

One of the most important factors that determines the column configuration is the formulation (or goals) of the separation task with respect to the total flow sheet. Although a mixture may consist of $C$ components, it does not mean that all $C$ products are necessary. The components contained in streams recycled into the process (e.g., unreacted reactants recycled to the reactor) usually do not have to be separated from each other. Also, separation of streams that are later mixed (blended) should be avoided, if possible. The separation system needs to be optimized together with the entire plant, either simultaneously or in a hierarchical approach, as described by Douglas (*The Conceptual Design of Chemical Processes,* McGraw-Hill, New York, 1988).

Heuristic methods have been widely used for the synthesis of distillation sequences to avoid lengthy calculations. Many heuristics are intuitive, such as "Remove corrosive components first," "Remove the most plentiful components first," or "Remove the lightest component first." Since heuristics are just rules of thumb, they sometimes conflict with one another, and they may provide wrong answers even if they are not in conflict among themselves [Malone, Glinos, Marques, and Douglas, *AIChE J.* **31:** 683 (1985)]. More exact, algorithmic synthesis methods and cost optimization should be used in practice. The total energy of separation has been identified as the major component of the total cost. Energy-saving distillation schemes for light hydrocarbons with high levels of flexibility and operability were discussed by Petterson and Wells [*Chem. Eng.* **84**(20): 78, 1977]. Tedder and Rudd presented a three-part paper [*AIChE J.* **24:** 303 (1978)] in which they

compared eight distillation systems for the separation of ternary mixtures and determined the regions of economic optimality (with respect to feed compositions and relative volatilities). They proposed several heuristics for comparing various configurations. They evaluated several rank-order functions that allow for a comparison of various configurations without detailed cost calculations. Interestingly, one of the rank-order functions used successfully to compare various systems was the total minimum vapor flow. Minimum vapor flow will also be used to compare various distillation systems presented here. Finally, in the third part of their paper, Tedder and Rudd proposed a design method for various column networks.

In other approaches, Gomez-Munoz and Seader [*Comp. & Chem. Eng.* **9:** 311 (1985)] proposed an optimization algorithm based on maximum thermodynamic efficiency. However, Smith and Linhoff [*Chem. Eng. Res. Des.* **66:** 195 (1988)] pointed out the importance of a simultaneous design of the separation network and the rest of the process. They developed a pinch method based on the temperature–heat duty diagram to accomplish this task. Nishida, Stephanopoulos, and Westerberg [*AIChE J.* **27:** 321 (1981)] presented a comprehensive review of process synthesis, including distillation. Westerberg [*Comp. & Chem. Eng.* **9:** 421 (1985)] discussed methods for the synthesis of distillation systems that include sharp splits, nonsharp splits, thermal linking, and heat integration. Agrawal [*AIChE J.* **49:** 379 (2003)] presented a method for systematic generation of distillation configurations, including conventional and complex columns. Sorting through the alternatives and selecting the low-cost systems can be quite tedious, and it is best done with computer-aided optimization strategies such as those proposed by Caballero and Grossmann [*Ind. Eng. Chem. Res.* **40:** 2260 (2001)]. Giridhar and Agrawal [*Comp. & Chem. Eng.* **34:** 73 (2010)] divided possible column configurations ( for the separation of zeotropic $C$-component mixtures into almost pure components) into two groups: (1) basic configurations, having $(C-1)$ columns; (2) nonbasic configurations, having more than $(C-1)$ columns, where the same product is made from more than one place. They calculated minimum energy requirements and observed that basic configurations always contain the column sequence with the lowest heat duty. Therefore they concluded that nonbasic configurations are not the most energy efficient and should be eliminated from the search space, thus reducing the number of possible column sequences. More recently, Shah and Agrawal [*AIChE J.* **56:** 1759 (2010)] developed a simple-to-use matrix method for generating all basic configurations. They applied it to identify more than 70 new column configurations that can potentially have lower heat duty than existing petroleum crude distillation.

## POSSIBLE CONFIGURATIONS OF DISTILLATION COLUMNS

This subsection describes one possible way of generating the feasible configurations of distillation columns for separation of mixtures that do not form azeotropes. Components are named A, B, C, D, . . . , and they are listed in the order of decreasing volatility (or increasing boiling temperature). We limit our considerations to splits where the most volatile (lightest) component and the least volatile (heaviest) component do not distribute between the top and bottom products. For simplicity, we consider only separations where final products are relatively pure components. Systems containing simultaneously simple and complex distillation columns are considered. Simple columns are the conventional columns with one feed stream and two product streams; complex columns have multiple feeds and/or multiple product streams.

The combinatorial possibilities for separating a three-component mixture ABC into two product streams in which the most volatile component and the least volatile component do not distribute between the top and bottom products are

1. A/BC—Top product A is separated from bottom product BC.
2. AB/BC—Component B distributes between both product streams.
3. AB/C—Top product AB is separated from bottoms C.

These separations are also often referred to as splits; sharp splits (none of the components distribute) in cases 1 and 3, and a nonsharp split in case 2. When we add binary separations, the column configuration corresponding to split 1 is known as the direct split; the column configuration corresponding to split 2 is called the prefractionator system, and configuration 3 is called the indirect split (see Fig. 13-60). In the prefractionator system, the binary columns separating components AB and BC may be stacked together, forming one column with three products A, B, and C as indicated by the dashed envelope in Fig. 13-60*b*. These systems are called here the *basic column configurations*. Basic column configurations are configurations in which the types of interconnecting streams are not defined. (Note that this is a different definition of basic configuration than the one used by Giridhar and Agrawal [*Comp. & Chem. Eng.* **34:** 73 (2010)].) The arrows on the flow sheets symbolize the net material flow, but the types of streams connecting the columns (liquid, vapor, two-phase, multiple streams) are not specified. Reboilers and condensers are deliberately not shown in Fig. 13-60 because for some types of interconnecting streams they are not necessary.

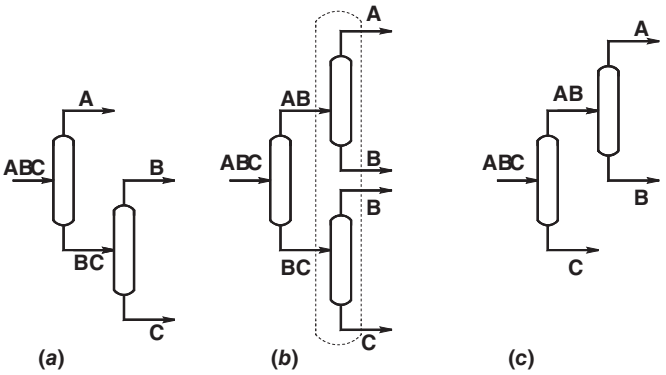

**FIG. 13-60** Basic column configurations. (*a*) Direct split. (*b*) Prefractionator system. (*c*) Indirect split.

Symbolic-network representations of these separation systems, called *state-task networks* (STNs), are shown in Fig. 13-61. In this representation, the states ( feeds, intermediate mixtures, and products) are represented by the nodes (ABC, AB, BC, A, B, C) in the network, and the tasks (separations) are depicted as lines (1, 2, . . . , 6) connecting the nodes, where arrows denote the net flow of material. This STN representation was used by Sargent to represent distillation systems [*Comp. & Chem. Eng.* **22:** 31 (1998)] and has been widely used ever since. Originally STNs were introduced by Kondili, Pantelides, and Sargent [*Comp. & Chem. Eng.* **17:** 211 (1993)] for representing batch processes.

Interconnecting streams may be liquids, vapors, or two-phase mixtures. The total energy of separation can be minimized for the direct split if the two columns have a liquid connection; for the indirect split, it is minimized if the columns have a vapor connection, and for the prefractionator system if the top connection is vapor and the bottom connection is liquid. See Fidkowski and Krolikowski [*AIChE J.* **33:** 643 (1987); **36:** 1275 (1990)].

A complete direct split configuration, including reboilers and condensers, is shown in Fig. 13-62*a*. The numbers used to represent the column sections in this figure correspond to the numbers used to represent the tasks in the STN (Fig. 13-61*a*). By eliminating the reboiler from the first column in Fig. 13-62*a* and supplying the boil-up from the second column, we obtain the side rectifier arrangement, shown in Fig. 13-62*b*. An alternative side rectifier arrangement is seen more clearly in Fig. 13-62*c*, where the stripping section of the binary BC column (section 4) has been moved and lumped with the first column. Note that all these three configurations can be represented by one state-task network, shown in Fig. 13-61*a*. In each configuration in Fig. 13-62, feed ABC is separated in section 1 to get component A and in section 2 to get mixture BC. Then mixture BC is further separated in section 3 to give component B and in section 4 to produce C. Therefore, all these three systems are topologically equivalent to the same basic column configuration represented by the STN in Fig. 13-61*a* and the column arrangement in Fig. 13-60*a*. However, if we take into account reboilers and condensers, we see that only the two side rectifier configurations (Fig. 13-62*b* and *c*) are topologically equivalent. Side stripper configurations can be obtained from the indirect split in an analogous way (Fig. 13-63*a, b,* and *c*).

By eliminating the reboiler and condenser in the prefractionator column in Fig. 13-64*a* (the column containing sections 1 and 2), we obtain a *thermally coupled system*, also known as a Petlyuk system, shown in Fig. 13-64*b* [Petlyuk, Platonov, and Slavinskii, *Int. Chem. Eng.* **5:** 555 (1965)]. Side stripper, side rectifier, and Petlyuk systems can also be built as divided wall columns, as explained in detail in the following subsection on thermally coupled systems.

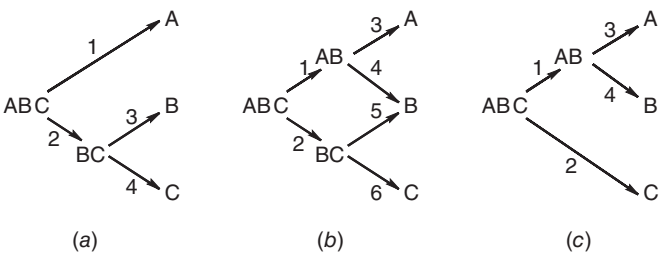

**FIG. 13-61** State-task networks. (*a*) Direct split. (*b*) Prefractionator system. (*c*) Indirect split.

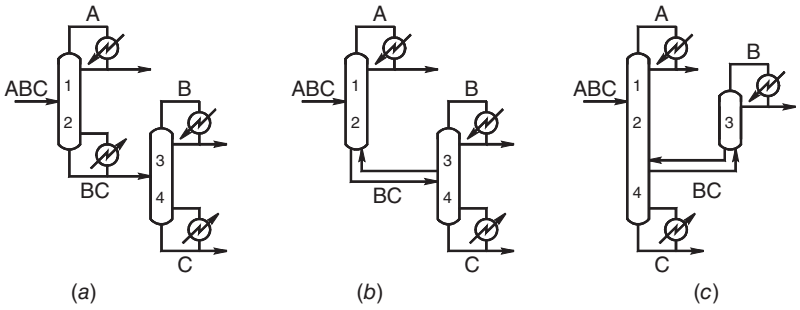

**FIG. 13-62** (*a*) Direct split configuration. (*b*), (*c*) Side rectifier configurations.

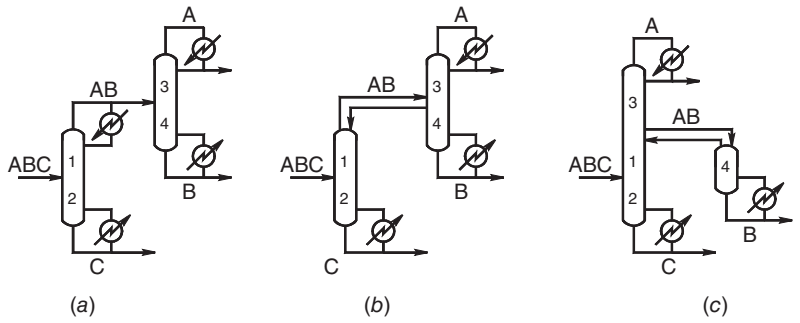

**FIG. 13-63** (*a*) Indirect split configuration. (*b*), (*c*) Side stripper configurations.

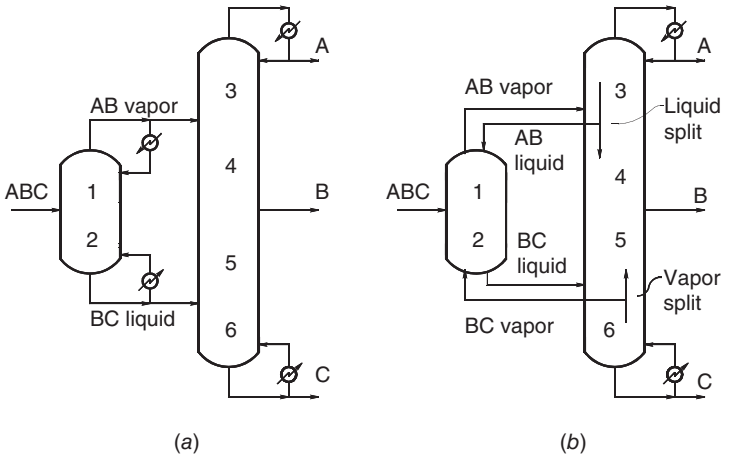

**FIG. 13-64** (*a*) Prefractionator system. (*b*) Thermally coupled system.

There are many other possible ternary column systems that have different interconnecting streams between the columns. For example, if we eliminate only the reboiler (or only the condenser) from the prefractionator column in Fig. 13-64*a,* we obtain a partially thermally coupled system [Agrawal and Fidkowski, *AIChE J.* **45:** 485 (1999), U.S. Patent 5,970,742]. In other instances, one may significantly increase the thermodynamic efficiency of the direct split and the indirect split if a portion of the interconnecting stream is vaporized and fed to the second column below the liquid connection [Agrawal and Fidkowski, *Ind. Eng. Chem. Res.* **38:** 2065 (1999)].

There are six possible types of splits for a quaternary mixture. The ternary mixtures resulting from these splits may be separated in one of the three possible ternary splits, as described previously. Table 13-12 summarizes the resulting number of possible basic column configurations. This number does not account for the various possible types of interconnecting streams.

This method of generating various column configurations [Fidkowski, *AIChE J.* **52:** 2098 (2006)] is very similar to the methods used previously for conventional systems; see, for example, Rathore, Van Wormer, and Powers [*AIChE J.* **20:** 491 (1974); **20:** 940 (1974)]. The only difference is that in addition to sharp splits, the nonsharp splits are included here, which leads to unconventional systems. Similar methods were proposed by Rong et al. [Rong, Kraslawski, and Turunen, *Ind. Eng. Chem. Res.* **42:** 1204 (2003)] to generate all the possible quaternary thermally coupled configurations.

The basic column configurations for all 22 quaternary distillation systems are shown in Fig. 13-65. Five of these configurations consist of only sharp splits; hence each species appears in only one product stream. Seventeen of the configurations have at least one nonsharp split, which results in each distributing component appearing in product streams from two different locations. Again, the interconnecting streams could be liquid,

**TABLE 13-12 Number of Basic Column Configurations for Separation of a Four-Component Mixture**

| Split | Distillate/bottoms | Number of configurations |
|---|---|---|
| 1 | A/BCD | 3 |
| 2 | AB/BCD | 3 |
| 3 | AB/CD | 1 |
| 4 | ABC/BCD | $3 \times 3 = 9$ |
| 5 | ABC/CD | 3 |
| 6 | ABC/D | 3 |
| | Total | 22 |

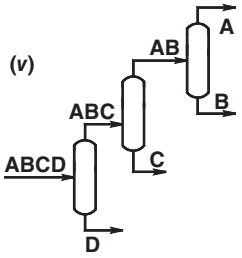

**FIG. 13-65** (*Continued*)

vapor, two-phase, or two-way liquid and vapor, as in thermally linked columns. There might also be several alternatives for column stacking, which increases the number of possible configurations even further. Subsequently, one can analyze possible splits for a five-component mixture, and so on. These splits create quaternary and ternary products that can be further separated by one of the column configurations we have discussed.

## THERMALLY COUPLED SYSTEMS AND DIVIDING WALL COLUMNS

In recent years there has been significant interest in thermally coupled systems and dividing wall columns for ternary mixtures. In this subsection we discuss such column arrangements, their energy requirements, design and optimization methods, controllability and operability, experimental and industrial experience, and extension to more than three components.

Two columns are thermally coupled if a vapor (liquid) stream is sent from the first column to the second column and then a return liquid (vapor) stream is implemented between the same locations. These streams, when introduced at the top or bottom of a column, provide (at least partial) reflux or boil-up to this column.

The development of thermally coupled systems started with attempts to find energy-saving schemes for the separation of ternary mixtures into three products. One of the first industrial applications was the side rectifier configuration for air separation. The side stripper configuration followed naturally. By combining the two, we obtain the fully thermally coupled system of Petlyuk, Platonov, and Slavinskii [*Int. Chem. Eng.* **5:** 555 (1965)]; see Fig. 13-64*b*. It consists of the prefractionator that accepts the ternary feed stream followed by the main column that produces the products (product column).

The dividing wall column was invented as a way of producing three pure products from a single column [Monro, U.S. Patent 2,134,882 (1933); Wright, U.S. Patent 2,471,134 (1949)]. In some cases it is possible to achieve high purity of the intermediate component in the sidestream of a distillation column. This is possible when the sidestream is withdrawn above the feed as a liquid or below the feed as a vapor and when the relative volatilities of components differ significantly. In many applications, however, a sidestream is contaminated to an appreciable extent by either the light or the heavy component. For example, if a sidestream is withdrawn from the rectifying section, it must contain not only the intermediate component but also some of the most volatile component. This contamination problem can be eliminated by adding a dividing wall that prevents the most volatile component (and the heaviest component) from entering the zone where the intermediate component is withdrawn; see Fig. 13-66.

The dividing wall column is topologically equivalent to the fully thermally coupled system (Fig. 13-64*b*). The prefractionator and the main product column are built in one shell, separated by a dividing wall (Fig. 13-66*c*). Similarly, the side rectifier (Fig. 13-62*c*) and side stripper (Fig. 13-63*c*) configurations can be built in one shell as dividing wall columns [Agrawal, *Ind. Eng. Chem. Res.* **40:** 4258 (2001)]. The corresponding dividing wall columns are shown in Fig. 13-66*a* and *b,* respectively. The corresponding sections in the thermally coupled systems and the dividing wall columns have exactly the same numbers and perform exactly the same separation tasks, indicating that the column arrangements are topologically equivalent.

Various design, simulation, and evaluation methods have been developed for the distillation systems shown in Figs. 13-62 to 13-64. These include those by Stupin and Lockhart [*Chem. Eng. Prog.* **68**(10): 71 (1972)]; Fidkowski and Krolikowski [*AIChE J.* **32:** 537 (1986)]; Nikolaides and Malone [*Ind. Eng. Chem. Res.* **27:** 811 (1988)]; Rudd [Distillation Supplement to *The Chemical Engineer*, S14 (1992)]; Triantafyllou and Smith [*Trans. Inst. Chem. Eng.* **70**(Part A): 118 (1992)]; Finn [*Gas Sep. Purif.* **10:** 169 (1996)]; Annakou and Mizsey [*Ind. Eng. Chem. Eng.* **35:** 1877 (1996)]; Hernandez and Jimenez [*Comp. & Chem. Eng.* **23:** 1005 (1999)]; Dunnebier and Pantelides [*Ind. Eng. Chem. Res.* **38:** 162 (1999)]; Watzdorf, Bausa, and Marquardt [*AIChE J.* **45:** 1615 (1999)]; and Kim [*J. Chem. Eng. Japan*, **34:** 236 (2001)]. The fully thermally coupled system uses less energy than any other ternary column configuration [Fidkowski and Krolikowski, *AIChE J.* **33:** 643–653 (1987)]. The energy savings may be on the order of 30 to 50 percent, depending on the feed composition and volatilities of the components. Similar energy savings are possible in partially thermally coupled columns, where only one connection (top or bottom) between the columns is thermally coupled and the other is just a single liquid or vapor stream together with an associated condenser or reboiler, respectively [Agrawal and Fidkowski, *AIChE J.* **45:** 485 (1999)]. Fidkowski and Krolikowski [*AIChE J.* **32:** 537 (1986)] solved analytically the optimization problem for the minimum vapor boil-up rate from the reboiler in the main column for the fully thermally coupled system (shown in Fig. 13-64*b*), assuming constant molar overflow and constant relative volatilities among the components. The solution depends on the splits of vapor and liquid between the main product column and the prefractionator [or between both sides of the dividing wall (Fig. 13-66*c*)]. The minimum vapor flow for each column in the system is shown in Fig. 13-67 as a function of β, where the parameter β is defined as the fractional recovery of the distributing component B in the top product of the prefractionator

$$\beta = \frac{V_1 y_B - L_1 x_B}{f_B} \tag{13-110}$$

where $V_1$ and $L_1$ are the vapor and liquid flows at the top of the prefractionator (section 1), $y_B$ and $x_B$ are corresponding mole fractions of component B, and $f_B$ denotes the molar flow of component B in the feed stream. The lower line in Fig. 13-67 is the minimum vapor flow in the first column, the prefractionator. At $\beta = 0$, it corresponds to the A/BC split and at $\beta = 1$ to the AB/C split.

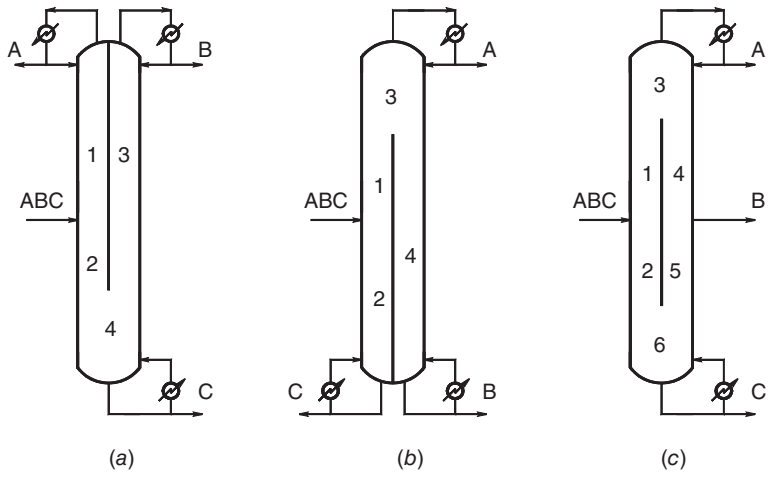

**FIG. 13-66** Dividing wall columns equivalent to (*a*) side rectifier configuration, (*b*) side stripper configuration, (*c*) thermally coupled system.

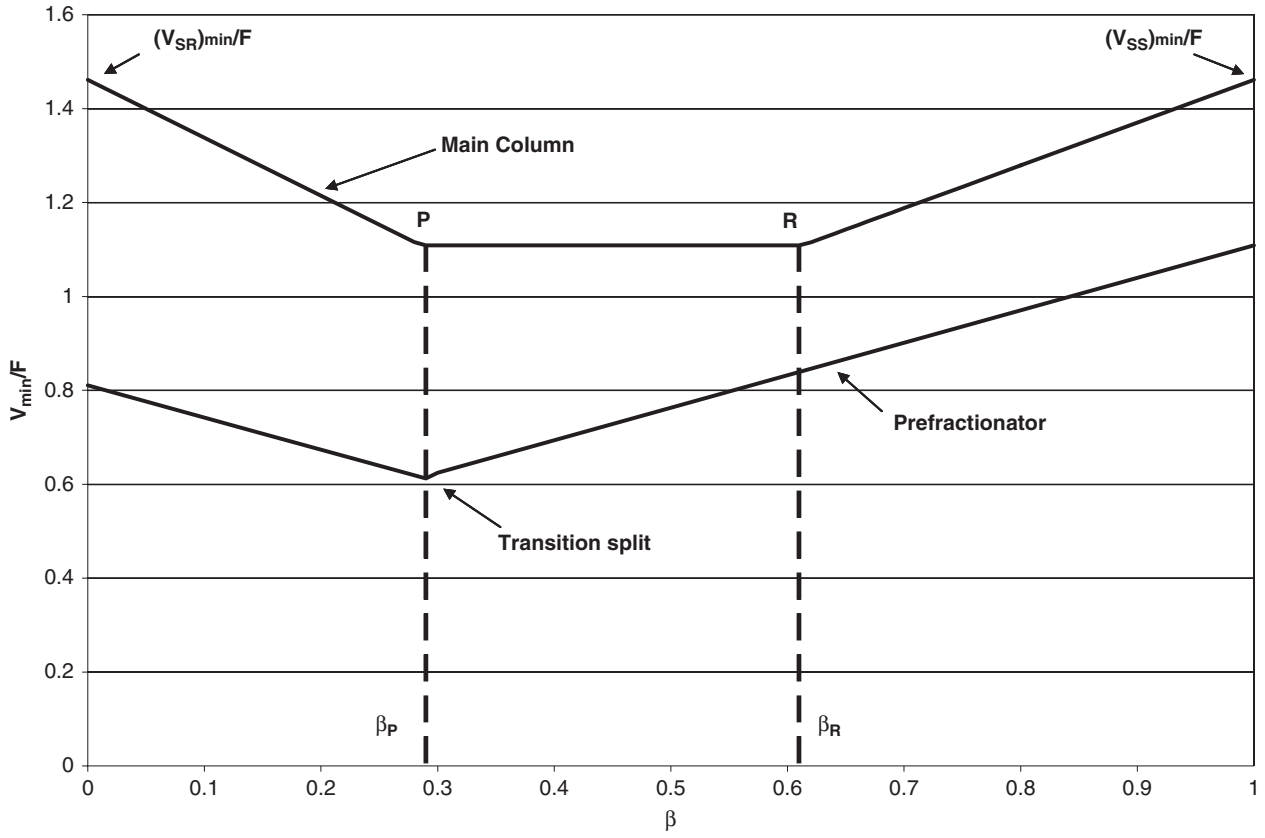

**FIG. 13-67** Minimum vapor flows in the thermally coupled system; bottom curve, minimum vapor flow in prefractionator; top curve, minimum vapor flow from the reboiler of the main column (total minimum vapor flow for entire system) for $\alpha_A = 6.25$, $\alpha_B = 2.5$, $\alpha_C = 1.0$ and feed mole fractions $z_A = 0.33$, $z_B = 0.33$, and $z_C = 0.34$.

There is a minimum in the minimum vapor flow in the prefractionator for $\beta = \beta_P$, the so-called transition split; $\beta_P$ can be calculated as

$$\beta_P = \frac{\alpha_B - \alpha_C}{\alpha_A - \alpha_C} \tag{13-111}$$

where the $\alpha$'s are relative to any reference component.

The transition split divides direct-type splits from indirect-type splits as discussed by Doherty and Malone (*Conceptual Design of Distillation Systems*, 2001, chaps. 4 and 5); also see Fidkowski, Doherty, and Malone [*AIChE J.* **39:** 1301(1993)]. The upper line in Fig. 13-67 is the minimum vapor flow leaving the reboiler of the main column, which also corresponds to the minimum vapor flow for the entire system since all the vapor for the total system is generated by this reboiler. For $\beta = 0$, the minimum vapor flow for the entire thermally coupled system (i.e., main column) becomes equal to the minimum vapor flow for the side rectifier system (i.e., main column of the side-rectifier system; see Fig. 13-62*b* or *c*) $(V_{SR})_{min}$; for $\beta = 1$ it is equal to the minimum vapor flow of the entire side stripper system $(V_{SS})_{min}$ (which is the sum of the vapor flows from both reboilers in this system; see Fig. 13-63*b* or *c*). Coincidentally, the values of these two minimum vapor flows are always the same: $(V_{SR})_{min} = (V_{SS})_{min}$. For $\beta = \beta_R$ the main column is pinched at both feed locations; that is, the minimum vapor flows for separations A/B and B/C are equal.

The minimum vapor flow for the entire thermally coupled system is flat over a wide range of $\beta$: $\beta_P \le \beta \le \beta_R$. This is the reason why dividing wall columns usually work well without tight control of the vapor or liquid split between both sides of the partition. The optimally designed fully thermally coupled system should operate with a fractional recovery of B in the top product of the prefractionator placed somewhere between points *P* and *R*. The transition split *P* is located at one end of the optimal section *PR,* and it is not a recommended design point for normal operation because process disturbances may move the operating point outside the optimal section *PR* shown in Fig. 13-67.

Although invented long ago, dividing wall columns and fully thermally coupled distillation systems were not implemented in practice until the late 1980s. The major objections concerned controllability and operability. More recently, however, several papers have shown that control of these systems is possible; see Hernandez and Jimenez [*Ind. Eng. Chem. Res.* **38:** 3957 (1999)]; Mutalib, Zeglam, and Smith [*Trans. Inst. Chem. Eng.* **76:** 319 (1998)]; and Halvorsen and Skogestad [*Comp. Chem. Eng.* **21,** Suppl., S249 (1997)]. A major control problem was attributed to an inability to set the vapor split between the main column and prefractionator due to conflicting pressure drop requirements between sections 6 and 2, as well as sections 1 and 3 in Fig. 13-64*b.* For the BC vapor to flow from section 6 to section 2, the pressure in the main column at the top of section 6 must be *higher* than the pressure in the prefractionator at the bottom of section 2. But the pressure at the bottom of section 3 in the main column must be *lower* than the pressure at the top of section 1 in the prefractionator, or else the AB vapor stream will not flow from the prefractionator to the main column. Liquid split control is easier to realize in practice by using liquid collectors, overflows, or pumps. How much vapor flows straight up the main column and how much vapor splits off to the prefractionator depends on the pressure drops in the middle sections of the main column (sections 4 and 5 in Fig. 13-64*b,* between the interconnecting streams) and in the prefractionator. These pressure drops depend on the height of these sections, the type of packing or stages, and liquid flows. Therefore, these pressure drops cannot be easily controlled in the configuration shown in Fig. 13-64*b;* moreover, they may even be such that vapor flows in the wrong direction.

Agrawal and Fidkowski [*AIChE J.* **44:** 2565 (1998); U.S. Patent 6,106,674] proposed robustly operable two-column configurations that cleverly overcome this design and control problem. One is shown in Fig. 13-68. This new configuration is topologically equivalent to the original thermally coupled configuration in Fig. 13-64*b* and retains its energy advantage. In the new Agrawal and Fidkowski configuration, column section 6 is just shifted from the product column to the bottom of the prefractionator; thus the two interconnecting vapor streams flow in the *same direction*. The first column (with sections 1, 2, and 6) in Fig. 13-68 operates at a slightly higher pressure than the second column, and the relative flows of the vapor streams can be changed by using a valve on one of them, as shown in the figure. The Agrawal and Fidkowski thermally coupled systems are expected to have higher investment cost than dividing wall columns, and the same investment cost as a Petlyuk thermally coupled system. However, for certain feed compositions and volatilities, the

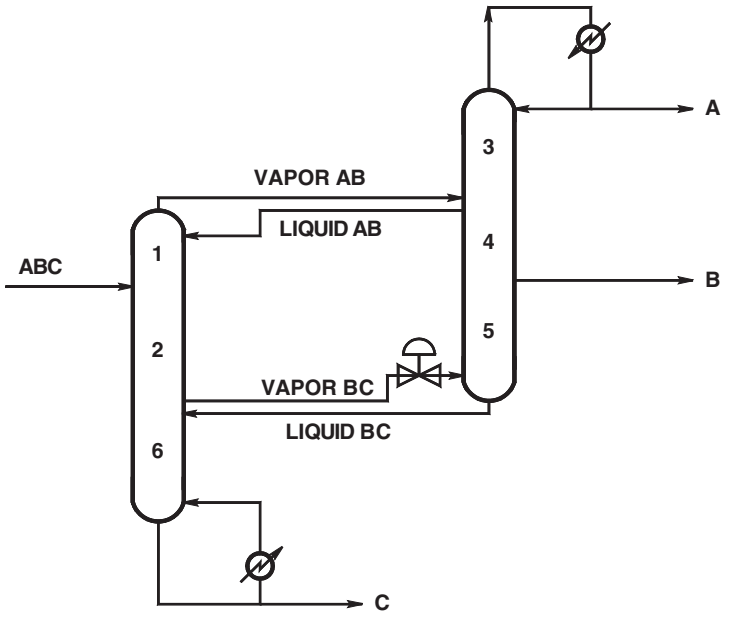

**FIG. 13-68** Agrawal and Fidkowski thermally coupled system (topologically equivalent to the Petlyuk system shown in Fig. 13-64*b*).

energy optimum in Fig. 13-67 may be narrow (i.e., the interval *PR* may be short), and dividing wall columns may not be able to operate at the optimum. On the other hand, the Agrawal and Fidkowski configurations can operate at the optimum because of better control. Also, the Agrawal and Fidkowski configurations are useful in cases where high-purity products (especially B) are required. This is so because the two columns are built in separate shells that may contain more stages in one of the shells than could be accommodated in the corresponding side of the dividing wall column.

Experimental tests of dividing wall columns were carried out by Mutalib, Zeglam, and Smith [*Trans. Inst. Chem. Eng.* **76:** 319 (1998)]. Today there are about 60 dividing wall columns in operation; 42 are owned by BASF [Parkinson, *CEP* (2005, July), p. 10].

Thermally coupled systems can also be devised for multicomponent mixtures. Sargent and Gaminibandara (in *Optimization in Action*, ed. L. W. C. Dixon, Academic Press, London, 1976, p. 267) presented a natural extension of the Petlyuk column sequence to multicomponent systems. Agrawal [*Ind. Eng. Chem. Res.* **35:** 1059 (1996); *Trans. Inst. Chem. Eng.* **78:** 454 (2000)] presented a method for generating an even more complete superstructure from which all the known column configurations (including thermally coupled systems) can be derived. Fidkowski and Agrawal [*AIChE J.* **47:** 2713 (2001)] presented a method for calculating the minimum vapor flows in multicomponent thermally coupled systems. They analyzed the quaternary fully thermally coupled system in detail (there are many equivalent column configurations, all with the minimum number of column sections, which is 10, as well as one reboiler and one condenser; one of the configurations is shown in Fig. 13-69). They showed that one of the optimum solutions (with the minimum value of the total minimum vapor flow rate from the single reboiler in the system) occurs when the quaternary feed column ( far left column in Fig. 13-69) and both ternary columns (the two middle columns in Fig. 13-69) perform transition splits. They also concluded that the optimized quaternary fully coupled system always requires less energy than the five sharp-split conventional systems (where each column performs a sharp split and has one feed, two products, one reboiler, and one condenser). The basic configurations for these five sharp-split systems are shown in Fig. 13-65*a, c, g, t,* and *v*. Selecting the best thermally coupled column configuration can be tedious without computer-aided tools

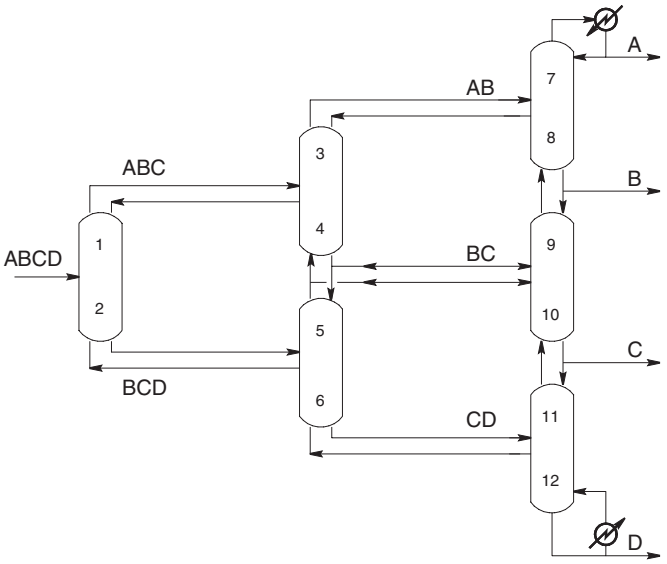

**FIG. 13-69** One configuration of a fully thermally coupled system for separation of a quaternary mixture.

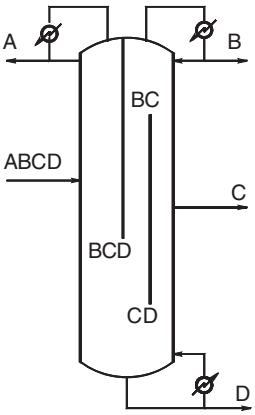

**FIG. 13-70** One possible dividing wall column for separation of a quaternary mixture.

such as the disjunctive programming approach developed by Caballero and Grossmann [*Ind. Eng. Chem. Res.* **40:** 2260 (2001)].

All the multicomponent thermally coupled configurations have a corresponding dividing wall column equivalent. Keibel [*Chem. Eng. Technol.* **10:** 92 (1987)] has shown examples of columns with multiple dividing walls, separating three, four, and six components. Agrawal [*Ind. Eng. Chem. Res.* **40:** 4258 (2001)] presented several examples of quaternary columns with partitions and multiple reboilers and condensers. One of these examples is shown in Fig. 13-70.

## THERMODYNAMIC EFFICIENCY

Thermodynamic efficiency can be a useful figure of merit (in place of total cost, or total vapor rate) for comparing alternative column configurations. This is especially true for cryogenic distillations where very low temperatures are necessary and where highly efficient "cold box" designs are needed to achieve them. The thermodynamic efficiency of thermally coupled and other distillation systems for the separation of ternary mixtures was analyzed by Agrawal and Fidkowski [*Ind. Eng. Chem. Res.* **37:** 3444 (1998)]. Feed composition regions for column configurations with the highest thermodynamic efficiency are shown in Fig. 13-71. Often, the efficiency of the direct split or the indirect split is better than the efficiency of thermally coupled systems. This is primarily due to the ability of these configurations to accept

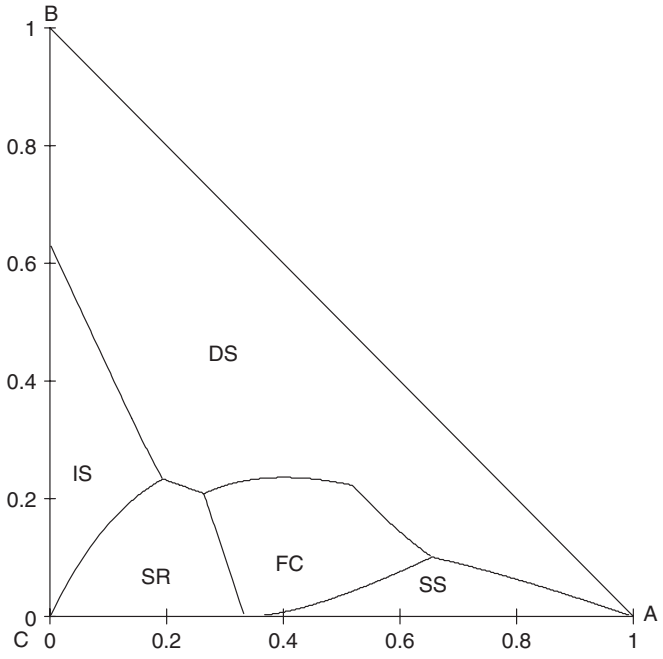

**FIG. 13-71** Feed composition regions of column configurations with highest thermodynamic efficiency; DS—direct split, IS—indirect split, SR—side rectifier, SS—side stripper, FC—fully thermally coupled. Example for $\alpha_A = 4.0$, $\alpha_B = 2.0$, and $\alpha_C = 1.0$.

or reject heat at the intermediate boiling or condensing temperatures of the binary submixtures. The fully thermally coupled system can only accept heat at the temperature of the highest-boiling component (boiling point of C) and reject heat at the lowest temperature (condensation temperature of A). This conclusion gave rise to new, more thermodynamically efficient thermally coupled configurations, as discussed by Agrawal and Fidkowski [*Ind. Eng. Chem. Res.* **38:** 2065 (1999); U.S. Patent 6,116,051].

## HEAT INTEGRATION

In this subsection we describe heat pumps, the multieffect distillation of binary mixtures, the synthesis of multicomponent distillation systems with heat integration, and multieffect distillation for thermally coupled configurations.

Two columns are heat-integrated when they exchange heat indirectly through a heat exchanger. This is different than in thermally linked configurations, where the heat exchange between columns is direct, through the material stream connecting the columns. The objective of heat integration in distillation systems is to save energy. Heat integration is realized by matching heat sources (usually condensers) with heat sinks (usually reboilers). The other heat exchangers considered for heat integration might be feed preheaters and product coolers. Typical examples of heat integration schemes are heat transfer from a condenser to a reboiler, or heat exchange between a (hot) column feed and a reboiler. If the temperature of the heat source (condenser) is higher than the temperature of the heat sink (reboiler), the opportunity for the match is straightforward. If the condenser temperature is too low, one may increase the condensing pressure or use a heat pump.

For example, the reboiler and condenser from the same column may be heat-integrated by using a heat pump, as discussed by Null [*Chem. Eng. Prog.* **72**(7): 58 (1976)]. A heat pump may use an external fluid that is vaporized in the condenser, then compressed and condensed in the column reboiler (Fig. 13-72*a*). Another heat pump (Fig. 13-72*b*) uses column overhead vapor, which is compressed and condensed in the reboiler and then returned to the top of the column as reflux. A third possibility is to use the column bottoms, which is let down in pressure and vaporized in the condenser, then compressed and fed back to the bottom of the column as boil-up (Fig. 13-72*c*).

The entire rectifying section can be pressurized, and the heat can be transferred between any desired stages of the rectifying and stripping sections. This is called *secondary reflux and vaporization* (SRV) distillation. It reduces the consumption of both hot and cold utilities and reduces the sizes of the reboiler and condenser. However, capital cost is increased by additional intermediate heat exchangers; moreover, since the process is more thermodynamically reversible, it requires more stages to achieve the desired separation.

In multiple-column systems, possibilities for heat integration may be created by increasing the pressure in one of the columns, to increase the temperature of the condenser. When the temperature of the condenser becomes higher than the temperature of some other column reboiler, it is possible to heat-integrate these streams via a heat exchanger and to reuse the heat rejected from the condenser. However, there are several drawbacks to this procedure. The required heat-transfer area in the integrated exchangers needs to be increased due to smaller temperature differences between the process streams than would normally exist when hot and cold external utilities are used to provide boil-up and condensation. Higher-pressure columns need hotter external heating utilities that are more expensive. Separation in higher-pressure columns is more difficult (because relative volatilities tend to decrease with increasing pressure), and more stages and energy may be required. Finally, higher-pressure column shells and piping may be more expensive, although this is not always certain, since the overall dimensions decrease with pressure.

One of the first industrial applications of heat-integrated distillation was a double column for air separation, developed by Linde in the beginning of the 20th century (Fig. 13-73). Air is compressed (typically to about 6 bar) and fed in the bottom of the high-pressure column. Nitrogen is condensed at the top of the high-pressure column. The heat of condensation provides boil-up to the low-pressure column by vaporizing oxygen in the sump located above the nitrogen condenser. Another industrial example of heat integration occurs in the large-scale methanol-water separation in the production of methanol from synthesis gas; see Siirola [*Adv. Chem. Eng.* **23:** 1 (1996)]. Several alternative designs were evaluated, and the regions of superior cost were developed on volatility-feed composition diagrams. Three heat-integrated designs were better than a single column:

1. *Split feed configuration*, in which the feed is split between the high-pressure and the low-pressure columns
2. *Sloppy first bottom split, second column pressurized*, in which the bottom from the first column is further separated in the high-pressure column
3. *Sloppy first bottom split, first column pressurized*, in which the bottom from the first, high-pressure column is further separated in the low-pressure column

These heat-integrated systems were economically advantageous because of the large feed flow rate. The last configuration was built.

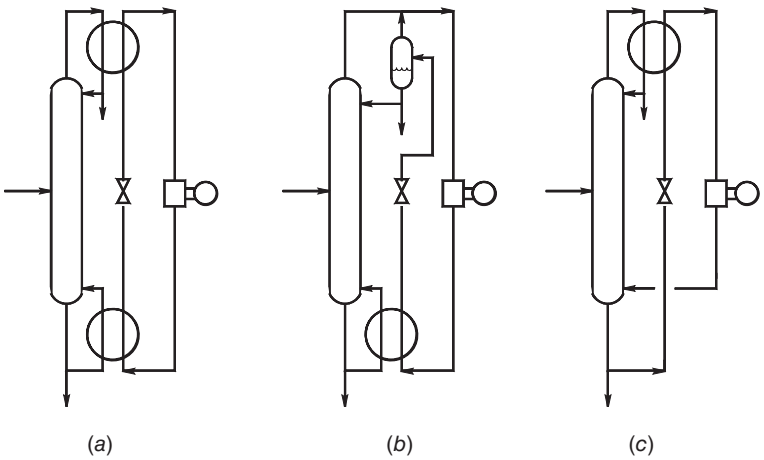

**FIG. 13-72** Heat pumps transfer heat from the top to the bottom of the column. (*a*) External fluid heat pump. (*b*) Heat pump using column overhead. (*c*) Heat pump using column bottoms.

Design heuristics and computer-aided design methods for heat-integrated distillation systems have been developed in many publications. Wankat [*Ind. Eng. Chem. Res.* **32:** 894 (1993)] analyzed 23 different multieffect distillation systems obtained by dividing a single column into two or three columns and operating them at various pressures or compositions, to obtain the temperatures necessary for heat integration. He developed heuristics to devise a feasible system. Rathore, Van Wormer, and Powers [*AIChE J.* **20:** 491 (1974) and **20:** 940 (1974)] presented an algorithmic synthesis method for multicomponent separation systems with energy integration. The five-component separation problem was solved by decomposing it into all the possible sharp splits and then examining all the possible integrations of heat exchangers. Thermally coupled systems, however, were not considered. Umeda, Niida, and Shiriko [*AIChE J.* **25:** 423 (1979)] published a thermodynamic approach to heat integration in distillation systems based on pinching heat source and heat sink curves on the temperature–heat duty diagram. Linhoff and coworkers (*A User Guide on Process Integration for the Efficient Use of Energy*, Institution of Chemical Engineers, Rugby, UK, 1982) developed the very successful *pinch technology* approach, commonly used for heat exchanger synthesis and heat integration of entire plants. But, most successfully, Andrechowich and Westerberg [*AIChE J.* **31:** 1461 (1985)] presented a simple conceptual design approach wherein temperature-enthalpy diagrams are used to select the best column stacking. This design method is the recommended starting point for heat integration studies.

Even thermally coupled systems can be heat-integrated, as discovered by Agrawal [*AIChE J.* **46:** 2211 (2000)]. To achieve heat integration without compressors, the vapor connections between the columns must be eliminated. This is shown in Fig. 13-74*a*. The configuration is constructed by extending the prefractionator to a full column with a reboiler and condenser, and adding sections 3x and 6x (analogous to sections 3 and 6 in the product column). By balancing heat duties, only liquid interconnecting streams remain, and the configuration is still thermodynamically equivalent to the original thermally coupled system (Fig. 13-64*b*). The new thermally coupled system with liquid connections only is easier to control than the original thermally coupled system because there is no need to control the internal split of the vapor flow. On a side note, Ramapriya et al. [*AIChE J.* **60:** 2949 (2014)] also developed dividing wall column schemes equivalent to this thermally coupled system with liquid connections only. It is now possible to heat-integrate the columns by pressurizing one of them and allowing heat transfer from the high-pressure condenser to the low-pressure reboiler (Fig. 13-74*b*). The thermally coupled system and dividing wall column are equally energy efficient. Therefore, the thermally coupled system with heat integration is even more energy efficient than the dividing wall column.

There is a significant cost associated with heat integration (e.g., for heat pump compressors, taller columns with more stages, thicker walls of high-pressure equipment, higher cost of high-temperature utilities), which is why such configurations are not widely used. The operational flexibility of a heat-integrated system also becomes more constrained. However, heat-integrated systems can be quite economical for some applications. Typical applications where heat-integrated systems are preferred include

- Cryogenic separation, where very low-temperature cooling utilities do not exist and need to be created, which is very expensive. Therefore, it makes sense to reuse the expensive refrigeration.
- Very large-scale processes, with large feed and product flow rates. Because of the large feed rate, multiple columns may be required to process a given feed, anyway. These cases have the potential to save a lot of energy due to heat integration. Also, pressurizing some equipment in these large-scale processes allows for decreased equipment sizes or increased production rates at a fixed equipment size.

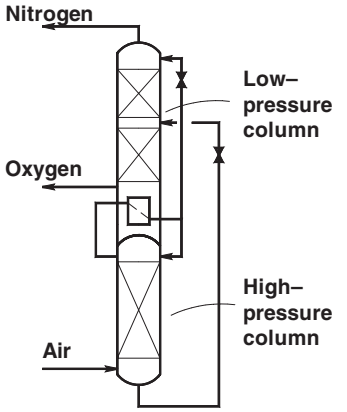

**FIG. 13-73** Double-column arrangement for air separation.

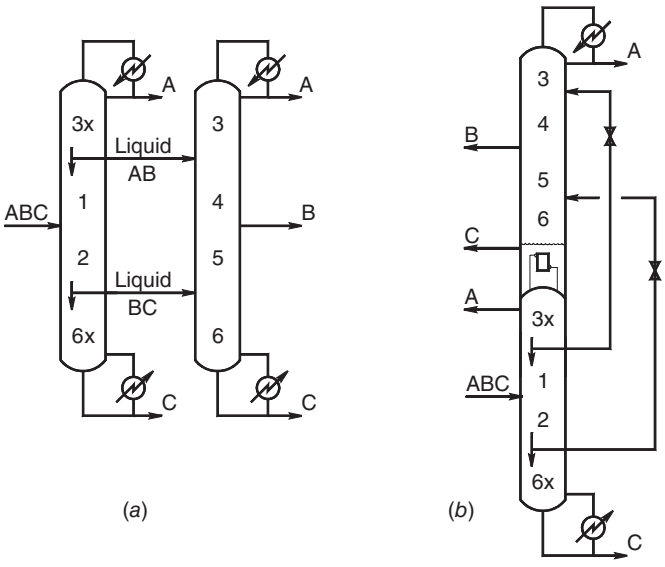

**FIG. 13-74** (*a*) Configuration equivalent to thermally coupled system, but without vapor interconnecting streams. (*b*) Heat-integrated thermally coupled system.

### IMBALANCED FEEDS

In many practical cases, feed compositions are far from equimolar, with some components present in very small amount (e.g., less than 2 percent). In these cases the top or bottom product flow rate is less than 2 percent of the feed flow rate. The design for imbalanced feeds may include

- Various column diameters
- Intermittent pumping of heavies from the reboiler
- Intermittent firing up a specially devoted column to purify the dirty product made at a small rate
- In a continuous operation, an overrefluxed section (to keep the column diameter the same over the height of the column)
- Producing an impure product to be purified later or discarded

## ENHANCED DISTILLATION

In distillation operations, separation results from differences in vapor- and liquid-phase compositions arising from the partial vaporization of a liquid mixture or the partial condensation of a vapor mixture. The vapor phase becomes enriched in the more volatile components, while the liquid phase is depleted of those same components. In many situations, however, the change in composition between the vapor and liquid phases in equilibrium becomes small (so-called pinched condition), and a large number of successive partial vaporizations and partial condensations are required to achieve the desired separation. In some cases, the vapor and liquid phases may have identical compositions because of the formation of an azeotrope, and no separation by simple distillation is possible.

Several enhanced distillation-based separation techniques have been developed for close-boiling or low-relative-volatility systems, and for systems that exhibit azeotropic behavior. All of these special techniques are ultimately based on the same differences between the vapor and liquid compositions as in ordinary distillation, but they rely on some additional mechanism to further modify the vapor-liquid behavior of the key components. These enhanced techniques can be classified according to their effect on the relationship between the vapor and liquid compositions:

1. *Azeotropic distillation and pressure-swing distillation.* Methods that cause or exploit azeotrope formation or behavior to change the boiling characteristics and separability of the mixture.
2. *Extractive distillation and salt distillation.* Methods that primarily modify liquid-phase behavior to change the relative volatility of the components of the mixture.
3. *Reactive distillation.* Methods that use chemical reaction to modify the composition of the mixture or, alternatively, use existing vapor-liquid differences between reaction products and reactants to enhance the performance of a reaction.

### AZEOTROPY

At low to moderate pressure ranges typical of most industrial applications, the fundamental composition relationship between the vapor and liquid phases in equilibrium can be expressed as a function of the total system pressure, the vapor pressure of each pure component, and the liquid-phase activity coefficient of each component $i$ in the mixture:

$$y_i P = x_i \gamma_i P_i^{\text{sat}} \tag{13-112}$$

In systems that exhibit ideal liquid-phase behavior, the activity coefficients $\gamma_i$ are equal to unity, and Eq. (13-112) simplifies to Raoult's law. For nonideal liquid-phase behavior, a system is said to show negative deviations from Raoult's law if $\gamma_i < 1$ and, conversely, positive deviations from Raoult's law if $\gamma_i > 1$. In sufficiently nonideal systems, the deviations may be so large that the temperature-composition phase diagrams exhibit extrema, as shown in Figs. 13-6, 13-7, and 13-8. At such maxima or minima, the equilibrium vapor and liquid compositions are identical. Thus,

$$y_i = x_i \qquad \text{for all } i = 1, \cdots, c \tag{13-113}$$

and the system is said to form an azeotrope ( from the Greek word meaning "to boil unchanged"). Azeotropic systems show a minimum in the $T$ versus $x, y$ diagram when the deviations from Raoult's law are positive (Fig. 13-6) and a maximum in the $T$ versus $x, y$ diagram when the deviations from Raoult's law are negative (Fig. 13-7). If, at these two conditions, a single liquid phase is in equilibrium with the vapor phase, the azeotrope is homogeneous. If multiple-liquid-phase behavior is exhibited at the azeotropic condition, the azeotrope is heterogeneous. For heterogeneous azeotropes, the vapor-phase composition is equal to the *overall* composition of the two (or more) liquid phases (Fig. 13-8). These conditions are consequences of the general definition of an azeotrope in any kind of mixture (i.e., homogeneous, heterogeneous, reactive, or in any combination), which is as follows:

At fixed and constant pressure, an azeotropic state (normally called "an azeotrope") is one in which mass transfer occurs between a vapor and one or more co-existing equilibrium liquid phases in a closed system while the composition of each phase remains constant, but not necessarily equal. Moreover, the temperature of all co-existing equilibrium phases is identical and constant during the entire vaporization or condensation process. As a consequence, at homogeneous azeotropes (in which there is only one equilibrium liquid phase) there is a stationary point (i.e., a minimum, maximum, or saddle, see Figs. 13-6 and 13-7) in the boiling temperature surface where the vapor composition is equal to the liquid composition (by Gibbs-Konovalov theory). At heterogeneous azeotropes (in which there are multiple equilibrium liquid phases), the composition of the vapor is equal to the *overall* composition of the two or more liquid phases. Heterogeneous azeotropes do not have a stationary point in the boiling temperature (pressure) surface at the azeotropic point (see Fig. 13-8), and maximum boiling (minimum pressure) heterogeneous azeotropes cannot exist.

Azeotropes of all types have one degree of freedom, which is why only one thermodynamic state variable (e.g., pressure) is allowed to be fixed. Temperature could also be selected as the variable to fix (in place of pressure), in which case the pressure of all co-existing equilibrium phases is identical and constant during the azeotropic transformation. In principle, a different variable (other than P or T) could be fixed, but this is normally not considered.

For brevity, an azeotrope is often defined to be a state whereby at constant pressure (or constant temperature) the mixture can be completely vaporized or condensed without change in the temperature (pressure) or composition of each co-existing equilibrium phase. It is understood by those skilled in the art that this short-hand definition carries with it all the additional detail cited above.

The property shared by homogeneous and heterogeneous azeotropes (i.e., that the overall liquid composition is equal to the vapor composition) provides a means for finding azeotropes experimentally and computationally.

For additional reading see Prigogine and Defay, *Chemical Thermodynamics*, 4th ed., Longmans Green and Co., London, 1967; Rowlinson, *Liquids and Liquid Mixtures*, 2d ed., Butterworths, London, 1969; Doherty and Malone, *Conceptual Design of Distillation Systems*, McGraw-Hill, 2001, chaps. 5, 8, app. C.

Mixtures with only small deviations from Raoult's law (i.e., ideal or nearly ideal mixtures) may form an azeotrope but only if the saturated vapor pressure curves of the two pure components cross each other (such a point is called a Bancroft point). In such a situation, the azeotrope occurs at the temperature and pressure where the curves cross, and perhaps also in the vicinity close to the Bancroft point [e.g., cyclohexane (n.b.p. 80.7°C) and benzene (n.b.p. 80.1°C) form an almost ideal mixture, yet they exhibit a minimum-boiling azeotrope with roughly equal proportions of each component]. As the boiling point difference between the components increases, the composition of the azeotrope shifts closer to one of the pure components (toward the lower-boiling pure component for minimum-boiling azeotropes, and toward the higher-boiling pure component for maximum-boiling azeotropes). For example, the minimum-boiling azeotrope between methanol (n.b.p. 64.5°C) and toluene (n.b.p. 110.6°C) occurs at about 90 mol% methanol, and the minimum-boiling azeotrope between methyl acetate (n.b.p. 56.9°C) and water (n.b.p. 100°C) occurs at about 90 mol% methyl acetate. Mixtures of components whose boiling points differ by more than about 50°C generally do not exhibit azeotropes distinguishable from the pure components, even if large deviations from Raoult's law are present. As a qualitative guide to liquid-phase activity coefficient behavior, Robbins [*Chem. Eng. Prog.* **76**(10): 58 (1980)] developed a matrix of chemical families, shown in Table 13-13, that indicates expected deviations from Raoult's law.

The formation of two liquid phases within some boiling temperature range is generally an indication that the system will also exhibit a minimum-boiling azeotrope, since two liquid phases may form when deviations from Raoult's law are large and positive. The fact that immiscibility does occur, however, does not guarantee that the azeotrope will be heterogeneous; the azeotropic composition may not necessarily fall within the composition range of the two-liquid phase region, as is the case for the methyl acetate–water and tetrahydrofuran-water systems. Since large positive deviations

from Raoult's law are required for liquid-liquid phase splitting, maximum-boiling azeotropes ($\gamma_i < 1$) are never heterogeneous.

Additional general information on the thermodynamics of phase equilibria and azeotropy is available in Malesinski (*Azeotropy and Other Theoretical Problems of Vapour-Liquid Equilibrium*, Interscience, London, 1965), Swietoslawski (*Azeotropy and Polyazeotropy,* Pergamon, London, 1963), Van Winkle (*Distillation,* McGraw-Hill, New York, 1967), Smith and Van Ness (*Introduction to Chemical Engineering Thermodynamics,* McGraw-Hill, New York, 1975), Wizniak [*Chem. Eng. Sci.* **38:** 969 (1983)], and Walas (*Phase Equilibria in Chemical Engineering,* Butterworths, Boston, 1985). Horsley (*Azeotropic Data-III,* American Chemical Society, Washington, 1983) compiled an extensive list of experimental azeotropic boiling point and composition data for binary and some multicomponent mixtures. Another source for azeotropic data and activity coefficient model parameters is the multivolume *Vapor-Liquid Equilibrium Data Collection* (DECHEMA, Frankfurt, 1977), a compendium of published experimental VLE data. Most of the data have been tested for thermodynamic consistency and have been fitted to the Wilson, UNIQUAC, Van Laar, Margules, and NRTL equations. An extensive two-volume compilation of azeotropic data for 18,800 systems involving 1700 compounds, entitled *Azeotropic Data* by Gmehling et al., was published in 1994 by VCH Publishers, Deerfield Beach, Fla. A computational method for determining the temperatures and compositions of all homogeneous azeotropes of a multicomponent mixture, from liquid-phase activity coefficient correlations, is given by Fidkowski, Malone, and Doherty [*Computers and Chem. Eng.* **17:** 1141 (1993)]. The method was generalized to determine all homogeneous and heterogeneous azeotropes by Wasylkiewicz, Doherty, and Malone [*Ind. Eng. Chem. Res.* **38:** 4901 (1999)].

## RESIDUE CURVE MAPS AND DISTILLATION REGION DIAGRAMS

The simplest form of distillation involves boiling a multicomponent liquid mixture in an open evaporation from a single-stage batch still. As the liquid is boiled, the vapor generated is removed from contact with the liquid as soon as it is formed. Because the vapor is richer in the more volatile components than the liquid, the composition and boiling temperature of the liquid remaining in the still change continuously over time and move progressively toward less volatile compositions and higher temperatures until the last drop is vaporized. This last composition may be a pure-component species, or a maximum-boiling azeotrope, and it may depend on the initial composition of the mixture charged to the still.

The trajectory of liquid compositions starting from some initial composition is called a residue curve, and the collection of all such curves for a given mixture is called a residue curve map. Arrows are usually added to these curves, pointing in the direction of increasing time, which corresponds to increasing temperature, and decreasing volatility. If the liquid is well mixed and the vaporization is slow, such that the escaping vapor is in phase equilibrium with the residual liquid, then residue curve maps contain exactly the same information as the corresponding phase equilibrium diagram for the mixture, but they represent it in a way that is much more useful for understanding distillation systems. Composition changes taking place in simple batch distillation can be described mathematically by the following ordinary differential equation

$$\frac{dx_i}{d\xi} = x_i - y_i \qquad \text{for all } i = 1, \cdots, c \tag{13-114}$$

where $\xi$ is a dimensionless nonlinear time scale. Normally, $y_i$ and $x_i$ are related by an isobaric VLE model. Integrating these equations forward in time leads to the less volatile final compositions; integrating them backward in time leads to the more volatile compositions that would produce a residue curve passing through the specified initial composition. A *residue curve map* (RCM) is generated by varying the initial composition and integrating Eq. (13-114) both forward and backward in time [Doherty and Perkins, *Chem. Eng. Sci.* **33:** 281 (1978); Doherty and Malone 2001, chap. 5]. Unlike a binary *y-x* plot, relative-volatility information is not represented on an RCM. Therefore, it is difficult to determine the ease of separation from a residue curve map alone. The steady states of Eq. (13-114) are the constant-composition trajectories corresponding to $dx_i/d\xi = 0$ for all $i = 1, \ldots, c$. The steady states therefore correspond to *all* the pure components and *all* the azeotropes in the mixture.

Residue curve maps can be constructed for mixtures of any number of components, but they can be pictured graphically only up to four components. For binary mixtures, a *T* vs. *x, y* diagram or a *y-x* diagram suffices; the system is simple enough that vapor-phase information can be included with liquid-phase information without confusion. For ternary mixtures, liquid-phase compositions are plotted on a triangular diagram, similar to that used in liquid-liquid extraction. Four-component systems can be plotted in a three-dimensional tetrahedron. The vertices of the triangular diagram or tetrahedron represent the pure components. Any binary, ternary, and quaternary azeotropes are placed at the appropriate compositions on the edges or the interior of the triangle and tetrahedron.

The simplest form of ternary RCM, as exemplified for the ideal normal-paraffin system of pentane-hexane-heptane, is illustrated in Fig. 13-75*a,* using a right-triangle diagram. Maps for all other nonazeotropic ternary mixtures are qualitatively similar. Each of the infinite number of possible residue curves originates at the pentane vertex, travels toward and then

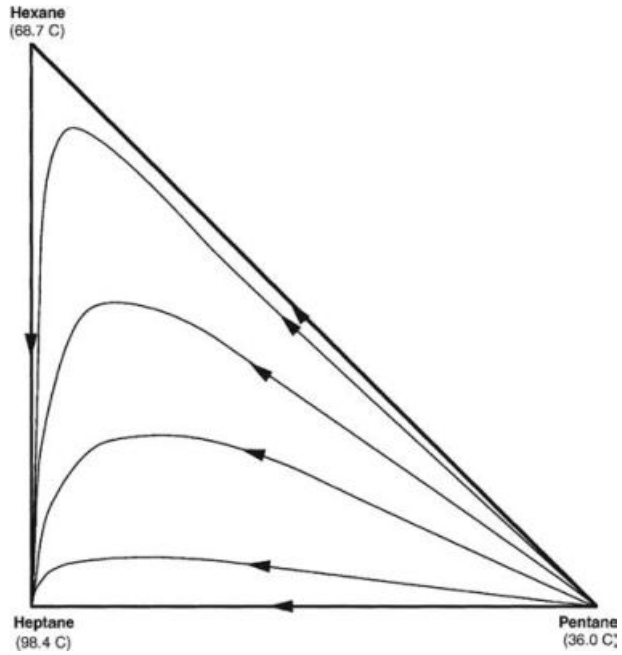

**FIG. 13-75*a*** Residue curve map: Nonazeotropic pentane-hexane-heptane system at 1 atm.

away from the hexane vertex, and terminates at the heptane vertex. The family of all residue curves that originate at one composition and terminate at another composition defines a *distillation region*. Systems that do not involve azeotropes have only one region—the entire composition space. However, for many systems, not all residue curves originate or terminate at the same two compositions. Such systems will have more than one distillation region. The residue curve that divides two distillation regions in which adjacent residue curves originate from different compositions or terminate at different compositions is called a *simple batch distillation boundary* or *separatrix*. Distillation boundaries are related to the existence of azeotropes. In the composition space for a binary system, the distillation boundary is a point (the azeotropic composition). For three components, the distillation boundary is a curve; for four components, the boundary is a surface; and so on.

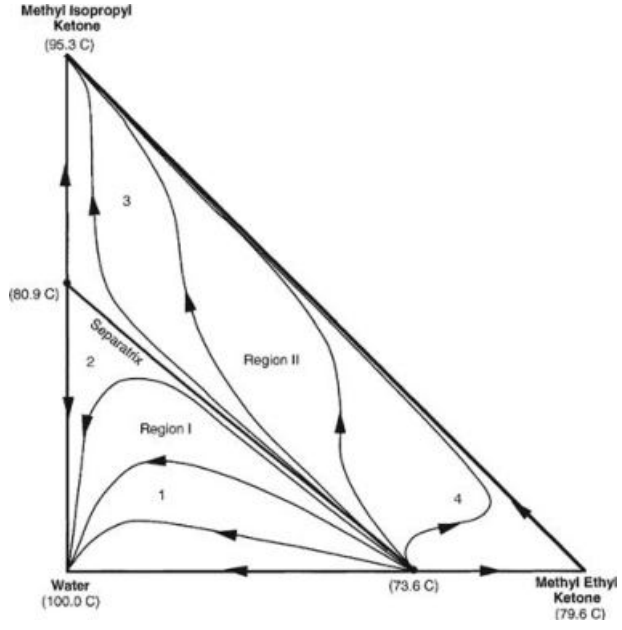

**FIG. 13-75*b*** Residue curve map: MEK-MIPK-water system at 1 atm containing two minumum-boiling binary azeotropes.

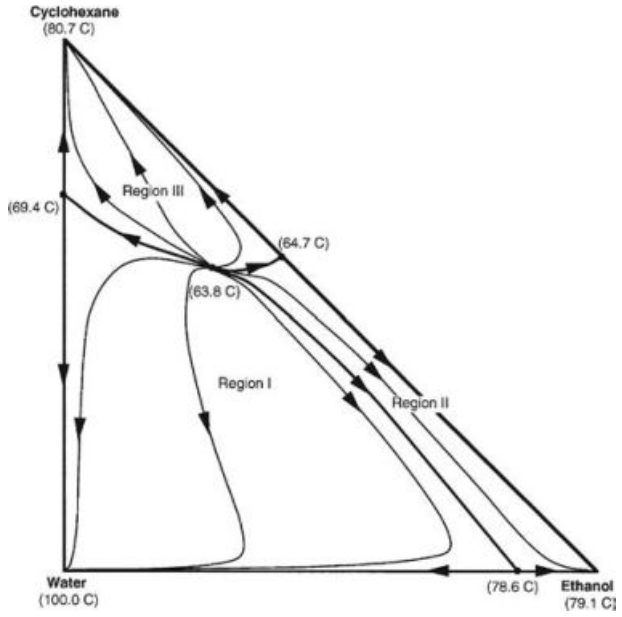

**FIG. 13-75*c*** Residue curve map: Ethanol-cyclohexane-water system at 1 atm containing four minimum-boiling azeotropes (three binary and one ternary) and three distillation regions.

The boundaries of the composition diagram (e.g., the edges of a composition triangle) also form region boundaries since they divide physically realistic residue curves with positive compositions from unrealistic curves with negative compositions. All pure components and azeotropes in a system lie on region boundaries. Within each region, the most volatile composition on the boundary (either a pure component or a minimum-boiling azeotrope, and the origin of all residue curves in that region) is called the *low-boiling node*. The least volatile composition on the boundary (either a pure component or a maximum-boiling azeotrope, and the terminus of all residue curves in that region) is called the *high-boiling node*. All other pure components and azeotropes are called *intermediate-boiling saddles*. Adjacent regions may share some (but not all) nodes and saddles. Pure components and azeotropes are labeled as nodes and saddles as a result of the boiling points of all the components and azeotropes in a system. If one species is removed, the labeling of all remaining pure components and azeotropes, particularly those that were saddles, may change. Distillation boundaries always originate or terminate at saddle azeotropes, but never at pure component saddles—distillation boundaries can be calculated by using the method proposed by Lucia and Taylor [*AIChE J.* **52:** 582 (2006)]. Ternary saddle azeotropes are particularly interesting because they are more difficult to detect experimentally (being neither minimum-boiling nor maximum-boiling). However, their presence in a mixture implies the existence of distillation boundaries, which may have an important impact on the design of a separation system. The first ternary saddle azeotrope to be detected experimentally was reported by Ewell and Welch [*Ind. Eng. Chem.* **37:** 1224 (1945)], and a particularly comprehensive set of experimental residue curves were reported by Bushmakin and Kish [*J. Appl. Chem. USSR (Engl. Trans.)* **30:** 205 (1957)] for a ternary mixture with a ternary saddle azeotrope (reproduced as Fig. 5.9 in Doherty and Malone 2001). More ternary saddle azeotropes are reported in Gmehling et al. (*Azeotropic Data*, 1994).

Both methylethylketone (MEK) and methylisopropylketone (MIPK) form minimum-boiling homogeneous azeotropes with water (Fig. 13-75*b*). In this ternary system, a distillation boundary connects the binary azeotropes and divides the RCM into two distillation regions, I and II. The high-boiling node of region I is pure water, while the low-boiling node is the MEK-water azeotrope. In region II, the high- and low-boiling nodes are MIPK and the MEK-water azeotrope, respectively. These two regions, however, have a different number of saddles—one in region I and two in region II. This leads to region I having three sides, while region II has four sides. The more complicated cyclohexane-ethanol-water system (Fig. 13-75*c*) has three boundaries and three regions, all of which are four-sided and share the ternary azeotrope as the low-boiling node.

The liquid composition profiles in continuous staged or packed distillation columns operating at infinite reflux and boil-up are closely approximated by simple distillation residue curves [Van Dongen and Doherty, *Ind. Eng. Chem. Fundam.* **24:** 454 (1985)]. Residue curves are also indicative of

many aspects of the general behavior of continuous columns operating at more practical reflux ratios. For example, to a first approximation, the stage-to-stage liquid compositions (along with the distillate and bottoms compositions) of a single-feed, two-product, continuous distillation column lie on the same residue curve. Therefore, for systems with distillation boundaries and multiple regions, distillation composition profiles are constrained to lie in specific regions. The precise boundaries of these distillation regions are a function of reflux ratio, but they are closely approximated by the RCM distillation boundaries. If an RCM distillation boundary exists in a system, a corresponding continuous distillation boundary will also exist. Both types of boundaries correspond exactly at all pure components and azeotropes.

Residue curves can be constructed from experimental data, or they can be calculated by integrating Eq. (13-114) if equation-of-state or activity-coefficient expressions are available (e.g., Wilson binary-interaction parameters, UNIFAC groups). However, considerable information on system behavior can still be deduced from a simple qualitative sketch of the RCM distillation boundaries based only on pure-component and azeotrope boiling point data and approximate azeotrope compositions. Rules for constructing such qualitative *distillation region diagrams* (DRDs) are given by Foucher et al. [*Ind. Eng. Chem. Res.* **30:** 760, 2364 (1991)]. For ternary systems containing no more than one ternary azeotrope and no more than one binary azeotrope between each pair of components, 125 such DRDs are mathematically possible [Matsuyama and Nishimura, *J. Chem. Eng. Japan* **10:** 181 (1977); Doherty and Caldarola, *Ind. Eng. Chem. Fundam.* **24:** 474 (1985); Peterson and Partin, *Ind. Eng. Chem. Res.* **36:** 1799 (1997)], although only a dozen or so represent most systems commonly encountered in practice.

Figure 13-76 illustrates all the 125 possible DRDs for ternary systems [see Peterson and Partin, *Ind. Eng. Chem. Res.* **36:** 1799 (1997)]. Azeotropes are schematically depicted generally to have equimolar composition, distillation boundaries are shown as straight lines, and the arrows on the distillation boundaries indicate increasing temperature. These DRDs are indexed in Table 13-14 according to a temperature profile sequence of position numbers, defined in a keyed triangular diagram at the bottom of the table, arranged by increasing boiling point. Positions 1, 3, and 5 are the pure components in order of decreasing volatility. Positions 2, 4, and 6 are binary azeotropes at the positions shown in the keyed triangle, and position 7 is the ternary azeotrope. Azeotrope position numbers are deleted from the temperature profile if the corresponding azeotrope is known not to exist. Note that not every conceivable temperature profile corresponds to a thermodynamically consistent system, and such combinations have been excluded from the index. As is evident from the index, some DRDs are consistent with more than one temperature profile. Also, some temperature profiles are consistent with more than one DRD. In such cases, the correct diagram for a system must be determined from residue curves obtained from experimental or calculated data.

Schematic DRDs are particularly useful in determining the implications of possibly unknown ternary saddle azeotropes by postulating position 7 at interior positions in the temperature profile. Also note that some combinations of binary azeotropes require the existence of a ternary saddle azeotrope. As an example, consider the system acetone (56.4°C), chloroform (61.2°C), and methanol (64.7°C) at 1 atm pressure. Methanol forms minimum-boiling azeotropes with both acetone (54.6°C) and chloroform (53.5°C), and acetone forms a maximum-boiling azeotrope (64.5°C) with chloroform. Experimentally there are no data for maximum- or minimum-boiling ternary azeotropes for this mixture. Assuming no ternary azeotrope, the temperature profile for this system is 461325, which from Table 13-14 is consistent with DRD 040 and DRD 042. However, Table 13-14 also indicates that the pure-component and binary azeotrope data are consistent with three temperature profiles involving a ternary saddle azeotrope, namely, 4671325, 4617325, and 4613725. All three of these temperature profiles correspond to DRD 107. Calculated residue curve trajectories for the acetone-chloroform-methanol system at 1 atm pressure, as shown in Fig. 13-77, show the existence of a ternary saddle azeotrope and DRD 107 as the correct approximation of the distillation regions. Ewell and Welch [*Ind. Eng. Chem.* **37:** 1224 (1945)] confirmed experimentally such a ternary saddle at 57.5°C.

## APPLICATIONS OF RCM AND DRD

Residue curve maps and distillation region diagrams are very powerful tools for understanding all types of batch and continuous distillation operations, particularly when combined with other information such as liquid-liquid binodal curves. Applications include

1. *System visualization.* Location of distillation boundaries, azeotropes, distillation regions, feasible products, and liquid-liquid regions.
2. *Evaluation of laboratory data.* Location and confirmation of saddle ternary azeotropes and a thermodynamic consistency check of data.
3. *Process synthesis.* Concept development, construction of flow sheets for new processes, and redesign or modification of existing process flow sheets.
4. *Process modeling.* Identification of infeasible or problematic column specifications that could cause simulation convergence difficulties or failure, and determination of initial estimates of column parameters, including feed-stage location, number of stages in the stripping and enriching sections, reflux ratio, and product compositions.
5. *Control analysis/design.* Analysis of column balances and profiles to aid in control system design and operation.
6. *Process troubleshooting.* Analysis of separation system operation and malfunction, examination of composition profiles, and tracking of trace impurities with implications for corrosion and process specifications.

Material balances for mixing or continuous separation operations at steady state are represented graphically on triangular composition diagrams such as residue curve maps or distillation region diagrams by straight lines connecting pertinent compositions. The straight lines are exact representations of the compositions due to the lever rule. Overall flow rates are found by the inverse-lever-arm rule. Distillation material balance lines are governed by two constraints:

1. The bottoms, distillate, and overall feed compositions must lie on the same straight line.
2. The bottoms and distillate compositions must lie (to a very close approximation) on the same residue curve.

Since residue curves do not cross simple batch distillation boundaries, the distillate and bottoms compositions must be in the same distillation region with the mass balance line intersecting a residue curve in two places. Mass balance lines for mixing and for other separations not involving vapor-liquid equilibria, such as extraction and decantation, are of course not limited by distillation boundaries.

For a given multicomponent mixture, a single-feed, two-product distillation column (simple column) can be designed with enough stages, reflux, and material balance control to produce separations ranging from the *direct-split* mode of operation (low-boiling node taken as distillate) to the *indirect-split* mode (high-boiling node taken as bottoms). The bow-tie-shaped set of reachable product compositions for a simple distillation column is roughly bounded by the (straight) material balance lines that connect the feed composition to the sharpest direct separation and the sharpest indirect separation possible (see Fig. 13-78). A more accurate approximation involves replacing two of the straight-line segments of the bow tie with the residue curve through the feed composition [Stichlmair and Herguijuela, *AIChE J.* **38:** 1523 (1992)]. The exact shape of the reachable product composition regions involves replacing two of the straight-line segments of the bow tie with a locus of pinch points, as explained by Wahnschafft et al. [*Ind. Eng. Chem. Res.* **31:** 2345 (1992)] and Fidkowski, Doherty, and Malone [*AIChE J.* **39:** 1303 (1993)]. Since residue curves are deflected by saddles, it is generally not possible to obtain a saddle product (pure component or azeotrope) from a simple distillation column.

Consider the recovery of MIPK from an MEK-MIPK-water mixture. The approximate bow tie regions of product compositions for three different feeds are shown in Fig 13-78. From feed F3, which is situated in a different distillation region than the desired product, pure MIPK cannot be obtained at all. Feed F1 is more favorable, with the upper edge of the bow tie region along the MEK-MIPK (water-free) face of the composition triangle and part of the lower edge along the MEK-water (MIPK-free) face. There are conditions under which both the water in the MIPK bottoms product can be driven to low levels (high-product purity) and MIPK in the distillate can be driven to low levels (high-product recovery), although achieving such an operation depends on having an adequate number of stages and reflux ratio.

Although feed F2 lies in the same distillation region as F1, the bow tie region for feed F2 is significantly different than that for F1, with the upper edge along the water-MIPK (MEK-free) face of the triangle and the lower edge along the distillation boundary. From this feed it is not possible to simultaneously achieve a high-purity MIPK specification while obtaining high MIPK recovery. If the column is operated to get a high purity of MIPK, then the material balance line runs into the distillation boundary. Alternatively, if the column is operated to obtain a high recovery of MIPK (by removing the MEK-water azeotrope as distillate), the material balance requires the bottoms to lie on the water-MIPK face of the triangle.

The number of saddles in a particular distillation region can have significant impact on column profile behavior, process stability, and convergence behavior in process simulation of the system. Referring to the MIPK-MEK-water system in Fig. 13-75*b,* region I contains one saddle (MIPK-water azeotrope), while region II contains two saddles (pure MEK and the MIPK-water azeotrope). These are three- and four-sided regions, respectively. In a three-sided region, all residue curves track toward the solitary saddle. However, in a four- (or more) sided region with saddles on either side of a node, some residue curves will tend to track toward one saddle, while others track toward another saddle. For example, residue curve 1 in region I originates from the MEK-water azeotrope low-boiling node and travels first toward the single

saddle of the region (MIPK-water azeotrope) before ending at the water high-boiling node. Likewise, residue curve 2 and all other residue curves in region I follow the same general path.

In region II, residue curve 3 originates from the MEK-water azeotrope, travels toward the MIPK-water saddle azeotrope, and ends at pure MIPK. However, residue curve 4 follows a completely different path, traveling toward the pure MEK saddle before ending at pure MIPK. Some multicomponent columns have been designed for operation in four-sided regions with the feed composition adjusted so that both the high-boiling and low-boiling nodes can be obtained simultaneously as products. However, small perturbations in feed composition or reflux can result in feasible operation on many different residue curves that originate and terminate at these product compositions. Multiple steady states and composition profiles that shift dramatically from tracking toward one saddle to the other are possible [Kovach and Seider, *AIChE J.* **33:** 1300 (1987); Pham, Ryan, and Doherty, *AIChE J.* **35:** 1585 (1989)]. Consider a column operating in region II of the MIPK-MEK-water diagram. Figure 13-79 shows the composition and temperature profiles for the column operating at three different sets of operating conditions and two feed locations, as given in Table 13-15. The desired product specification is 97 mol% MIPK, no more than 3 mol% MEK, and less than 10 ppm residual water. For case A (Fig. 13-79*a*), the column profile tracks up the water-free side of the diagram. A pinched zone (i.e., section of little change in tray temperature and composition) occurs above the feed between the feed tray (tray 4) and tray 18. The temperature remains constant at about 93°C throughout the pinch zone. Product specifications are met.

When the feed composition becomes slightly enriched in water, as with case B, the column profile changes drastically (Fig. 13-79*b*). At the same reflux and boil-up, the column no longer meets specifications. The MIPK product is too lean in MIPK and too rich in water. The profile now tracks generally up the left side of region II. Note also the dramatic change in the temperature profile. A pinched zone still exists above the feed between trays 4 and 18, but the tray temperature in the zone has dropped to 80°C (from 93°C). Most of the trays are required to move through the vicinity of the saddle. Typically, pinches (if they exist) occur close to saddles and nodes.

In case C (Fig. 13-79*c*), increasing the boil-up ratio to 6 brings the MIPK product back within specifications, but the production rate and recovery have dropped off. In addition, the profile has switched back to the right side of the region, and the temperatures on trays in the pinched zone (trays 4 through 18) are back to 93°C. Such a drastic fluctuation in tray temperature with a relatively minor adjustment of the manipulated variable (boil-up in this case) can make control difficult. This is especially true if the control strategy involves maintaining a constant temperature on one of the trays between trays 4 and 18. If a tray is selected that exhibits wide temperature swings, the control system may have a difficult time compensating for disturbances. Such columns are also often difficult to model with a process simulator. Design algorithms often rely on

Ternary DRD table lookup procedure:

1. Classify a system by writing down each position number in ascending order of boiling points.
   - A position number is not written down if there is no azeotrope at that position.
   - The resulting sequence of numbers is known as the *temperature profile*.
   - Each temperature profile will have a minimum of three numbers and a maximum of seven numbers.
   - List multiple temperature profiles when you have incomplete azeotropic data.
   - All seven position numbers are shown on the diagram.
2. Using the table, look up the temperature profile(s) to find the corresponding DRD #.

*Table 13-14 and Fig. 13-76 developed by Eric J. Peterson, Eastman Chemical Co.

perturbation of a variable (such as reflux or reboil) while checking for convergence of column heat and material balances. In situations where the column profile is altered drastically by minor changes in the perturbed variable, the simulator may be close to a feasible solution, but successive iterations may appear to be very far apart. The convergence routine may continue to oscillate between column profiles and never reach a solution. Likewise, when an attempt is made to design a column to obtain product compositions in different distillation regions, the simulation will never converge.

## AZEOTROPIC DISTILLATION

The term *azeotropic distillation* has been applied to a broad class of fractional distillation-based separation techniques when specific azeotropic behavior is exploited to effect a separation. The agent that causes the

specific azeotropic behavior, often called the *entrainer,* may already be present in the feed mixture (a self-entraining mixture) or may be an added mass separation agent. Azeotropic distillation techniques are used throughout the petrochemical and chemical processing industries for the separation of close-boiling, pinched, or azeotropic systems for which simple distillation is either too expensive or impossible. With an azeotropic feed mixture, the presence of the azeotroping agent results in the formation of a more favorable azeotropic pattern for the desired separation. For a close-boiling or pinched feed mixture, the azeotroping agent changes the dimensionality of the system and allows separation to occur along a less pinched path. Within the general heading of azeotropic distillation techniques, several approaches have been followed in devising azeotropic distillation flow sheets, including:

1. Choosing an entrainer to give a residue curve map with specific distillation regions and node temperatures
2. Exploiting changes in azeotropic composition with total system pressure
3. Exploiting the curvature of distillation region boundaries
4. Choosing an entrainer to cause azeotrope formation in combination with liquid-liquid immiscibility

The first three of these are solely VLE-based approaches, involving a series of simple distillation column operations and recycles. The final approach relies on distillation (VLE), but it also exploits another physical phenomenon, liquid-liquid phase formation (phase splitting), to assist in entrainer recovery. This approach is the most powerful and versatile. Examples of industrial uses of azeotropic distillation grouped by method are given in Table 13-16.

The choice of the appropriate azeotropic distillation method and the resulting flow sheet for the separation of a particular mixture are strong functions of the separation objective. For example, it may be desirable to recover all constituents of the original feed mixture as pure components, or only some as pure components and others as azeotropic mixtures suitable for recycle. Not every objective may be obtainable by azeotropic distillation for a given mixture and portfolio of candidate entrainers.

**Exploiting Homogeneous Azeotropes** Homogeneous azeotropic distillation refers to a flow sheet structure in which azeotrope formation is exploited or avoided in order to accomplish the desired separation in one or more distillation columns. Either the azeotropes in the system do not exhibit two-liquid-phase behavior, or the liquid-phase behavior is not or cannot be exploited in the separation sequence. The structure of a particular sequence will depend on the geometry of the residue curve map or distillation region diagram for the feed mixture-entrainer system. Two approaches are possible:

1. Selection of an entrainer such that the desired products all lie within the *same* distillation region (the products may be pure components or azeotropic mixtures)
2. Selection of an entrainer such that some type of distillation boundary-crossing mechanism is employed to separate desired products that lie in *different* regions.

As mentioned previously, ternary mixtures can be represented by 125 different residue curve maps or distillation region diagrams. However, feasible distillation sequences using the first approach can be developed for breaking homogeneous binary azeotropes by the addition of a third component only for those more restricted systems that do not have a distillation boundary connected to the azeotrope and for which one of the original components is a node. For example, from Fig. 13-76 the following eight residue curve maps are suitable for breaking homogeneous minimum-boiling azeotropes: DRD 002, 027, 030, 040, 051, 056, 060, and 061 as collected in Fig. 13-80. To produce the necessary distillation region diagrams, an entrainer must be found that is either: (1) an intermediate boiler that forms no azeotropes (DRD 002), or (2) lowest-boiling or intermediate-boiling and forms a maximum-boiling azeotrope with the lower-boiling original component (A). In these cases, the entrainer may also optionally form a minimum-boiling azeotrope with the higher boiling of the original components or a minimum-boiling ternary azeotrope. In all cases, after the addition of the entrainer, the higher-boiling original component (B) is a high-boiling node and is removed as bottoms product from a first column operated in the indirect-split mode with the lower-boiling original component recovered as distillate in a second column; see the flow sheet in Fig. 13-80.

The seven residue curve maps suitable for breaking homogeneous maximum-boiling binary azeotropes (DRD 028, 031, 035, 073, 078, 088, 089) are shown in Fig. 13-81. In this case, the entrainer must form a minimum-boiling azeotrope with the higher-boiling original component and either a maximum-boiling azeotrope or no azeotrope with the lower-boiling original component. In all cases, after the addition of the entrainer, the lower-boiling original component is a low-boiling node and is removed as distillate from a first column operated in the direct-split mode with the higher-boiling original component recovered as bottoms product in a second column; see the flow sheet in Fig. 13-81.

The restrictions on the boiling point and azeotrope formation of the entrainer act as efficient screening criteria for entrainer selection. Entrainers that do not show appropriate boiling point characteristics can be discarded without detailed analysis. However, the entrainers in Fig. 13-80 do suffer from serious drawbacks that limit their practical application. DRD 002 requires that the entrainer be an intermediate-boiling component that forms no azeotropes. Unfortunately, these are often difficult criteria to meet because any intermediate boiler will be closer-boiling to both of the original components and, therefore, will be more likely to be at least pinched or even form azeotropes. The remaining feasible distillation region diagrams require that the entrainer form a maximum-boiling azeotrope with the lower-boiling original component. Because maximum-boiling azeotropes are relatively rare, finding a suitable entrainer may be difficult.

For example, the dehydration of organics that form homogeneous azeotropes with water is a common industrial problem. It is extremely difficult to find an intermediate-boiling entrainer that also does not form an azeotrope with water. Furthermore, the resulting separation is likely to be close-boiling or pinched throughout most of the column, requiring a large number of stages. For example, consider the separation of valeric acid (187.0°C) and water. This system exhibits a minimum-boiling azeotrope (99.8°C) with a composition and boiling point close to those of pure water. Ignoring for the moment potentially severe corrosion problems, formic acid (100.7°C), which is an intermediate boiler and which forms a maximum-boiling azeotrope with water (107.1°C), is a candidate entrainer (DRD 030, Fig. 13-82*a*). In the conceptual sequence shown in Fig. 13-82*b,* a recycle of the formic acid–water maximum-boiling azeotrope is added to the original valeric acid–water feed, which may be of any composition. Using the indirect-split mode of operation, the high-boiling node valeric acid is removed in high purity and high recovery as bottoms in a first column, which by mass balance produces a formic acid–water distillate. This binary mixture is fed to a second column that produces pure water as distillate and the formic acid–water azeotrope as bottoms for recycle to the first column. The inventory of formic acid is an important optimization variable in this theoretically feasible but difficult separation scheme.

**Exploiting Pressure Sensitivity** Breaking a homogeneous azeotrope that is part of a distillation boundary (i.e., the desired products lie in different distillation regions on either side of the boundary) requires that the boundary be "crossed" by the separation system. This may be done by mixing some external stream with the original feed stream in one region such that the resulting composition is in another region for further processing. However, the external stream must be completely regenerated, and mass balance must be preserved. For example, it is not possible to break a homogeneous binary azeotrope simply by adding one of the products to cross the azeotropic composition.

The composition of many azeotropes varies with the system pressure (Horsley, *Azeotropic Data-III,* American Chemical Society, Washington, 1983; Gmehling et al., *Azeotropic Data,* VCH Publishers, Deerfield Beach, Fla., 1994). This effect can be exploited to separate azeotropic mixtures by so-called pressure-swing distillation if at some pressure the azeotrope simply disappears, such as does the ethanol-water azeotrope at pressures below 11.5 kPa. However, pressure sensitivity can still be exploited if the azeotropic composition and related distillation boundary change sufficiently over a moderate change in total system pressure. A composition in one distillation region at one pressure could be in a different region at a different pressure. A two-column sequence for separating a binary maximum-boiling azeotrope is shown in Fig. 13-83 for a system in which the azeotropic composition at pressure P1 is richer in component B than the azeotropic composition at pressure P2. The first column, operating at pressure P1, is fed a mixture of fresh feed plus recycle stream from the

**TABLE 13-16 Examples of Azeotropic Distillation**

| System | Type | Entrainer(s) | Remark |
|---|---|---|---|
| Exploitation of homogeneous azeotropes | | | |
| No known industrial examples | | | |
| Exploitation of pressure sensitivity | | | |
| THF-water | Minimum-boiling azeotrope | None | Alternative to extractive distillation |
| Methyl acetate-methanol | Minimum-boiling azeotrope | None | Element of recovery system for alternative to production of methyl acetate by reactive distillation; alternative to azeotropic, extractive distillation |
| Alcohol-ketone systems | Minimum-boiling azeotropes | None | |
| Ethanol-water | Minimum-boiling azeotrope | None | Alternative to extractive distillation, salt extractive distillation, heterogeneous azeotropic distillation; must reduce pressure to less than 11.5 kPa for azeotrope to disappear |
| Exploitation of boundary curvature | | | |
| Hydrochloric acid-water | Maximum-boiling azeotrope | Sulfuric acid | Alternative to salt extractive distillation |
| Nitric acid-water | Maximum-boiling azeotrope | Sulfuric acid | Alternative to salt extractive distillation |
| Exploitation of azeotropy and liquid phase immiscibility | | | |
| Ethanol-water | Minimum-boiling azeotrope | Cyclohexane, benzene, heptane, hexane, toluene, gasolene, diethyl ether | Alternative to extractive distillation, pressure-swing distillation |
| Acetic acid-water | Pinched system | Ethyl acetate, propyl acetate, diethyl ether, dichloroethane, butyl acetate | |
| Butanol-water | Minimum-boiling azeotrope | Self-entraining | |
| Acetic acid-water-vinyl acetate | Pinched, azeotropic system | Self-entraining | |
| Methyl acetate-methanol | Minimum-boiling azeotrope | Toluene, methyl isobutyl ketone | Element of recovery system for alternative to production of methyl acetate by reactive distillation; alternative to extractive pressure-swing distillation |
| Diethoxymethanol-water-ethanol | Minimum-boiling azeotropes | Self-entraining | |
| Pyridine-water | Minimum-boiling azeotrope | Benzene | Alternative to extractive distillation |
| Hydrocarbon-water | Minimum-boiling azeotrope | Self-entraining | |

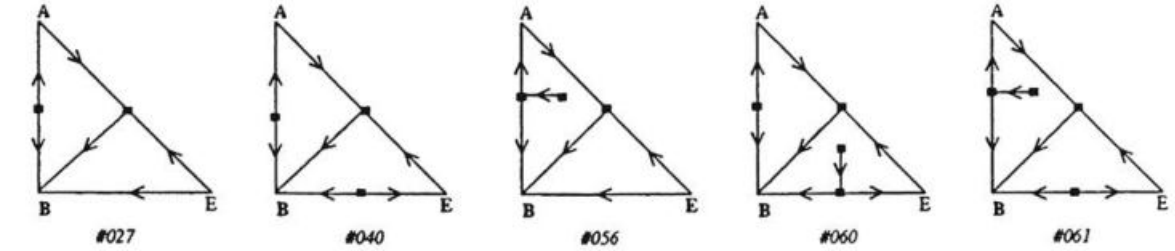
second column such that the overall composition lies on the A-rich side of the azeotropic composition at P1. Pure component A is recovered as distillate, and a mixture near the azeotropic composition is produced as bottoms. The pressure of this bottoms stream is changed to P2 and fed to the second column. This feed is on the B-rich side of the azeotropic composition at P2. Pure component B is now recovered as the distillate, and the azeotropic bottoms composition is recycled to the first column. An analogous flow sheet can be used for separating binary homogeneous minimum-boiling azeotropes. In this case the pure components are recovered as bottoms in both columns, and the distillate from each column is recycled to the other column.

For pressure-swing distillation to be practical, the azeotropic composition must vary at least 5 percent (preferably 10 percent or more) over a moderate pressure range (not more than 10 atm between the two pressures). With a very large pressure range, refrigeration may be required for condensation of the low-pressure distillate, or an impractically high reboiler temperature may result in the high-pressure column. The smaller the variation of azeotrope composition over the pressure range, the larger the recycle flow rates between the two columns. In particular, for minimum-boiling azeotropes, the pressure-swing distillation approach requires high energy usage and high capital costs (large-diameter columns) because both recycled azeotropic compositions must be taken overhead. Moreover, one lobe of an azeotropic VLE diagram is often pinched regardless of pressure; therefore, one of the columns will require a large number of stages to produce the corresponding pure-component product.

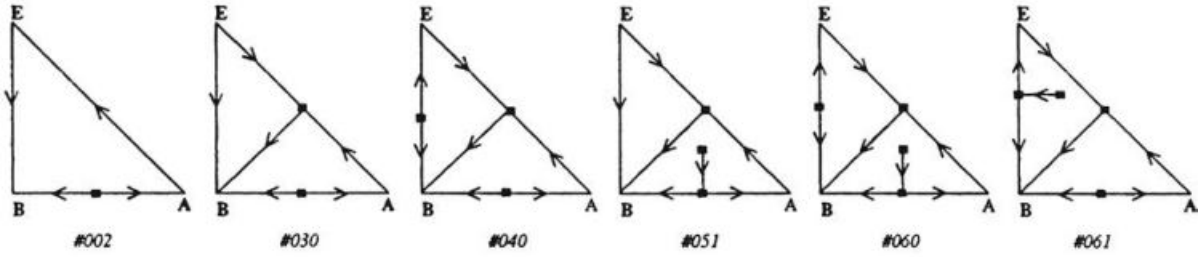
General information on pressure-swing distillation can be found in Van Winkle (*Distillation,* McGraw-Hill, New York, 1967), Wankat (*Equilibrium-Staged Separations,* Elsevier, New York, 1988), and Knapp and Doherty [*Ind. Eng. Chem. Res.* **31:** 346 (1992)]. Only a relatively small fraction of azeotropes are sufficiently pressure-sensitive for a pressure-swing process to be economical. Some applications include the minimum-boiling azeotrope tetrahydrofuran-water [Tanabe et al.; U.S. Patent 4,093,633 (1978)], and maximum-boiling azeotropes of hydrogen chloride–water and formic acid–water (Horsley, *Azeotropic Data-III,* American Chemical Society, Washington, 1983). Since distillation boundaries move with pressure-sensitive azeotropes, the pressure-swing principle can also be used for overcoming distillation boundaries in multicomponent azeotropic mixtures.

**Exploiting Boundary Curvature** A second approach to boundary crossing exploits boundary curvature to produce compositions in different distillation regions. When distillation boundaries exhibit extreme curvature, it may be possible to design a column such that the distillate and bottoms compositions are on the same residue curve in one distillation region, while the feed composition (which is not required to lie on the column composition profile) is in another distillation region. For such a column to meet material balance constraints (i.e., bottom, distillate, feed compositions on a straight line), the feed must be located in a region where the boundary is concave.

As an example, Van Dongen (Ph.D. thesis, University of Massachusetts, 1983) considered the separation of a methanol–methyl acetate mixture, which forms a homogeneous azeotrope, using *n*-hexane as an entrainer. The distillation boundaries for this system (Fig. 13-84*a*) are somewhat curved. A separation sequence that exploits this boundary curvature is shown in Fig. 13-84*b.* Recycled methanol–methyl acetate binary azeotrope and methanol–methyl acetate–hexane ternary azeotrope are added to the original feed F0 to produce a net feed composition F1 for column C1 designed to lie on a line between pure methanol and the curved part of the boundary between regions I and II. Column C1 is operated in the indirect-split mode, producing the high-boiling node methanol as a bottoms product, and by mass balance, a distillate near the curved boundary. The distillate, although in region I, becomes feed F2 to column C2, which is operated in the direct-split mode entirely in region II, producing the low-boiling node ternary azeotrope as distillate and, by mass balance, a methanol–methyl acetate mixture as bottoms (B2). This bottoms mixture is on the opposite side of the methanol–methyl acetate azeotrope from the original feed F0. The bottoms product from C2 is finally fed to binary distillation column C3, which produces pure methyl acetate as bottoms product (B3) and the methanol–methyl acetate azeotrope as distillate (D3). The distillates from columns C2 and C3 are recycled to column C1. The distillate and bottoms compositions for column C2 lie on the same residue curve, and the composition profile lies entirely within region II, even though its feed composition is in region I.



LOW-BOILING ENTRAINER.



INTERMEDIATE-BOILING ENTRAINER.

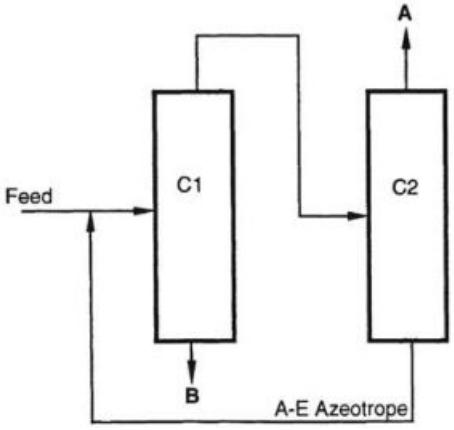


**FIG. 13-80** Feasible distillation region diagrams and associated distillation system for breaking a homogeneous minimum-boiling binary azeotrope A-B. Component B boils at a higher temperature than does A.

Additional information on exploiting boundary curvature, including the useful concept of a *pitchfork distillation boundary*, can be found in Doherty and Malone (*Conceptual Design of Distillation Systems*, McGraw-Hill, 2001, sec. 5.4).

Exploiting boundary curvature for breaking azeotropes is very similar to exploiting pressure sensitivity from a mass balance point of view, and it suffers from the same disadvantages. These separation schemes have large recycle flows, and in the case of minimum-boiling azeotropes, the recycle streams are distillates. However, in the case of maximum-boiling azeotropes, these recycles are bottoms products, and the economics are improved. One such application, illustrated in Fig. 13-85, is the separation of the maximum-boiling nitric acid–water azeotrope by adding sulfuric acid. Recycled sulfuric acid is added to a nitric acid–water mixture near the azeotropic composition to produce a net feed F1 in region II. The first column, operated in the direct-split mode, produces a nitric acid distillate and a bottoms product, by mass balance, near the distillation boundary. In this case, sulfuric acid associates with water so strongly and the distillation boundary is so curved and nearly tangent to the water–sulfuric acid edge of the composition diagram that the second column operating in the indirect-split mode in region I, producing sulfuric acid as bottoms product, also produces a distillate close enough to the water specification that a third column is not required (Thiemann et al., in *Ullmann's Encyclopedia of Industrial Chemistry,* 5th ed., vol. A17, VCH Verlagsgesellschaft mbH, Weinheim, 1991).

**Exploiting Azeotropy and Liquid-Phase Immiscibility** One powerful and versatile separation approach exploits several physical phenomena simultaneously, including nonideal vapor-liquid behavior, where possible, and liquid-liquid behavior to bypass difficult distillation separations. For example, the overall separation of close-boiling mixtures can be made easier by the addition of an entrainer that introduces liquid-liquid immiscibility and forms a heterogeneous minimum-boiling azeotrope with one (generally the lower-boiling) of the key components. Two-liquid-phase formation provides a means of breaking this azeotrope, thus simplifying the entrainer recovery and recycle process. Moreover, since liquid-liquid tie lines are unaffected by distillation boundaries (and the separate liquid phases are often located in different distillation regions), liquid-liquid phase splitting is a powerful mechanism for crossing distillation boundaries. The phase separator is usually a simple decanter, but sometimes a multistage extractor is substituted. The decanter or extractor can also be replaced by some other non-VLE-based separation

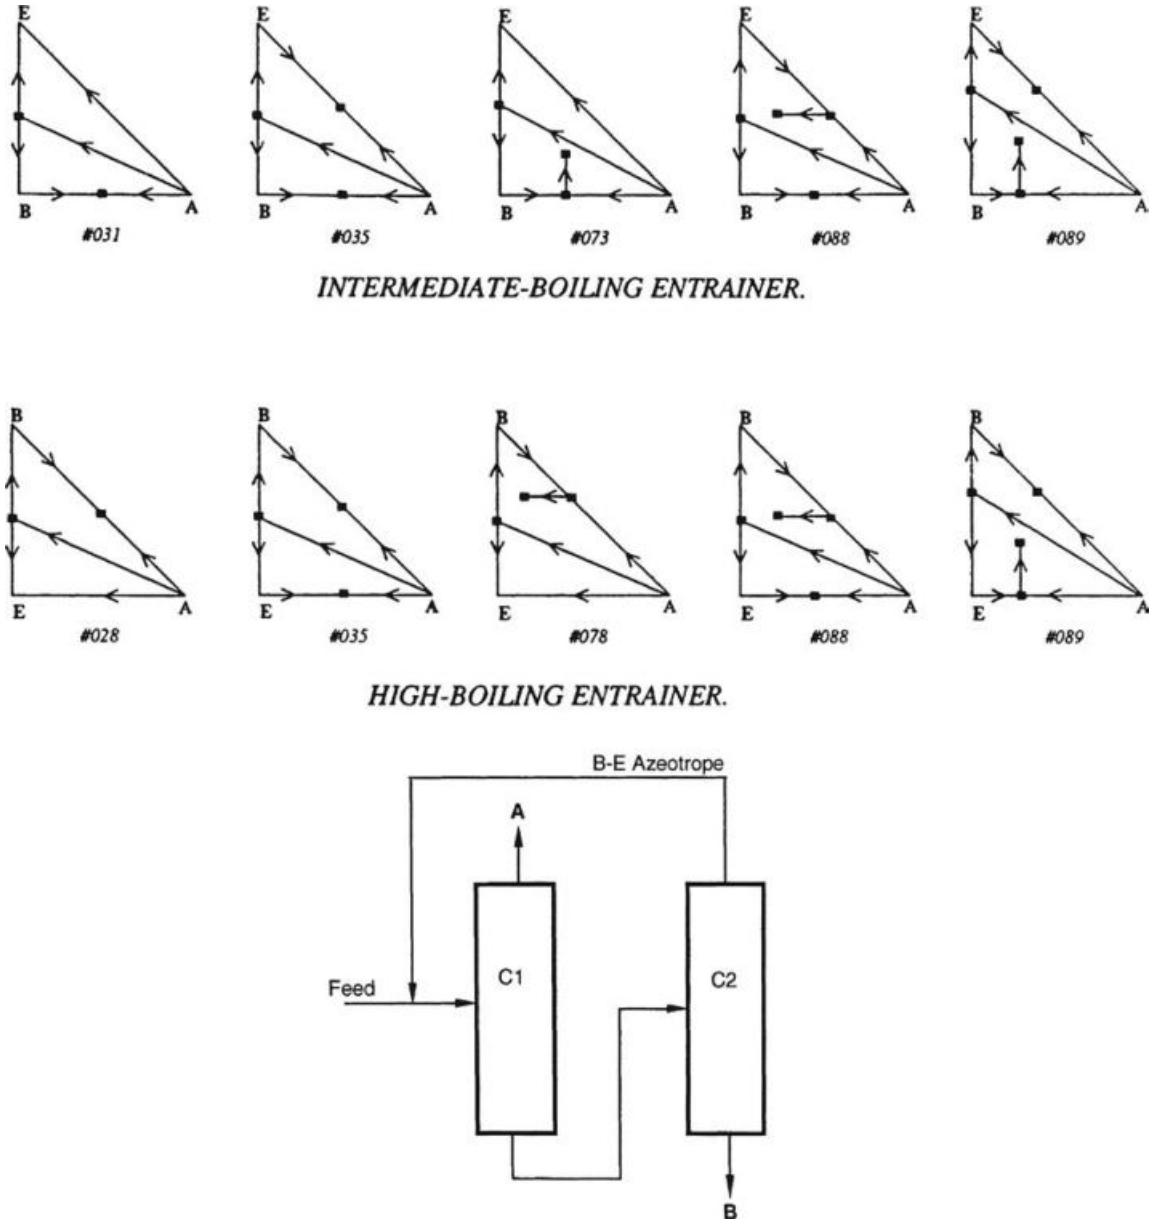

**FIG. 13-81** Feasible distillation region diagrams and associated distillation system for breaking a homogeneous maximum-boiling binary azeotrope A-B. Component B boils at a higher temperature than does A.

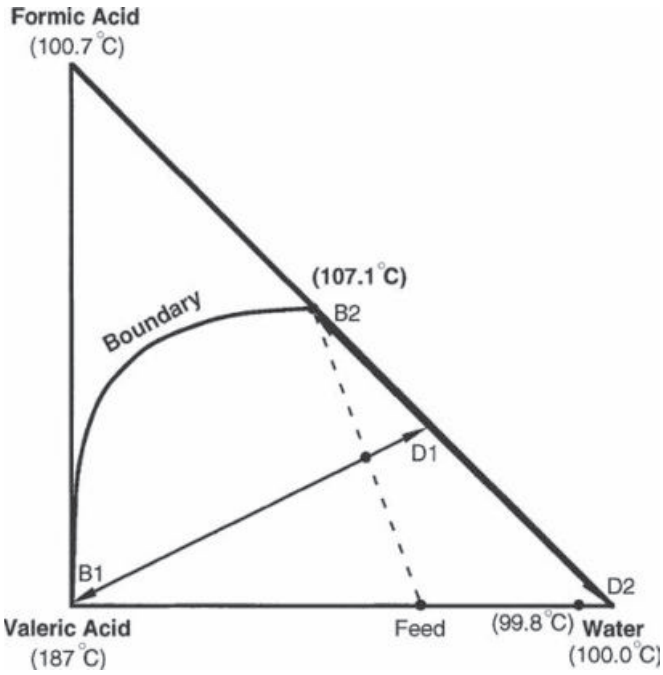
technique, such as membrane permeation, chromatography, adsorption, or crystallization. Also, sequences may include additional separation operations (distillations or other methods) for preconcentration of the feed mixture, entrainer recovery, and final-product purification.

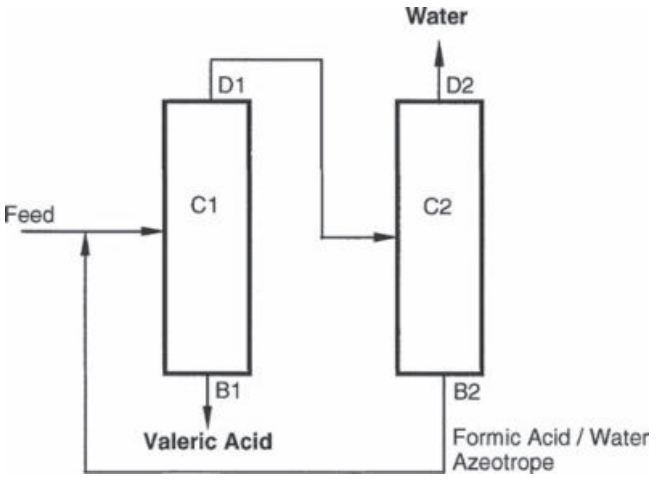
The simplest case of combining VLE and LLE is the separation of a binary heterogeneous azeotropic mixture. One example is the dehydration of 1-butanol, a self-entraining system, in which butanol (117.7°C) and water form a minimum-boiling heterogeneous azeotrope (93.0°C). As shown in Fig. 13-86, the fresh feed may be added to either column C1 or C2, depending on whether the feed is on the organic-rich side or the water-rich side of the azeotrope. The feed may also be added into the decanter directly if it does not move the overall composition of the decanter outside of the two-liquid phase region. Column C1 produces anhydrous butanol as a bottoms product and a composition close to the butanol-water azeotrope as the distillate. After condensation, the azeotrope rapidly phase-separates in the decanter. The upper layer, consisting of 78 wt% butanol, is refluxed totally to column C1 for further butanol recovery. The water layer, consisting of 92 wt% water, is fed to column C2. This column produces pure water as a bottoms product and, again, a composition close to the azeotrope as distillate for recycle to the decanter. Sparged steam may be used in C2, saving the cost of a reboiler. A similar flow sheet can be used for dehydration of hydrocarbons and other species that are largely immiscible with water.

A second example of the use of liquid-liquid immiscibilities in an azeotropic distillation sequence is the separation of the ethanol-water minimum-boiling homogeneous azeotrope. For this separation, a number of entrainers have been proposed, which are usually chosen to be immiscible with water and form a ternary minimum-boiling (preferably heterogeneous) azeotrope with ethanol and water (and, therefore, usually also binary minimum-boiling azeotropes with both ethanol and water). All such systems correspond to DRD 058, although the labeling of the vertices depends on whether the entrainer is lower-boiling than ethanol, intermediate-boiling, or higher-boiling than water. The residue curve map for the case of cyclohexane as entrainer was illustrated in Fig. 13-75*c*. One three-column distillation sequence is shown in Fig. 13-87. Other two-, three-, or four-column sequences have been described by Knapp and Doherty (*Kirk-Othmer Encyclopedia of Chemical Technology*, 5th ed., vol. 8, Wiley, New York, 2004, p. 786).

Fresh aqueous ethanol feed is first preconcentrated to nearly the azeotropic composition in column C3, while producing a water bottoms product.



(*a*)



(*b*)

**FIG. 13-82** Valeric acid–water separation with formic acid. (*a*) Mass balances on distillation region diagram. (*b*) Conceptual sequence.

The distillate from C3 is sent to column C1, which is refluxed with the entire organic (entrainer-rich) layer, recycled from a decanter. Mixing of these two streams is the key to this sequence as it allows the overall feed composition to cross the distillation boundary into region II. Column C1 is operated to recover pure high-boiling node ethanol as a bottoms product and to produce a distillate close to the ternary azeotrope. If the ternary azeotrope is heterogeneous (as it is in this case), it is sent to the decanter for phase separation. If the ternary azeotrope is homogeneous (as it is in the alternative case of ethyl acetate as the entrainer), the distillate is first mixed with water before being sent to the decanter. The inventory of entrainer is adjusted to allow column C1 to operate essentially between two nodes, although such practice, as discussed previously, is relatively susceptible to instabilities from minor feed or reflux perturbations. Refluxing a fraction of the water-rich decanter layer results in an additional degree of freedom to mitigate against variability in the feed composition. The remaining portion of the water layer from the decanter is stripped of residual cyclohexane in column C2, which may be operated either in the direct-split mode (producing low-boiling node ternary azeotrope as distillate and, by mass balance, an ethanol-water bottoms for recycle to C3) or in the indirect-split mode (producing high-boiling node water as bottoms

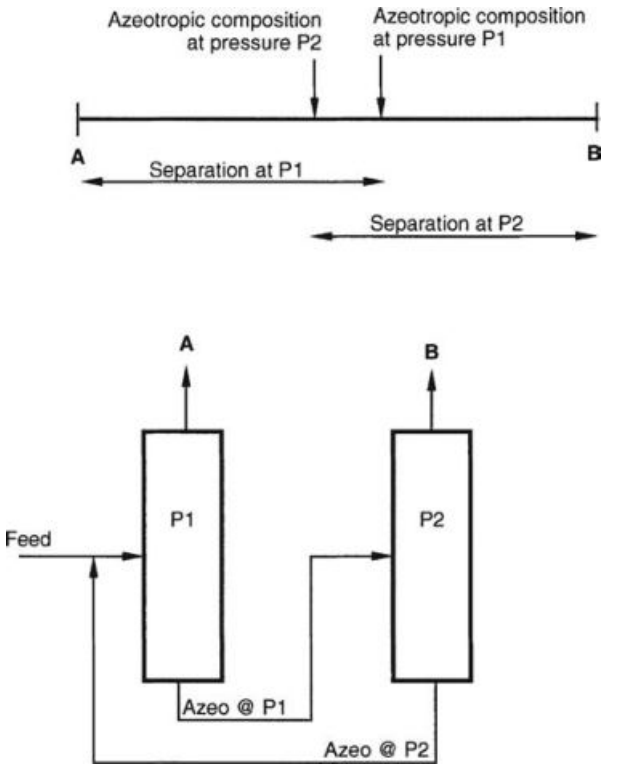


**FIG. 13-83** Conceptual sequence for separating maximum-boiling binary azeotrope with pressure-swing distillation.

and, by mass balance, a ternary distillate near the distillation boundary). (The distillate may be recycled to the decanter, the top of column C1, or the C1 feed.) The indirect-split mode alternatives are discussed in greater detail by Knapp and Doherty (*Kirk-Othmer Encyclopedia of Chemical Technology,* 5th ed., vol. 8, Wiley, New York, 2004, p. 786).

**Design and Operation of Azeotropic Distillation Columns** Simulation and design of azeotropic distillation columns are a difficult computational problem, but one that is readily handled, in most cases, by widely

available commercial computer process simulation packages [Glasscock and Hale, *Chem. Eng.* **101**(11): 82 (1994)]. Most simulators are capable of modeling the steady-state and dynamic behavior of both homogeneous azeotropic distillation systems and those systems involving two-liquid phase behavior within the column, if accurate thermodynamic data and activity coefficient or equation-of-state models are available. However, VLE and VLLE estimated or extrapolated from binary data or predicted from such methods as UNIFAC may not be able to accurately locate boundaries and predict the extent of liquid immiscibilities. Moreover, different activity coefficient models fit to the same experimental data often give very different results for the shape of distillation boundaries and liquid-liquid regions. Therefore, the design of separation schemes relying on boundary curvature should not be attempted unless accurate, reliable experimental equilibrium data are available.

Two liquid phases can occur within a column in the distillation of heterogeneous systems. Older references, e.g., Robinson and Gilliland (*Elements of Fractional Distillation,* McGraw-Hill, New York, 1950), state that the presence of two liquid phases in a column should be avoided as much as possible because performance may be reduced. However, subsequent studies indicate that problems with two-phase flow have been overstated [Herron et al., *AIChE J.* **34:** 1267 (1988); Harrison, *Chem. Eng. Prog.* **86**(11): 80 (1990)]. Based on case history data and experimental evidence, there is no reason to expect unusual capacity or pressure-drop limitations, and standard correlations for these parameters should give acceptable results. Because of the intense nature of the gas-liquid-liquid mixing on trays, mass-transfer efficiencies are relatively unaffected by liquid-liquid phase behavior. The falling-film nature of gas-liquid-liquid contact in packing, however, makes that situation more uncertain. Reduced efficiencies may be expected in systems where one of the keys distributes between the phases.

## EXTRACTIVE DISTILLATION

Extractive distillation is a partial vaporization process in the presence of a miscible, high-boiling, nonvolatile mass separation agent, normally called the *solvent,* which is added to an azeotropic or nonazeotropic feed mixture to alter the volatilities of the key components without the formation of any additional azeotropes. Extractive distillation is used throughout the petrochemical and chemical processing industries for the separation of close-boiling, pinched, or azeotropic systems for which simple single-feed distillation is either too expensive or impossible. It can also be used to obtain products that are residue curve saddles, a task not generally possible with single-feed distillation.

Figure 13-88 illustrates the classical implementation of an extractive distillation process for the separation of a binary mixture. The configuration consists of a double-feed extractive column (C1) and a solvent recovery column (C2). The components A and B may have a low relative volatility or form a minimum-boiling azeotrope. The solvent is introduced into the extractive column at a high concentration a few stages below the condenser, but above the primary-feed stage. Since the solvent is chosen to be nonvolatile, it remains at a relatively high concentration in the liquid phase throughout the sections of the column below the solvent-feed stage.

One of the components, A (not necessarily the most volatile species of the original mixture), is withdrawn as an essentially pure distillate stream. Because the solvent is nonvolatile, at most a few stages above the solvent-feed stage are sufficient to rectify the solvent from the distillate. The bottoms product, consisting of B and the solvent, is sent to the recovery column.

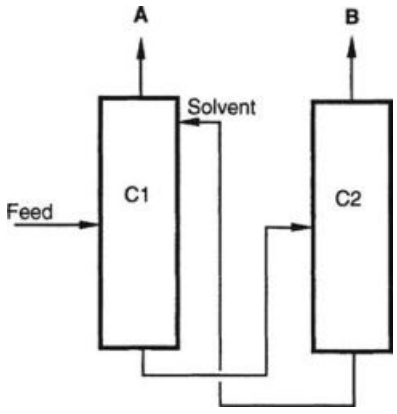

**FIG. 13-88** Typical extractive distillation sequence. Component A is less associated with the solvent.

The distillate from the recovery column is pure B, and the solvent-bottoms product is recycled to the extractive column.

Extractive distillation works by the exploitation of the selective solvent-induced enhancements or moderations of the liquid-phase nonidealities of the original components to be separated. The solvent selectively alters the activity coefficients of the components being separated. To do this, a high concentration of solvent is necessary. Several features are essential:

1. The solvent must be chosen to affect the liquid-phase behavior of the key components differently; otherwise, no enhancement in separability will occur.
2. The solvent must be higher-boiling than the key components of the separation and must be relatively nonvolatile in the extractive column, in order to remain largely in the liquid phase.
3. The solvent should not form additional azeotropes with the components in the mixture to be separated.
4. The extractive column *must* be a double-feed column, with the solvent feed above the primary feed. The column must have an extractive section (middle section) between the rectifying section and the stripping section.

As a consequence of these restrictions, separation of binary mixtures by extractive distillation corresponds to only two possible three-component distillation region diagrams, depending on whether the binary mixture is pinched or close-boiling (DRD 001), or forms a minimum-boiling azeotrope (DRD 003). The addition of high-boiling solvents can also facilitate the breaking of maximum-boiling azeotropes (DRD 014)—for example, splitting the nitric acid–water azeotrope with sulfuric acid. However, as explained in the subsection on azeotropic distillation, this type of separation might be better characterized as exploiting extreme boundary curvature rather than extractive distillation because the important liquid-phase activity coefficient modification occurs in the bottom of the column. Although many references show sulfuric acid being introduced high in the column, in fact two separate feeds are not required.

Examples of industrial uses of extractive distillation grouped by distillation region diagram type are given in Table 13-17. Achievable product compositions in double-feed extractive distillation columns are very different from the bow tie regions for single-feed columns. For a given solvent, only one of the pure components in the original binary mixture can be obtained as distillate from the extractive column (the higher-boiling of which is a saddle for close-boiling systems, and both of which are saddles for minimum-boiling azeotropic systems). However, different solvents are capable of selecting either A or B as distillate (but not both). Simple tests are available for determining which component is the distillate, as discussed later in this section.

Extractive distillation is generally only applicable to systems in which the components to be separated contain one or more different functional groups. Extractive distillation is usually uneconomical for separating stereoisomers, homologs, or structural isomers containing the same functional groups, unless the differences in structure also contribute to significantly different polarity, dipole moment, or hydrophobic character. One such example is the separation of ethanol from isopropanol, where the addition of methyl benzoate raises the relative volatility from 1.09 to 1.27 [Berg et al., *Chem. Eng. Comm.* **66:** 1 (1988)].

**Solvent Effects in Extractive Distillation** In the ordinary distillation of ideal or nonazeotropic mixtures, the component with the lowest pure-component boiling point is always recovered primarily in the distillate, while the highest boiler is recovered primarily in the bottoms. The situation is not as straightforward for an extractive distillation operation. With some solvents, the key component with the lower pure-component boiling point in the original mixture will be recovered in the distillate as in ordinary distillation. For another solvent, the expected order may be reversed, and the component with the higher pure-component boiling point will be recovered in the distillate. The possibility that the expected relative volatility may be reversed by the addition of solvent is entirely a function of the way the solvent interacts with and modifies the activity coefficients and, thus, the volatility of the components in the mixture.

In normal applications of extractive distillation (i.e., pinched, close-boiling, or azeotropic systems), the relative volatilities between the light and heavy key components will be unity or close to unity. Assuming an ideal vapor phase and subcritical components, the relative volatility between the light and heavy keys of the desired separation can be written as the product of the ratios of the pure-component vapor pressures and activity coefficients whether the solvent is present or not:

$$\alpha_{L,H} = \left(\frac{P_L^{\text{sat}}}{P_H^{\text{sat}}}\right)\left(\frac{\gamma_L}{\gamma_H}\right) \tag{13-115}$$

where $L$ and $H$ denote the lower-boiling and higher-boiling key pure component, respectively.

**TABLE 13-17 Examples of Extractive Distillation, Salt Extractive Distillation**

| System | Type | Solvent(s) | Remark |
|---|---|---|---|
| Ethanol-water | Minimum-boiling azeotrope | Ethylene glycol, acetate salts for salt process | Alternative to azeotropic distillation, pressure swing distillation |
| Benzene-cyclohexane | Minimum-boiling azeotrope | Aniline | |
| Ethyl acetate-ethanol | Minimum-boiling azeotrope | Higher esters or alcohols, aromatics | Process similar for other alcohol-ester systems |
| THF-water | Minimum-boiling azeotrope | Propylene glycol | Alternative to pressure swing distillation |
| Acetone-methanol | Minimum-boiling azeotrope | Water, aniline, ethylene glycol | |
| Isoprene-pentane | Minimum-boiling azeotrope | Furfural, DMF, acetonitrile | |
| Pyridine-water | Minimum-boiling azeotrope | Bisphenol | |
| Methyl acetate-methanol | Minimum-boiling azeotrope | Ethylene glycol monomethyl ether | Element of recovery system for alternative to production of methyl acetate by reactive distillation; alternative to azeotropic, pressure, swing distillation |
| C4 alkenes/C4 alkanes/ C4 dienes | Close-boiling and minimum-boiling azeotropes | Furfural, DMF, acetonitrile, *n*-methylpyrolidone | |
| C5 alkenes/C5 alkanes/ C5 dienes | Close-boiling and minimum-boiling azeotropes | Furfural, DMF, acetonitrile, *n*-methylpyrolidone | |
| Heptane isomers-cyclohexane | Close-boiling | Aniline, phenol | |
| Heptane isomers-toluene | Close-boiling and minimum-boiling azeotropes | Aniline, phenol | |
| Vinyl acetate-ethyl acetate | Close-boiling | Phenol, aromatics | Alternative to simple distillation |
| Propane-propylene | Close-boiling | Acrylonitrile | Alternative to simple distillation, adsorption |
| Ethanol-isopropanol | Close-boiling | Methyl benzoate | Alternative to simple distillation |
| Hydrochloric acid-water | Maximum-boiling azeotrope | Sulfuric acid, calcium chloride for salt process | Sulfuric acid process relies heavily on boundary curvature |
| Nitric acid-water | Maximum-boiling azeotrope | Sulfuric acid, magnesium nitrate for salt process | Sulfuric acid process relies heavily on boundary curvature |

The addition of the solvent has an indirect effect on the vapor-pressure ratio. Because the solvent is high-boiling and is generally added at a relatively high molar ratio to the primary-feed mixture, the temperature of an extractive distillation process tends to increase over that of a simple distillation of the original mixture (unless the system pressure is lowered). The result is a corresponding increase in the vapor pressure of both key components. However, the rise in operating temperature generally *does not* result in a significant modification of the relative volatility; the ratio of vapor pressures often remains approximately constant, unless the slopes of the vapor-pressure curves differ significantly. The ratio of the vapor pressures typically remains greater than unity, following the "natural" volatility of the system.

Since activity coefficients have a strong dependence on composition, the effect of the solvent on the activity coefficients is generally more pronounced. However, the magnitude and direction of change are highly dependent on the solvent concentration as well as on the liquid-phase interactions between the solvent and the key components. The solvent acts to lessen the nonidealities of the key component whose liquid-phase behavior is similar to that of the solvent, while enhancing the nonideal behavior of the dissimilar key. The solvent and the key component that show most similar liquid-phase behavior tend to exhibit weak molecular interactions. These components form an ideal or nearly ideal liquid solution. The activity coefficient of this key approaches unity, or may even show negative deviations from Raoult's law if solvating or complexing interactions occur. On the other hand, the dissimilar key and the solvent demonstrate unfavorable molecular interactions, and the activity coefficient of this key increases. The positive deviations from Raoult's law are further enhanced by the diluting effect of the high-solvent concentration, and the value of the activity coefficient of this key may approach the infinite dilution value, often a very large number.

The natural relative volatility of the system is enhanced when the activity coefficient of the lower-boiling pure component is increased by the solvent addition ($\gamma_L/\gamma_H$ increases and $P_L^{\text{sat}}/P_H^{\text{sat}} > 1$). In this case, the lower-boiling pure component will be recovered in the distillate as expected. For the higher-boiling pure component to be recovered in the distillate, the addition of the solvent must decrease the ratio $\gamma_L/\gamma_H$ such that the product of $\gamma_L/\gamma_H$ and $P_L^{\text{sat}}/P_H^{\text{sat}}$ (that is, $\alpha_{LH}$) in the presence of the solvent is less than unity. Generally, the latter is more difficult to achieve and requires higher solvent-to-feed ratios. It is normally better to select a solvent that forces the lower-boiling component overhead.

The effect of solvent concentration on the activity coefficients of the key components is shown in Fig. 13-89 for the methanol-acetone system with either water or methylisopropylketone (MIPK) as a solvent. For an initial feed mixture of 50 mol% methanol and 50 mol% acetone (no solvent present), the ratio of the activity coefficients of methanol and

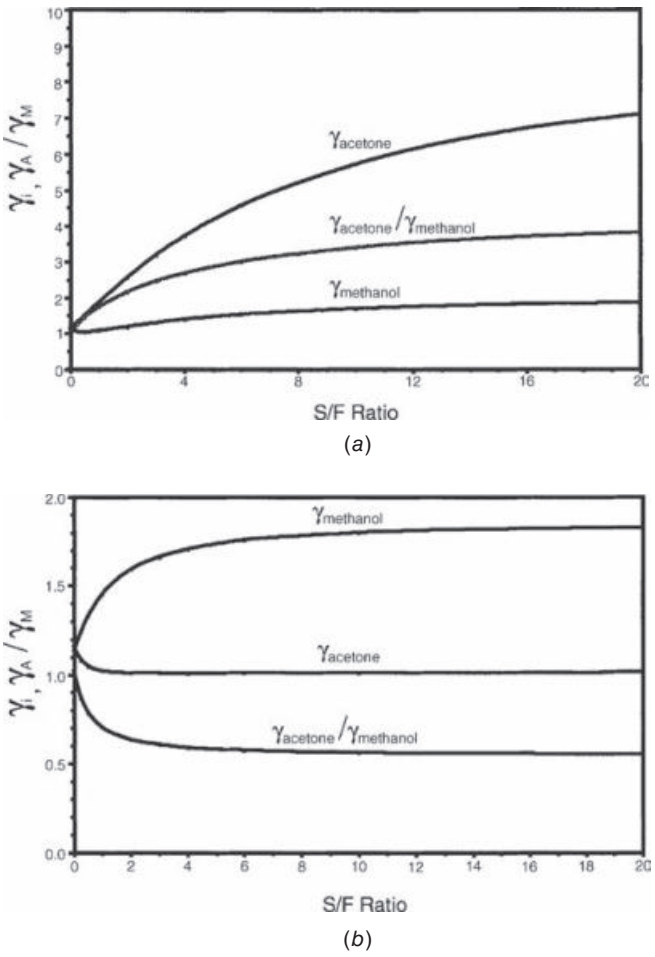

**FIG. 13-89** Effect of solvent concentration on activity coefficients for acetone-methanol system. (*a*) Water solvent. (*b*) MIPK solvent.

acetone is close to unity. With water as the solvent, the activity coefficient of the similar key (methanol) rises slightly as the solvent concentration increases, while the coefficient of acetone approaches the relatively large infinite dilution value. With methylisopropylketone as the solvent, acetone is the similar key, and its activity coefficient drops toward unity as the solvent concentration increases, while the activity coefficient of the methanol increases.

Several methods are available for determining whether the lower- or higher-boiling pure component will be recovered in the distillate. For a series of solvent concentrations, the binary *y-x* phase diagram for the low-boiling and high-boiling keys can be plotted on a solvent-free basis. At a particular solvent concentration (dependent on the selected solvent and keys), the azeotropic point in the binary plot disappears at one of the pure-component corners. The component corresponding to the corner where the azeotrope disappears is recovered in the distillate (Knapp and Doherty, *Kirk-Othmer Encyclopedia of Chemical Technology,* 5th ed., vol. 8, Wiley, New York, 2004, p. 786). LaRoche et al. [*Can. J. Chem. Eng.* **69:** 1302 (1991)] present a related method in which the $\alpha_{LH} = 1$ line is plotted on the ternary composition diagram. If this line intersects the lower-boiling pure component + solvent binary face, then the lower-boiling component will be recovered in the distillate, and vice versa if the $\alpha_{LH} = 1$ line intersects the higher-boiling pure component + solvent face. A very simple method, if an accurate residue curve map is available, is to examine the shape and inflection of the residue curves as they approach the pure solvent vertex. Whichever solvent-key component face the residue curves predominantly tend toward as they approach the solvent vertex is the key component that will be recovered in the bottoms with the solvent (see property 6, p. 193, in Doherty and Malone, *Conceptual Design of Distillation Systems*, McGraw-Hill, 2001). In Fig. 13-90*a,* all residue curves approaching the water (solvent) vertex are inflected toward the methanol-water face, with the result that methanol will be recovered in the bottoms and acetone in the distillate. Alternatively, with MIPK as the solvent, all residue curves show inflection toward the acetone-MIPK face (Fig. 13-90*b*), indicating that acetone will be recovered in the bottoms and methanol in the distillate.

**Extractive Distillation Design and Optimization** Extractive distillation column composition profiles have a very characteristic shape on a ternary diagram. The composition profile for the separation of methanol-acetone with water is given in Fig. 13-91. Stripping and rectifying profiles start at the bottoms and distillate compositions, respectively, track generally along the faces of the composition triangle, and then turn toward the high-boiling (solvent) node and low-boiling node, respectively. For a feasible single-feed design, these profiles must cross at some point. However, in an extractive distillation they cannot cross. The extractive section profile acts at the bridge between these two sections. Most of the key component separation occurs in this section in the presence of high solvent composition.

The variable that has the most significant impact on the economics of an extractive distillation is the solvent-to-feed flow rate ratio *S*/*F*. For close-boiling or pinched nonazeotropic mixtures, no minimum-solvent flow rate is required to effect the separation because the separation is always theoretically possible (if not economical) in the absence of the solvent. However, the extent of enhancement of the relative volatility is largely determined by the solvent composition in the lower column sections and hence the *S*/*F* ratio. The relative volatility tends to increase as the *S*/*F* ratio increases. Thus, a given separation can be accomplished in fewer equilibrium stages. As an illustration, the total number of theoretical stages required as a function of *S*/*F* ratio is plotted in Fig. 13-92*a* for the separation of the nonazeotropic mixture of vinyl acetate and ethyl acetate using phenol as the solvent.

For the separation of a minimum-boiling binary azeotrope by extractive distillation, there is clearly a minimum-solvent flow rate below which the separation is impossible (due to the azeotrope). For azeotropic separations, the number of equilibrium stages is infinite at or below $(S/F)_{min}$ and decreases rapidly with increasing solvent feed flow, and then may asymptote, or rise slowly. The relationship between the total number of stages and the *S*/*F* ratio for a given purity and recovery for the azeotropic acetone-methanol system with water as solvent is shown in Fig 13-92*b*. A rough idea of $(S/F)_{min}$ can be determined from a pseudobinary diagram or by plotting the $\alpha_{LH} = 1$ line on a ternary diagram. The solvent composition at which the azeotrope disappears in a corner of the pseudobinary diagram is an indication of $(S/F)_{min}$ [LaRoche et al., *Can. J. Chem. Eng.* **69:** 1302 (1991)]. An exact method for calculating $(S/F)_{min}$ is given by Knapp and Doherty [*AIChE J.* **40:** 243 (1994)]. Typically, operating *S*/*F* ratios for economically acceptable solvents are between 2 and 5. Higher *S*/*F* ratios tend to increase the diameter of both the extractive column and the solvent recovery columns, but they tend to reduce the required number of equilibrium stages and minimum reflux ratio. Moreover, higher *S*/*F* ratios lead to higher reboiler temperatures,

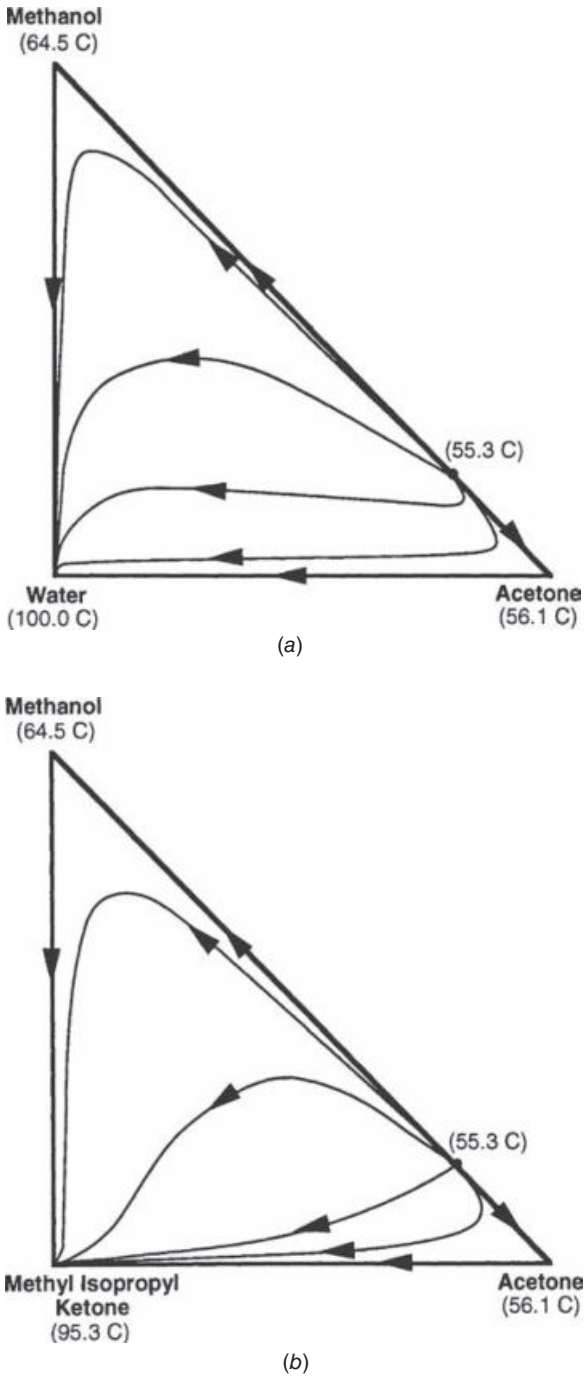

**FIG. 13-90** Residue curve maps for acetone-methanol systems. (*a*) With water. (*b*) With MIPK.

resulting in the use of higher-cost utilities, higher utility usages, and greater risk of degradation.

Knight and Doherty [*Ind. Eng. Chem. Fundam.* **28:** 564 (1989)] have published rigorous methods for computing minimum reflux for extractive distillation; they found that an operating reflux ratio of 1.2 to 1.5 times the minimum value is usually acceptable. Interestingly, unlike other forms of distillation, in extractive distillation the distillate purity or recovery does not increase monotonically with increasing reflux ratio for a given number of stages. Above a maximum reflux ratio, the separation can no longer be achieved, and the distillate purity actually decreases for a given number of stages [LaRoche et al., *AIChE J.* **38:** 1309 (1992)]. The difference between $R_{min}$ and $R_{max}$ increases as the *S*/*F* ratio increases. Large amounts of reflux lower the solvent composition in the upper section of the column, degrading

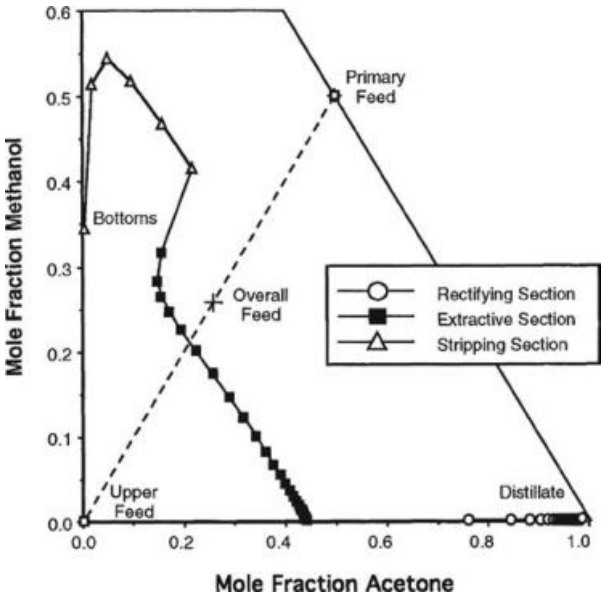

**FIG. 13-91** Extractive distillation column composition profile for the separation of acetone-methanol with water.

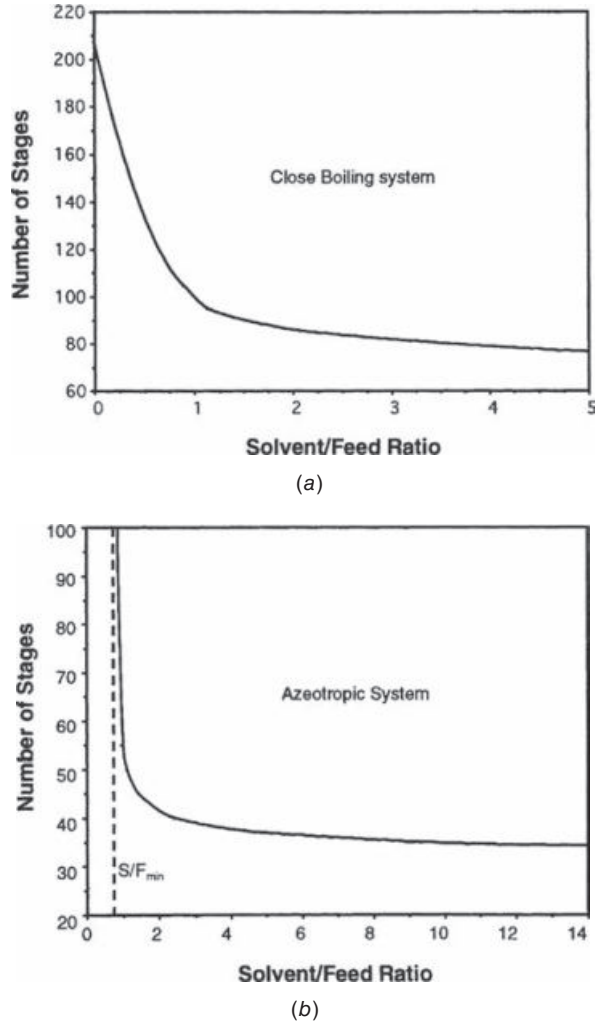

**FIG. 13-92** Number of theoretical stages versus solvent-to-feed ratio for extractive distillation. (*a*) Close-boiling vinyl acetate–ethyl acetate system with phenol solvent. (*b*) Azeotropic acetone-methanol system with water solvent.

rather than enhancing column performance. Because the reflux ratio goes through a maximum, the conventional control strategy of increasing reflux to maintain purity can be detrimental rather than beneficial. However, $R_{max}$ generally occurs at impractically high reflux ratios and is typically not a major concern.

The thermal quality of the solvent feed has no effect on the value of $S/F_{min}$, but it does affect the minimum reflux to some extent, especially as the $S/F$ ratio increases. The maximum reflux ratio $R_{max}$ occurs at higher values of the reflux ratio as the upper-feed quality decreases; a subcooled upper feed provides additional refluxing capacity, and less external reflux is required for the same separation. It is also sometimes advantageous to introduce the primary feed to the extractive distillation column as a vapor to help maintain a higher solvent composition on the feed tray and the trays immediately below.

Robinson and Gilliland (*Elements of Fractional Distillation,* McGraw-Hill, New York, 1950), Smith (*Design of Equilibrium Stage Processes,* McGraw-Hill, New York, 1963), Van Winkle (*Distillation,* McGraw-Hill, New York, 1967), and Walas (*Chemical Process Equipment,* Butterworths, Boston, 1988) discuss rigorous stage-to-stage design techniques as well as shortcut and graphical methods for determining minimum stages, $(S/F)_{min}$, minimum reflux, and the optimum locations of the solvent and primary feed points. Knapp and Doherty [*AIChE J.* **40:** 243 (1994)] have published column design methods based on geometric arguments and fixed-point analysis that are capable of calculating $(S/F)_{min}$, as well as the minimum and maximum reflux ratios. Most commercial simulators can solve multiple-feed extractive distillation heat and material balances, but they do not include straightforward techniques for calculating $(S/F)_{min}$ or the minimum and maximum reflux ratios.

**Solvent Screening and Selection** Choosing an effective solvent can have the most profound effect on the economics of an extractive distillation process. The approach most often adopted is to first generate a short list of potential solvents by using simple qualitative screening and selection methods. Experimental verification is best undertaken only after a list of promising candidate solvents has been generated and some chance at economic viability has been demonstrated via preliminary process modeling.

Solvent selection and screening approaches can be divided into two levels of analysis. The first level focuses on the identification of functional groups or chemical families that are likely to give favorable solvent–key component molecular interactions. The second level of analysis identifies and compares individual candidate solvents. The various methods of analysis are described briefly and illustrated with an example of choosing a solvent for the methanol-acetone separation.

***First Level: Broad Screening by Functional Group or Chemical Family***

*Homologous series.* Select candidate solvents from the high-boiling homologous series of both light and heavy key components. Favor homologs of the heavy key because this tends to enhance the natural relative volatility of the system. Homologous components tend to form ideal solutions and are unlikely to form azeotropes [Scheibel, *Chem. Eng. Prog.* **44**(12): 927 (1948)].

*Robbins chart.* Select candidate solvents from groups in the Robbins chart (Table 13-13) that tend to give positive (or no) deviations from Raoult's law for the key component desired in the distillate and negative (or no) deviations for the other key.

*Hydrogen-bonding characteristics.* Select candidate solvents from groups that are likely to cause the formation of hydrogen bonds with the key component to be removed in the bottoms, or disruption of hydrogen bonds with the key to be removed in the distillate. The formation and disruption of hydrogen bonds are often associated with strong negative and positive deviations, respectively, from Raoult's law. Several authors have developed charts indicating expected hydrogen bonding interactions between families of compounds [Ewell et al., *Ind. Eng. Chem.* **36:** 871 (1944); Gilmont et al., *Ind. Eng. Chem.* **53:** 223 (1961); Berg, *Chem. Eng. Prog.* **65**(9): 52 (1969)]. Table 13-18 presents a hydrogen bonding classification of chemical families and a summary of deviations from Raoult's law.

*Polarity characteristics.* Select candidate solvents from chemical groups that tend to show higher polarity than one key component or lower polarity than the other key. Polarity effects are often cited as a factor in causing deviations from Raoult's law [Hopkins and Fritsch, *Chem. Eng. Prog.* **51**(8): (1954); Carlson et al., *Ind. Eng. Chem.* **46:** 350 (1954); Prausnitz and Anderson, *AIChE J.* **7:** 96 (1961)]. The general trend in polarity based on the functional group of a molecule is given in Table 13-19. The chart is best for molecules of similar size. A more quantitative measure of the polarity of a molecule is the polarity contribution to the three-term Hansen solubility parameter. A tabulation of calculated three-term solubility parameters is provided by Barton (*CRC Handbook of Solubility Parameters and Other Cohesion Parameters,* CRC Press, Boca Raton, Fla., 1991), along with a group contribution method for calculating the three-term solubility parameters of compounds not listed in the reference.

**TABLE 13-18 Hydrogen Bonding Classification of Chemical Families**

| Class | Chemical family | | | |
|---|---|---|---|---|
| H-Bonding, Strongly Associative (HBSA) | Water<br>Primary amides<br>Secondary amides | Polyacids<br>Dicarboxylic acids<br>Monohydroxy acids | Polyphenols<br>Oximes<br>Hydroxylamines | Amino alcohols<br>Polyols |
| H-Bond Acceptor-Donor (HBAD) | Phenols<br>Aromatic acids<br>Aromatic amines<br>Alpha H nitriles | Imines<br>Monocarboxylic acids<br>Other monoacids<br>Peracids | Alpha H nitros<br>Azines<br>Primary amines<br>Secondary amines | *n*-alcohols<br>Other alcohols<br>Ether alcohols |
| H-Bond Acceptor (HBA) | Acyl chlorides<br>Acyl fluorides<br>Hetero nitrogen aromatics<br>Hetero oxygen aromatics | Tertiary amides<br>Tertiary amines<br>Other nitriles<br>Other nitros<br>Isocyanates<br>Peroxides | Aldehydes<br>Anhydrides<br>Cyclo ketones<br>Aliphatic ketones<br>Esters<br>Ethers | Aromatic esters<br>Aromatic nitriles<br>Aromatic ethers<br>Sulfones<br>Sulfolanes |
| π-Bonding Acceptor (π-HBA) | Alkynes<br>Alkenes | Aromatics<br>Unsaturated esters | | |
| H-Bond Donor (HBD) | Inorganic acids<br>Active H chlorides | Active H fluorides<br>Active H iodides | Active H bromides | |
| Non-Bonding (NB) | Paraffins<br>Nonactive H chlorides | Nonactive H fluorides<br>Sulfides | Nonactive H iodides<br>Disulfides | Nonactive H bromides<br>Thiols |

Deviations from Raoult's Law

| H-Bonding classes | Type of deviations | Comments |
|---|---|---|
| HBSA + NB<br>HBAD + NB | Alway positive dev., HBSA + NB often limited miscibility | H-bonds broken by interactions |
| HBA + HBD | Always negative dev. | H-bonds formed by interactions |
| HBSA + HBD<br>HBAD + HBD | Always positive deviations, HBSA + HBD often limited miscibility | H-bonds broken and formed; dissociation of HBSA or HBAD liquid most important effect |
| HBSA + HBSA<br>HBSA + HBAD<br>HBSA + HBA<br>HBAD + HBAD<br>HBAD + HBA | Usually positive deviations; some give maximum-boiling azeotropes | H-bonds broken and formed |
| HBA + HBA<br>HBA + NB<br>HBD + HBD<br>HBD + NB<br>NB + NB | Ideal, quasi-ideal systems; always positive or no deviations; azeotropes, if any, minimum-boiling | No H-bonding involved |

NOTE: π-HBA is *enhanced* version of HBA.

***Second Level: Identification of Individual Candidate Solvents***

*Boiling point characteristics.* Select only candidate solvents that boil at least 30°C to 40°C above the key components to ensure that the solvent is relatively nonvolatile and remains largely in the liquid phase. With this boiling point difference, the solvent should also not form azeotropes with the other components.

*Selectivity at infinite dilution.* Rank candidate solvents according to their selectivity at infinite dilution. The selectivity at infinite dilution is defined as the ratio of the activity coefficients at infinite dilution of the two key components in the solvent. Since solvent effects tend to increase as solvent concentration increases, the infinite-dilution selectivity gives an upper bound on the efficacy of a solvent. Infinite-dilution activity coefficients can be predicted by using such methods as UNIFAC, ASOG, MOSCED (Reid et al., *Properties of Gases and Liquids,* 4th ed., McGraw-Hill, New York, 1987). They can be found experimentally by using a rapid gas-liquid chromatography method based on relative retention times in candidate solvents (Tassios, in *Extractive and Azeotropic Distillation,* Advances in Chemistry Series 115, American Chemical Society, Washington, 1972), and they can be correlated to bubble point data [Kojima and Ochi, *J. Chem. Eng. Japan* **7**(2): 71 (1974)]. DECHEMA (*Vapor-Liquid Equilibrium Data Collection,* Frankfort, 1977) has also published a compilation of experimental infinite-dilution activity coefficients.

**TABLE 13-19 Relative Polarities of Functional Groups**

| | |
|---|---|
| MOST POLAR | Water |
| | Organic acids |
| | Amines |
| | Polyols |
| | Alcohols |
| | Esters |
| | Ketones |
| | Aldehydes |
| | Ethers |
| | Aromatics |
| | Olefins |
| LEAST POLAR | Paraffins |
| Effect of branching | |
| MOST POLAR | Normal |
| | Secondary |
| LEAST POLAR | Tertiary |

*Experimental measurement of relative volatility.* Rank candidate solvents by the increase in relative volatility caused by the addition of the solvent. One technique is to experimentally measure the relative volatility of a fixed-composition, key component + solvent mixture (often a 1/1 ratio of each key, with a 1/1 to 3/1 solvent/key ratio) for various solvents [Carlson et al., *Ind. Eng. Chem.* **46:** 350 (1954)]. The Othmer equilibrium still is the apparatus of choice for these measurements [Zudkevitch, *Chem. Eng. Comm.* **116:** 41 (1992)].

At atmospheric pressure, methanol and acetone boil at 64.5°C and 56.1°C, respectively, and they form a minimum-boiling azeotrope at 55.3°C. The natural volatility of the system is acetone > methanol, so the favored solvents most likely will be those that cause acetone to be recovered in the distillate. However, for the purposes of the example, a solvent that reverses the natural volatility will also be identified. First, by examining the polarity of ketones and alcohols (Table 13-19), solvents favored for the recovery of methanol in the bottoms would come from groups more polar than methanol, such as acids, water, and polyols. Turning to the Robbins chart (Table 13-13), we see that favorable groups are amines, alcohols, polyols, and water since these show expected positive deviations for acetone and zero or negative deviations for methanol. For reversing the natural volatility, solvents should be chosen that are less polar than acetone, such as ethers, hydrocarbons, and aromatics. Unfortunately, both ethers and hydrocarbons are expected to give positive deviations for both acetone and methanol, so they should be discarded. Halohydrocarbons and ketones are expected to give positive

**TABLE 13-20 Comparison of Candidate Solvents for Methanol/Acetone Extractive Distillation**

| Solvent | Boiling pt. (°C) | Azeotrope formation | $\gamma^{\infty}_{Acetone}$ | $\gamma^{\infty}_{MeOH}$ | $\gamma^{\infty}_{Acetone}/\gamma^{\infty}_{MeOH}$ |
|---|---|---|---|---|---|
| MEK | 79.6 | With MeOH | 1.01 | 1.88 | 0.537 |
| MIPK | 102.0 | No | 1.01 | 1.89 | 0.534 |
| MIBK | 115.9 | No | 1.06 | 2.05 | 0.517 |
| Ethanol | 78.3 | No | 1.85 | 1.04 | 1.78 |
| 1-Propanol | 97.2 | No | 1.90 | 1.20 | 1.58 |
| 1-Butanol | 117.8 | No | 1.93 | 1.33 | 1.45 |
| Water | 100.0 | No | 11.77 | 2.34 | 5.03 |
| EG | 197.2 | No | 3.71 | 1.25 | 2.97 |

$\gamma^{\infty}_{Acetone} = 1.79$ (in MeOH)
$\gamma^{\infty}_{MeOH} = 1.81$ (in acetone)

deviations for methanol and either negative or no deviations for acetone. The other qualitative indicators show that both homologous series (ketones and alcohols) look promising. Thus, after discounting halohydrocarbons for environmental reasons, the best solvents will probably come from alcohols, polyols, and water for recovering methanol in the bottoms and ketones for recovering acetone in the bottoms. Table 13-20 shows the boiling points and experimental or estimated infinite-dilution activity coefficients for several candidate solvents from the aforementioned groups. Methylethylketone boils too low, as does ethanol, and it also forms an azeotrope with methanol. These two candidates can be discarded. Other members of the homologous series, along with water and ethylene glycol, have acceptable boiling points (at least 30°C higher than those of the keys). Of these, water (the solvent used industrially) clearly has the largest effect on the activity coefficients, followed by ethylene glycol. Although inferior to water or ethylene glycol, both MIPK and MIBK would probably be acceptable for reversing the natural volatility of the system.

**Extractive Distillation by Salt Effects** A second method of modifying the liquid-phase behavior (and thus the relative volatility) of a mixture to effect a separation is by the addition of a nonvolatile, soluble, ionic salt. The process is analogous to extractive distillation with a high-boiling liquid. In the simplest case, for the separation of a binary mixture, the salt is fed at the top of the column by dissolving it in the hot reflux stream before introduction into the column. To function effectively, the salt must be adequately soluble in both components throughout the range of compositions encountered in the column. Since the salt is completely nonvolatile, it remains in the liquid phase on each tray and alters the relative volatility throughout the length of the column. No rectification section is needed above the salt feed. The bottoms product is recovered from the salt solution by evaporation or drying, and the salt is recycled. The ions of a salt are typically capable of causing much larger and more selective effects on liquid-phase behavior than the molecules of a liquid solvent. As a result, salt-to-feed ratios of less than 0.1 are typical.

The use of a salting agent presents a number of problems not associated with a liquid solvent, such as the difficulty of transporting and metering a solid or saturated salt solution, slow mixing or dissolution rate of the salt, limits to solubility in the feed components, and the potential for corrosion. However, in the limited number of systems for which an effective salt can be found, the energy usage, equipment size, capital investment, and ultimate separation cost can be significantly reduced compared to that for extractive distillation using a liquid solvent [Furter, *Chem. Eng. Commun.* **116:** 35 (1992)]. Applications of salt extractive distillation include acetate salts to produce absolute ethanol, magnesium nitrate for the production of concentrated nitric acid as an alternative to the sulfuric acid solvent process, and calcium chloride to produce anhydrous hydrogen chloride. Other examples are noted by Furter [*Can. J. Chem. Eng.* **55:** 229 (1977)].

One problem limiting the consideration of salt extractive distillation is the fact that the performance and solubility of a salt in a particular system are difficult to predict without experimental data. Some recent advances have been made in modeling the VLE behavior of organic aqueous salt solutions using modified UNIFAC, NRTL, UNIQUAC, and other approaches [Kumar, *Sep. Sci. Tech.* **28**(1): 799 (1993)].

## REACTIVE DISTILLATION

Reactive distillation is a process in which chemical reaction and distillation are carried out simultaneously within a fractional distillation apparatus. Reactive distillation may be advantageous for liquid-phase reaction systems when the reaction must be carried out with a large excess of one or more of the reactants, when a reaction can be driven to completion by the removal of one or more of the products as they are formed, or when the product recovery or by-product recycle scheme is complicated or made infeasible by azeotrope formation.

For consecutive reactions in which the desired product is formed in an intermediate step, excess reactant can be used to suppress additional series reactions by keeping the intermediate-species concentration low. A reactive distillation can achieve the same result by removing the desired intermediate from the reaction zone as it is formed. Similarly, if the equilibrium constant of a reversible reaction is small, high conversions of one reactant can be achieved by the use of a large excess of the other reactant. Alternatively, by Le Chatelier's principle, the reaction can be driven to completion by the removal of one or more of the products as they are formed. Typically, reactants can be kept much closer to stoichiometric proportions in a reactive distillation.

When a reaction mixture exhibits azeotropes, the recovery of products and recycle of excess reagents can be quite complicated and expensive. Reactive distillation can provide a means of breaking azeotropes by altering or eliminating the condition for azeotrope formation in the reaction zone through the combined effects of vaporization-condensation and consumption-production of the species in the mixture. Alternatively, a reaction may be used to convert the species to components that are more easily distilled. In each of these situations, the conversion and selectivity often can be improved markedly, with much lower reactant inventories and recycle rates, and much simpler recovery schemes. The capital savings can be quite dramatic. A list of applications of reactive distillation appearing in the literature is given in Table 13-21. Additional industrial applications are described by Sharma and Mahajani (chap. 1 in Sundmacher and Kienle, eds., *Reactive Distillation*, Wiley-VCH, New York, 2003).

| Production of methylal and high purity formaldehyde | | Masamoto and Matsuzaki, *J. Chem. Eng. Jap.* **27:** 1 (1994) |

Although reactive distillation has many potential applications, it is not appropriate for all situations. Since it is in essence a distillation process, it has the same range of applicability as other distillation operations. Distillation-based equipment is not designed to effectively handle solids, supercritical components (where no separate vapor and liquid phases exist), gas-phase reactions, or high-temperature or high-pressure reactions such as hydrogenation, steam reforming, gasification, and hydrodealkylation.

**Simulation, Modeling, and Design Feasibility** Because reaction and separation phenomena are closely coupled in a reactive distillation process, simulation and design are significantly more complex than those of sequential reaction and separation processes. In spite of the complexity, however, most commercial computer process modeling packages offer reliable and flexible routines for simulating steady-state reactive distillation columns, with either equilibrium or kinetically controlled reaction models [Venkataraman et al., *Chem. Eng. Prog.* **86**(6): 45 (1990)]. As with other enhanced distillation processes, the results are very sensitive to the thermodynamic models chosen and the accuracy of the VLE data used to generate model parameters. Of equal if not greater significance is the accuracy of data and models for reaction rate as a function of catalyst concentration, temperature, and composition. Very different conclusions can be drawn about the feasibility of a reactive distillation if the reaction is assumed to reach chemical equilibrium on each stage of the column or if the reaction is assumed to be kinetically controlled [Barbosa and Doherty, *Chem. Eng. Sci.* **43:** 541 (1988); Chadda, Malone, and Doherty, *AIChE J.* **47:** 590 (2001)]. Tray holdup and stage requirements are two important variables directly affected by the reaction time relative to the residence time inside the column. Unlike distillation without reaction, product feasibility can be quite sensitive to changes in tray holdup and production rate.

When an equilibrium reaction occurs in a vapor-liquid system, the phase compositions depend not only on the relative volatility of the components in the mixture, but also on the consumption (and production) of species. Thus, the condition for azeotropy in a nonreactive system ($y_i = x_i$ for all $i$) no longer holds true in a reactive system and must be modified to include reaction stoichiometry:

$$\frac{y_1 - x_1}{\nu_1 - \nu_T x_1} = \frac{y_i - x_i}{\nu_i - \nu_T x_i} \quad \text{for all} \quad i = 1, \ldots, c \tag{13-116}$$

where $$\nu_T = \sum_{i=1}^{c} \nu_i$$

and $\nu_i$ represents the stoichiometric coefficient of component $i$ (negative for reactants, positive for products).

Phase compositions that satisfy Eq. (13-116) are stationary points on a phase diagram and have been labeled *reactive azeotropes* by Barbosa and Doherty [*Chem. Eng. Sci.* **43:** 529 (1988)]. At a reactive azeotrope, the mass exchange between the vapor and liquid phases and the generation (or consumption) of each species are balanced such that the composition of neither phase changes. Reactive azeotropes show the same distillation properties as ordinary azeotropes and therefore affect the achievable products. Reactive azeotropes are predicted to exist in many reacting mixtures, and they have been confirmed experimentally in the reactive boiling mixture of acetic acid + isopropanol + isopropyl acetate + water [Song et al., *Nature* **388:** 561 (1997); Huang et al., *Chem. Eng. Sci.* **60:** 3363 (2005)].

Reactive azeotropes are not easily visualized in conventional *y-x* coordinates but become apparent upon a transformation of coordinates, which depends on the number of reactions, the order of each reaction ( for example, $A + B \rightleftharpoons C$ or $A + B \rightleftharpoons C + D$), and the presence of nonreacting components. The general vector-matrix form of the transform for $c$ reacting components, with $R$ reactions, and $I$ nonreacting components, has been derived by Ung and Doherty [*Chem. Eng. Sci.* **50:** 23 (1995)]. For the transformed mole fraction of component $i$ in the liquid phase $X_i$, they give

$$X_i = \left[ \frac{x_i - \mathbf{v}_i^T (\mathbf{v}_{\text{Ref}})^{-1} \mathbf{x}_{\text{Ref}}}{1 - \mathbf{v}_{\text{TOT}}^T (\mathbf{v}_{\text{Ref}})^{-1} \mathbf{x}_{\text{Ref}}} \right] \quad i = 1 \cdots c - R \tag{13-117}$$

where $\mathbf{v}_i^T$ = row vector of stoichiometric coefficients of component $i$ for each reaction
$\mathbf{v}_{\text{Ref}}$ = square matrix of stoichiometric coefficients for $R$ reference components in $R$ reactions
$\mathbf{x}_{\text{Ref}}$ = column vector of mole fractions for $R$ reference components in liquid phase
$\mathbf{v}_{\text{TOT}}^T$ = row vector composed of the sum of stoichiometric coefficients for each reaction

An equation identical to (13-117) defines the transformed mole fraction of component $i$ in the vapor phase $Y_i$, where the terms in $x$ are replaced by terms in $y$.

The transformed variables describe the system composition with or without reaction and sum to unity as do $x_i$ and $y_i$. The condition for reactive azeotropy becomes $X_i = Y_i$. Barbosa and Doherty have shown that phase diagrams and distillation diagrams constructed by using the transformed composition coordinates have the same properties as phase and distillation diagrams for nonreactive systems and similarly can be used to help design feasibility and operability studies [*Chem. Eng. Sci.* **43:** 529, 541, 1523, and 2377 (1988)]. Residue curve maps in transformed coordinates for the reactive system methanol–acetic acid–methyl acetate–water are shown in Fig. 13-93. Note that the nonreactive azeotrope between water and methyl acetate has disappeared, while the methyl acetate–methanol azeotrope remains intact. Only those azeotropes containing all the reactants or products will be altered by the reaction (water and methyl acetate can back-react to form acetic acid and methanol, whereas methanol and methyl acetate

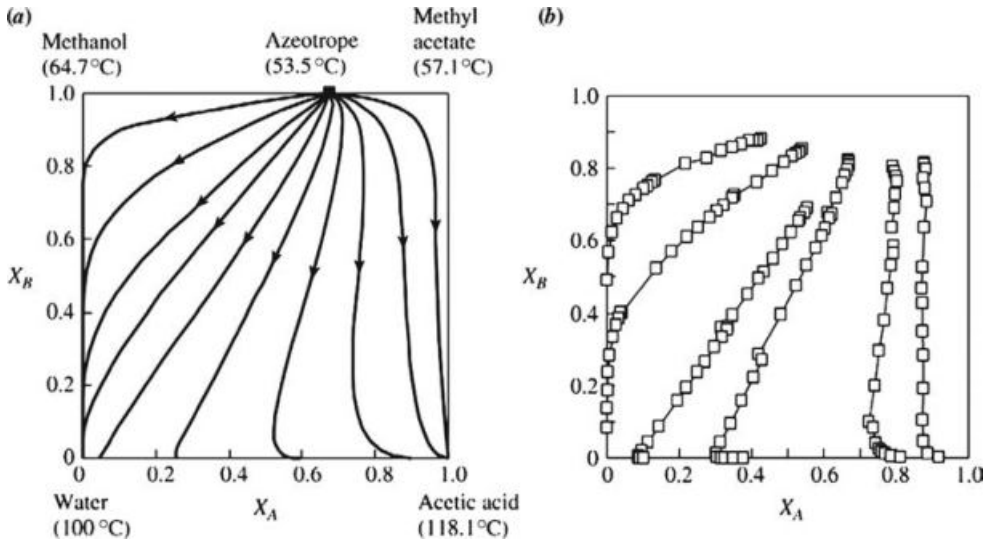

**FIG. 13-93** Residue curve maps for the reactive system methanol–acetic acid–methyl acetate–water in phase and chemical equilibrium at 1 atm pressure. (*a*) Calculated by Barbosa and Doherty [*Chem. Eng. Sci.* **43:** 1523 (1988)]. (*b*) Measured by Song et al. [*Ind. Eng. Chem. Res.* **37:** 1917 (1998)].

cannot further react in the absence of either water or acetic acid). This reactive system consists of only one distillation region in which the methanol–methyl acetate azeotrope is the low-boiling node and acetic acid is the high-boiling node.

The situation becomes more complicated when the reaction is kinetically controlled and does not come to complete chemical equilibrium under the conditions of temperature, liquid holdup, and rate of vaporization in the column reactor. Venimadhavan et al. [*AIChE J.* **40:** 1814 (1994); **45:** 546 (1999)] and Rev [*Ind. Eng. Chem. Res.* **33:** 2174 (1994)] show that the concept of a reactive azeotrope generalizes to the concept of a *reactive fixed point*, whose existence and location are a function of approach to equilibrium as well as the evaporation rate [see also Frey and Stichlmair, *Trans IChemE* **77,** Part A, 613 (1999); Chadda, Malone, and Doherty, *AIChE J.* **47:** 590 (2001); Chiplunkar et al., *AIChE J.* **51:** 464 (2005)]. In the limit of simultaneous phase and reaction equilibrium, a reactive fixed point becomes identical to the thermodynamic concept of a reactive azeotrope.

These ideas have been extended to reacting systems with (1) multiple chemical reactions [Ung and Doherty, *Ind. Eng. Chem. Res.* **34:** 2555, 3195 (1995)], (2) multiple liquid phases [Ung and Doherty, *Chem. Eng. Sci.* **50:** 3201 (1995); Qi, Kolah, and Sundmacher, *Chem. Eng. Sci.* **57:** 163 (2002); Qi and Sundmacher, *Comp. Chem. Eng.* **26:** 1459 (2002)], (3) membrane separations [Huang et al., *Chem. Eng. Sci.* **59:** 2863 (2004)], (4) finite rates of vapor-liquid mass transfer [Baur, Taylor, and Krishna, *Chem. Eng. Sci.* **56:** 2085 (2001); Nisoli, Doherty, and Malone, *AIChE J.* **50:** 1795 (2004)], (5) column design and multiple steady-states (Güttinger, Dorn, and Morari, *Ind. Eng. Chem. Res.* **36:** 794 (1997); Hauan, Hertzberg, and Lien, *Comput. Chem. Eng.* **21:** 1117 (1997); Sneesby et al., *Ind. Eng. Chem. Res.* **36:** 1855 (1997); Bessling et al., *Chem. Eng. Technol.* **21:** 393 (1998); Okasinski and Doherty, *Ind. Eng. Chem. Res.* **37:** 2821 (1998); Sneesby, Tade, and Smith, *Trans. IChemE.* **76,** Part A, 525 (1998); Güttinger and Morari, *Ind. Eng. Chem. Res.* **38:** 1633, 1649 (1999); Higler, Taylor, and Krishna, *Chem. Eng. Sci.* **54:** 1389 (1999); Mohl et al., *Chem. Eng. Sci.* **54:** 1029 (1999); Chen et al., *Comput. Chem. Eng.* **26:** 81 (2002)]. Much useful information is available in Taylor and Krishna [*Chem. Eng. Sci.* **55:** 5183 (2000)] and Sundmacher and Kienle (*Reactive Distillation*, Wiley-VCH, New York, 2003).

**Mechanical Design and Implementation Issues** The choice of catalyst has a significant impact on the mechanical design and operation of the reactive column. The catalyst must allow the reaction to occur at reasonable rates at the relatively low temperatures and pressures common in distillation operations (typically less than 10 atm and between 50°C and 250°C). The selection of a homogeneous catalyst, such as a high-boiling mineral acid, allows the use of more traditional tray designs and internals (albeit designed with exotic materials of construction to avoid corrosion, and allowance for high-liquid holdups to achieve suitable reaction contact times). With a homogeneous catalyst, lifetime is not a problem, as it is added (and withdrawn) continuously. Alternatively, heterogeneous solid catalysts require either complicated mechanical means for continuous replenishment or relatively long lifetimes to avoid constant maintenance. As with other multiphase reactors, the use of a solid catalyst adds resistance to mass transfer from the bulk liquid (or vapor) to the catalyst surface, which may be the limiting resistance. The catalyst containment system must be designed to ensure adequate liquid-solid contacting and to minimize bypassing. A number of specialized column internal designs, catalyst containment methods, and catalyst replenishment systems have been proposed for both homogeneous and heterogeneous catalysts. A partial list of these methods is given in Table 13-22; see also the useful ideas presented by Krishna [*Chem. Eng. Sci.* **57:** 1491 (2002); and chap. 7 in Sundmacher and Kienle, eds., *Reactive Distillation*, Wiley-VCH, New York, 2003].

Heat management is another important consideration in the implementation of a reactive distillation process. Conventional reactors for highly exothermic or endothermic reactions are often designed as modified shell-and-tube heat exchangers for efficient heat transfer. However, a trayed or packed distillation column is a rather poor mechanical design for the management of the heat of reaction. Although heat can be removed or added in the condenser or reboiler easily, the only mechanism for heat transfer in the column proper is through vaporization (or condensation). For highly exothermic reactions, a large excess of reactants may be required as a heat sink, necessitating high reflux rates and larger-diameter columns to return the vaporized reactants back to the reaction zone. Often a prereactor of conventional design is used to accomplish most of the reaction and heat removal before feeding to the reactive column for final conversion, as exemplified in most processes for the production of tertiary amyl methyl ether (TAME) [Brockwell et al., *Hyd. Proc.* **70**(9): 133 (1991)]. Highly endothermic reactions may require intermediate reboilers. None of these heat management issues preclude the use of reactive distillation, but they must be taken into account during the design phase. A comparison of heat of reaction and average heat of vaporization data for a system, as in Fig. 13-94, gives some indication of potential heat imbalances [Sundmacher, Rihko, and Hoffmann, *Chem. Eng. Comm.* **127:** 151 (1994)]. The heat-neutral systems [$-\Delta H_{react} \approx \Delta H_{vap}$ (avg)] such as methyl acetate and other esters can be accomplished in one reactive column, whereas the MTBE and TAME processes, with higher heats of reaction than that of vaporization, often include an additional prereactor. One exception is the catalytic distillation process for cumene production, which is accomplished without a prereactor. Three moles of benzene reactant are vaporized (and refluxed) for every mole of cumene produced. The relatively high heat of reaction is advantageous in this case as it reduces the overall

heat duty of the process by about 30 percent [Shoemaker and Jones, *Hyd. Proc.* **57**(6): 57 (1987)].

Distillation columns with multiple conventional side reactors were first suggested by Schoenmakers and Buehler [*German Chem. Eng.* **5:** 292 (1982)] and have the potential to accommodate gas-phase reactions, highly exo- or endothermic reactions, catalyst deactivation, and operating conditions outside the normal range suitable for distillation (e.g., short contact times, high temperature and pressure); see Krishna (chap. 7 in Sundmacher and Kienle, eds., *Reactive Distillation*, Wiley-VCH, New York, 2003). This process concept has been applied commercially to produce ethyl acetate from ethanol [Gadewar et al., U.S. Patent 9,079,851 B2 (2015)].

**Process Applications** The production of esters from alcohols and carboxylic acids illustrates many of the principles of reactive distillation as applied to equilibrium-limited systems. The true thermodynamic equilibrium constants for esterification reactions are usually in the range of 5 to 20. Large excesses of alcohols must be used to obtain acceptable yields, resulting in large recycle flow rates. In a reactive distillation scheme, the reaction is driven to completion by removal of the water of esterification. The method used for removal of the water depends on the boiling points, compositions, and liquid-phase behavior of any azeotropes formed between the products and reactants and largely dictates the structure of the reactive distillation flow sheet.

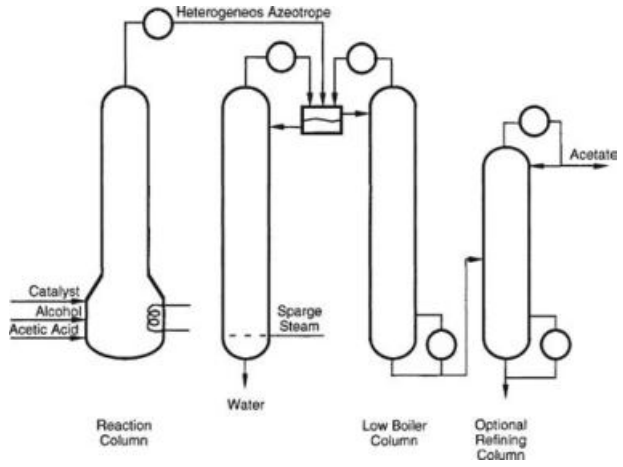

**FIG. 13-95** Flow sheet for making esters that form a heterogeneous minimum-boiling azeotrope with water.

When the ester forms a binary low-boiling azeotrope with water or a ternary alcohol-ester-water azeotrope and that azeotrope is heterogeneous (or can be moved into the two-liquid phase region), the flow sheet illustrated in Fig. 13-95 can be used. Such a flow sheet works for the production of ethyl acetate and higher homologs. In this process scheme, acetic acid and the alcohol are continuously fed to the reboiler of the esterification column (reflux not shown in the column) along with a homogeneous strong-acid catalyst. Since the catalyst is largely nonvolatile, the reboiler acts as the primary reaction section. The alcohol is usually fed in slight excess to ensure complete reaction of the acid and to compensate for alcohol losses through distillation of the water-ester-(alcohol) azeotrope. The esterification column is operated so that the low-boiling, water-laden azeotrope is taken as the distillation product. Upon cooling, the distillate separates into two liquid phases. The aqueous layer is steam-stripped, with the organics recycled to the decanter or reactor. The ester layer from the decanter contains some water and possibly alcohol. Part of this layer may be refluxed to the esterification column (reflux not shown in the figure). The remainder is fed to a low-boiler column where the water-ester and alcohol-ester azeotropes are removed overhead and recycled to the decanter or reactor. The dry, alcohol-free ester is then optionally taken overhead in a final refining column. Additional literature on the application of reactive distillation to ester production includes papers by Hanika, Kolena, and Smejkal [*Chem. Eng. Sci.* **54:** 5205 (1999)], Schwarzer and Hoffmann [*Chem. Eng. Technol.* **25:** 975 (2002)], Steinigeweg and Gmehling [*Ind. Eng. Chem. Res.* **41:** 5483 (2002)], and Omata, Dimian, and Bliek [*Chem. Eng. Sci.* **58:** 3159, 3175 (2003)].

Methyl acetate cannot be produced in high purity by using the simple esterification scheme just described. The methyl acetate–methanol–water system does not exhibit a ternary minimum-boiling azeotrope, the methyl acetate–methanol azeotrope is lower-boiling than the water–methyl acetate azeotrope, a distillation boundary extends between these two binary azeotropes, and the heterogeneous region does not include either azeotrope, nor does it cross the distillation boundary. Consequently, the water of esterification cannot be removed effectively, and methyl acetate cannot be separated from the methanol and water azeotropes by a simple decantation in the same manner as that previously outlined. Conventional sequential reaction-separation processes rely on large excesses of acetic acid to drive the reaction to higher conversion to methyl acetate, necessitating a capital- and energy-intensive acetic acid–water separation and large recycle streams. The crude methyl acetate product, contaminated with water and methanol, can be purified by a number of enhanced distillation techniques, such as pressure-swing distillation (Harrison, U.S. Patent 2,704,271, 1955), extractive distillation with ethylene glycol monomethylether as the solvent (Kumerle, German Patent 1,070,165, 1959), or azeotropic distillation with an aromatic or ketone entrainer (Yeomans, Eur. Patent Appl. 060717 and 060719, 1982). The end result is a capital- and energy-intensive process typically requiring multiple reactors and distillation columns.

The reactive distillation process in Fig. 13-96 provides a mechanism for overcoming both the limitations on conversion due to chemical equilibrium and the difficulties in purification imposed by the water–methyl acetate and methanol–methyl acetate azeotropes [Agreda and Partin, U.S. Patent 4,435,595, 1984; Agreda, Partin, and Heise, *Chem. Eng. Prog.* **86**(2): 40 (1990)]. Conceptually, this flow sheet can be thought of as four heat-integrated distillation columns (one of which is also a reactor) stacked on top of each other. The primary reaction zone consists of a series of countercurrent flashing stages in the middle of the column. Adequate residence time for the reaction is provided by high-liquid-holdup bubble cap trays with specially designed downcomer sumps to further increase tray holdup. A nonvolatile homogeneous catalyst is fed at the top of the reactive section and exits with the underflow water by-product. The extractive distillation section, immediately above the reactive section, is critical in achieving high methyl acetate purity. As shown in Fig. 13-93, simultaneous reaction and distillation eliminates the water–methyl acetate azeotrope (and the distillation boundary of the nonreactive system). However, pure methyl acetate remains a saddle in the reactive system and cannot be obtained as a pure component by simple reactive distillation. The acetic acid feed acts as a solvent in an extractive-distillation section placed above the reaction section, breaking the methanol-methyl acetate azeotrope, and yielding a pure methyl acetate distillate product. The uppermost rectification stages serve to remove any acetic acid from the methyl acetate product, and the bottommost stripping section removes any methanol and methyl acetate from the water by-product. The countercurrent flow of the reactants results in high local excesses at each end of the reactive section, even though the overall feed to the reactive column is stoichiometric. Therefore, the large excess of acetic acid at the top of the reactive section prevents methanol from reaching the distillate; similarly, methanol at the bottom of the reactive section keeps acetic acid from the water bottoms. Temperature and composition profiles for this reactive extractive distillation column are shown in Fig. 13-97*a* and *b,* respectively.

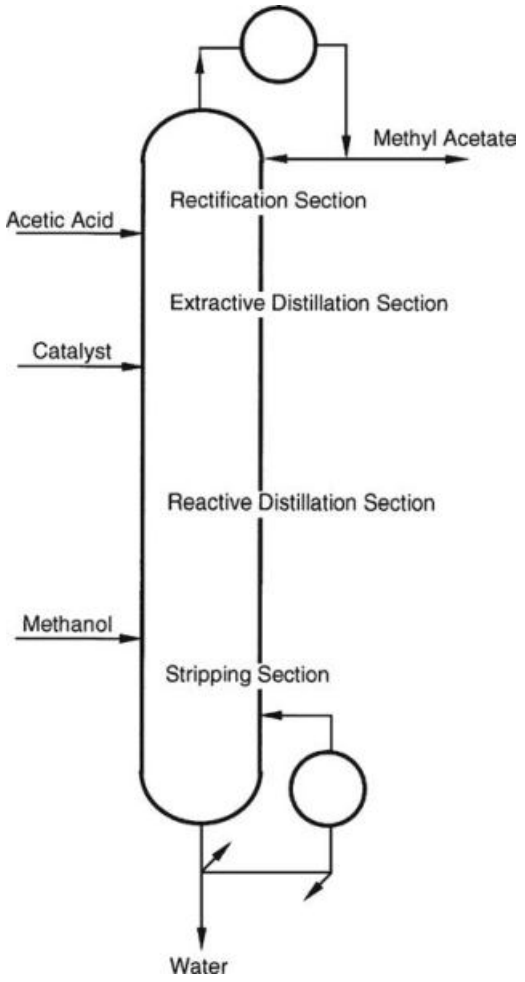

**FIG. 13-96** Integrated reactive extractive distillation column for the production of methyl acetate.

Much has been written about this reactive distillation scheme, including works by Bessling et al. [*Chem. Eng. Tech.* **21:** 393 (1998)], Song et al. [*Ind. Eng. Chem. Res.* **37:** 1917 (1998)], Huss et al. [*Comput. Chem. Eng.* **27:** 1855 (2003)], Siirola ("An Industrial Perspective on Process Synthesis," in *Foundations of Computer-Aided Process Design*, ed. Biegler and Doherty, AIChE, New York, 1995, pp. 222–233), and Krishna (chap. 7 in *Reactive Distillation*, ed. Sundmacher and Kienle, Wiley-VCH, New York, 2003).

## SYNTHESIS OF MULTICOMPONENT SEPARATION SYSTEMS

The sequencing of distillation columns and other types of equipment for the separation of multicomponent mixtures has received much attention in recent years. Although one separator of complex design can sometimes be devised to produce more than two products, more often a sequence of two-product separators is preferable. Often, the sequence includes simple distillation columns. A summary of sequencing methods, prior to 1977, that can lead to optimal or near-optimal designs is given by Henley and Seader (1981). Methods for distillation column sequencing are reviewed by Modi and Westerberg [*Ind. Eng. Chem. Res.* **31:** 839 (1992)], who also present a more generally applicable method based on a marginal price that is the change in price of a separation operation when the separation is carried out in the absence of nonkey components. The synthesis of sequences that consider a wide range of separation operations in a knowledge-based approach is given by Barnicki and Fair for liquid mixtures [*Ind. Eng. Chem. Res.* **29:** 421 (1990)] and for gas/vapor mixtures [*Ind. Eng. Chem. Res.* **31:** 1679 (1992)]. The problem decomposition approach of Wahnschafft, Le Rudulier, and Westerberg [*Ind. Eng. Chem. Res.* **32:** 1121 (1993)] is directed to the synthesis of complex separation sequences that involve nonsharp splits and recycle, including azeotropic distillation. The method was applied by using a computer-aided separation process designer called *SPLIT.* The approach developed by Ryll, Blagov, and Hasse [*Chem. Eng Sci.* **84:** 315 (2012)] for the synthesis of multicomponent azeotropic distillation systems is especially notable. An expert system, called *EXSEP,* for the synthesis of solvent-based separation trains is presented by Brunet and Liu [*Ind. Eng. Chem. Res.* **32:** 315 (1993)]. The use of ternary composition diagrams and residue curve maps is reviewed and evaluated for application to the synthesis of complex separation sequences by Fien and Liu [*Ind. Eng. Chem. Res.* **33:** 2506 (1994)]. In recent years, many optimization-based process synthesis schemes have been proposed for distillation systems; see the review by Chen and Grossmann [*Annu. Rev. Chem. Biomol. Eng.* **8** (2017)].

Synthesis schemes for reactive distillation have been proposed by Ismail, Proios, and Pistikopoulos [*AIChE J.* **47:** 629 (2001)], Jackson and Grossmann [*Comput. Chem. Eng.* **25:** 1661 (2001)], Schembecker and Tlatlik [*Chem. Eng. Process.* **42:** 179 (2003)], and Burri and Manousiouthakis [*Comput. Chem. Eng.* **28:** 2509 (2004)].

# PETROLEUM AND COMPLEX-MIXTURE DISTILLATION

Although the principles of multicomponent distillation apply to petroleum, synthetic crude oil, and other complex mixtures, this subject warrants special consideration for the following reasons:

1. Such feedstocks are of exceedingly complex composition, consisting of, in the case of petroleum, many different types of hydrocarbons and perhaps of inorganic and other organic compounds. The number of carbon atoms in the components may range from 1 to more than 50, so the compounds may exhibit atmospheric-pressure boiling points from −162°C (−259°F) to more than 538°C (1000°F). In a given boiling range, the number of different compounds that exhibit only small differences in volatility multiplies rapidly with increasing boiling point. For example, 16 of the 18 octane isomers boil within a range of only 12°C (22°F).

2. Products from the distillation of complex mixtures are in themselves complex mixtures. The character and yields of these products vary widely, depending on the source of the feedstock. Even crude oils from the same locality may exhibit marked variations.

3. The scale of petroleum-distillation operations is generally large, and as discussed in detail by Nelson (*Petroleum Refinery Engineering,* 4th ed., McGraw-Hill, New York, 1958) and Watkins (*Petroleum Refinery Distillation,* 2d ed., Gulf, Houston, 1979), such operations are common in several petroleum refinery processes, including atmospheric distillation of crude oil, vacuum distillation of bottoms residuum obtained from atmospheric distillation, main fractionation of gaseous effluent from catalytic cracking of various petroleum fractions, and main fractionation of effluent from thermal coking of various petroleum fractions. These distillation operations are conducted in large pieces of equipment that can consume large quantities of energy. Therefore, the optimization of design and operation is very important and often leads to a relatively complex equipment configuration.

## CHARACTERIZATION OF PETROLEUM AND PETROLEUM FRACTIONS

Although much progress has been made in identifying the chemical species in petroleum, it is generally sufficient for the purposes of designing and analyzing the operation of distillation plants to characterize petroleum and petroleum fractions by gravity, laboratory distillation curves, component analysis of light ends, and hydrocarbon-type analysis of middle and heavy ends. From such data, as discussed in the *Technical Data Book—Petroleum Refining* [American Petroleum Institute (API), Washington], five different average boiling points and an index of paraffinicity can be determined. These are then used to predict the physical properties of complex mixtures by a number of well-accepted correlations, whose use will be explained in detail and illustrated with examples. Many other characterizing properties or attributes such as sulfur content, pour point, water and sediment content, salt content, metals content, Reid vapor pressure, Saybolt Universal viscosity, aniline point, octane number, freezing point, cloud point, smoke point, diesel index, refractive index, cetane index, neutralization number, wax content, carbon content, and penetration are generally measured for a crude oil or certain of its fractions, according to well-specified ASTM tests. But these attributes are of much less interest here, even though feedstocks and products may be required to meet certain specified values of the attributes.

The gravity of a crude oil or petroleum fraction is generally measured by the ASTM D287 test or the equivalent ASTM D1298 test, and it may be reported as specific gravity (SG) 60/60°F [measured at 60°F (15.6°C) and referred to water at 60°F (15.6°C)] or, more commonly, as API gravity, which is defined as

$$\text{API gravity} = 141.5/(\text{SG } 60/60°\text{F}) - 131.5 \qquad (13\text{-}118)$$

Water thus has an API gravity of 10.0, and most crude oils and petroleum fractions have values of API gravity in the range of 10 to 80. Light hydrocarbons (*n*-pentane and lighter) have values of API gravity ranging upward from 92.8.

The volatility of crude oil and petroleum fractions is characterized in terms of one or more laboratory distillation tests that are summarized in Table 13-23. The ASTM D86 and D 1160 tests are reasonably rapid batch laboratory distillations involving the equivalent of approximately one equilibrium stage and no reflux except for that caused by heat losses. Apparatus typical of the D 86 test is shown in Fig. 13-98 and consists of a heated 100-mL or 125-mL Engler flask containing a calibrated thermometer of suitable range to measure the temperature of the vapor at the inlet to the condensing tube, an inclined brass condenser in a cooling bath using a suitable coolant, and a graduated cylinder for collecting the distillate. A stem correction is not applied to the temperature reading. Related tests using similar apparatus are the D 216 test for natural gasoline and the Engler distillation.

In the widely used ASTM D86 test, 100 mL of sample is charged to the flask and heated at a sufficient rate to produce the first drop of distillate from the lower end of the condenser tube in 5 to 15 min, depending on the nature of the sample. The temperature of the vapor at that instant is recorded as the initial boiling point (IBP). Heating is continued at a rate such that the time from the IBP to 5 vol% recovered of the sample in the cylinder is 60 to 75 s. Again, vapor temperature is recorded. Then successive vapor temperatures are recorded for 10 to 90 percent recovered in intervals of 10, and at 95 percent recovered, with the heating rate adjusted so that 4 to 5 mL is collected per minute. At 95 percent recovered, the burner flame is increased if necessary to achieve a maximum vapor temperature, referred to as the endpoint (EP) in 3 to 5 additional min. The percent recovery is reported as the maximum percent recovered in the cylinder. Any residue remaining in the flask is reported as percent residue, and percent loss is reported as the difference between 100 mL and the sum of the percent recovery and percent residue. If the atmosphere test pressure $P$ is other than 101.3 kPa (760 torr), temperature readings may be adjusted to that pressure by the Sidney Young equation, which for degrees Fahrenheit is

$$T_{760} = T_P + 0.00012(760 - P)(460 + T_P) \qquad (13\text{-}119)$$

Another pressure correction for percent loss can also be applied, as described in the ASTM test method.

The results of a typical ASTM distillation test for an automotive gasoline are given in Table 13-24, in which temperatures have already been corrected to a pressure of 101.3 kPa (760 torr). It is generally assumed that percent loss corresponds to volatile noncondensables that are distilled off at the beginning of the test. In that case, the percent recovered values in Table 13-24 do not correspond to percent evaporated values, which are of greater scientific value. Therefore, it is common to adjust the reported temperatures according to a linear interpolation procedure given in the ASTM test method to obtain corrected temperatures in terms of percent evaporated at the standard intervals as included in Table 13-24. In the example, the corrections are not large because the loss is only 1.5 vol%.

Although most crude petroleum can be heated to 600°F (316°C) without noticeable cracking, when ASTM temperatures exceed 475°F (246°C), fumes may be evolved, indicating decomposition, which may cause thermometer readings to be low. In that case, the following correction attributed to S. T. Hadden may be applied:

$$\Delta T_{\text{corr}} = 10^{\,-1.587 + 0.0047357T} \qquad (13\text{-}120)$$

where $T$ = measured temperature, °F
$\Delta T_{\text{corr}}$ = correction to be added to $T$, °F

**TABLE 13-23 Laboratory Distillation Tests**

| Test name | Reference | Main applicability |
|---|---|---|
| ASTM (atmospheric) | ASTM D 86 | Petroleum fractions or products, including gasolines, turbine fuels, naphthas, kerosines, gas oils, distillate fuel oils, and solvents that do not tend to decompose when vaporized at 760 mmHg |
| ASTM [vacuum, often 10 torr (1.3 kPa)] | ASTM D 1160 | Heavy petroleum fractions or products that tend to decompose in the ASTM D 86 test but can be partially or completely vaporized at a maximum liquid temperature of 750°F (400°C) at pressures down to 1 torr (0.13 kPa) |
| TBP [atmospheric or 10 torr (1.3 kPa)] | Nelson,* ASTM D 2892 | Crude oil and petroleum fractions |

*Nelson, *Petroleum Refinery Engineering,* 4th ed., McGraw-Hill, New York, 1958, pp. 95–99.
†Ibid., pp. 104–105.

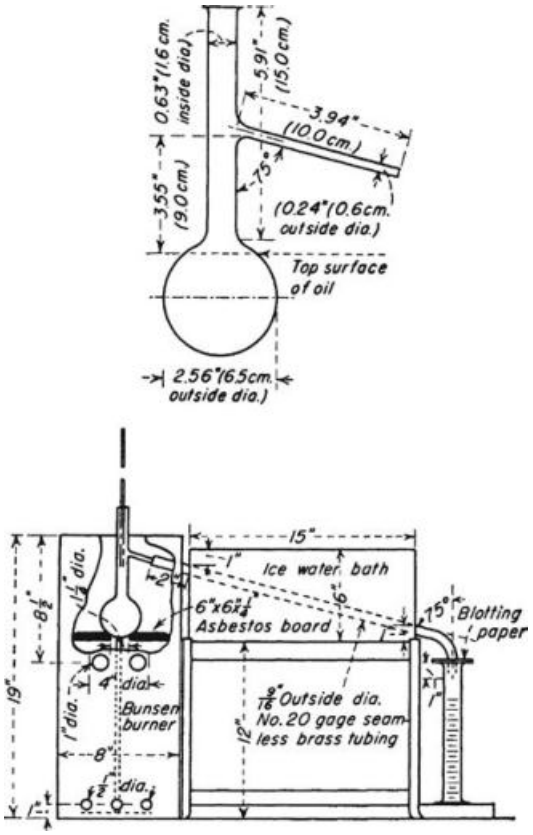

**FIG. 13-98** ASTM distillation apparatus; detail of distilling flask is shown in the upper figure.

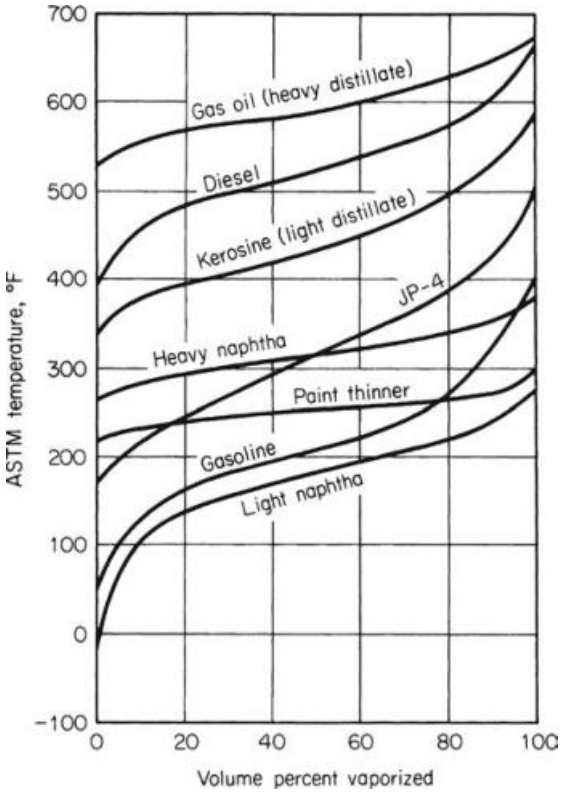

**FIG. 13-99** Representative ASTM D86 distillation curves.

At 500°F and 600°F (260°C and 316°C), the corrections are 6°F and 18°F (3.3°C and 10°C), respectively.

As discussed by Nelson (*Petroleum Refinery Engineering*, 4th ed., McGraw-Hill, New York, 1958), virtually no fractionation occurs in an ASTM distillation. Thus, components in the mixture do distill one by one in the order of their boiling points but as mixtures of successively higher boiling points. The IBP, EP, and intermediate points have little theoretical significance, and, in fact, components boiling below the IBP and above the EP are present in the sample. Nevertheless, because ASTM distillations are quickly conducted, have been successfully automated, require only a small sample, and are quite reproducible, they are widely used for comparison and as a basis for specifications on a large number of petroleum intermediates and products, including many solvents and fuels. Typical ASTM curves for several such products are shown in Fig. 13-99.

Data from a *true boiling point* (TBP) distillation test provide a much better theoretical basis for characterization. If the sample contains compounds that have moderate differences in boiling points such as in a light gasoline containing light hydrocarbons (e.g., isobutane, *n*-butane, isopentane), a plot of overhead vapor distillate temperature versus percent distilled in a TBP test would appear in the form of steps as in Fig. 13-100. However, if the sample has a higher average boiling range when the number of close-boiling isomers increases, the steps become indistinct, and a TBP curve such as that in Fig. 13-101 results. Because the degree of separation for a TBP distillation test is much higher than that for an ASTM distillation test, the IBP is lower and the EP is higher for the TBP method than for the ASTM method, as shown in Fig. 13-101.

A standard TBP laboratory distillation test method has not been well accepted. Instead, as discussed by Nelson (1958, pp. 95–99), batch distillation equipment that can achieve a good degree of fractionation is usually considered suitable. In general, TBP distillations are conducted in columns with 15 to 100 theoretical stages at reflux ratios of 5 or greater. Thus, the new ASTM D2892 test method, which involves a column with 14 to 17 theoretical

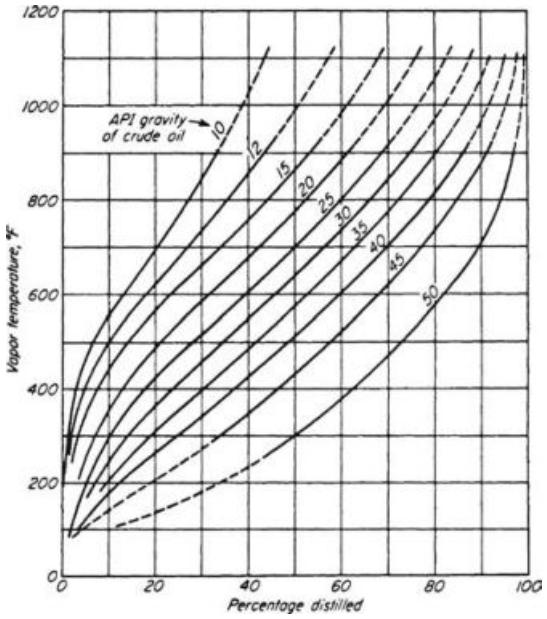

**FIG. 13-102** Average true-boiling-point distillation curves of crude oils. *(From W. E. Edmister,* Applied Hydrocarbon Thermodynamics, *vol. 1, 1st ed., 1961 Gulf Publishing Company, Houston, Texas, Used with permission. All rights reserved.)*

stages and a reflux ratio of 5, essentially meets the minimum requirements. Distillate may be collected at a constant or a variable rate. Operation may be at 101.3-kPa (760-torr) pressure or at a vacuum at the top of the column as low as 0.067 kPa (0.5 torr) for high-boiling fractions, with 1.3 kPa (10 torr) being common. Results from vacuum operation are extrapolated to 101.3 kPa (760 torr) by the vapor-pressure correlation of Maxwell and Bonner [*Ind. Eng. Chem.* **49:** 1187 (1957)], which is given in great detail in the API *Technical Data Book—Petroleum Refining* (1966) and in the ASTM D2892 test method. It includes a correction for the nature of the sample (paraffin, olefin, naphthene, and aromatic content) in terms of the UOP characterization factor, UOP-K, as given by

$$\text{UOP-K} = \frac{(T_B)^{1/3}}{\text{SG}} \tag{13-121}$$

where $T_B$ is the mean average boiling point in degrees Rankine, which is the arithmetic average of the molal average boiling point and the cubic volumetric average boiling point. Values of UOP-K for *n*-hexane, 1-hexene, cyclohexene, and benzene are 12.82, 12.49, 10.99, and 9.73, respectively. Thus, paraffins with their lower values of specific gravity tend to have high values, and aromatics tend to have low values of UOP-K. A movement toward an international TBP standard is discussed by Vercier and Mouton [*Oil Gas J.* **77**(38): 121 (1979)].

A crude oil assay always includes a whole crude API gravity and a TBP curve. As discussed by Nelson (1958, pp. 89–90) and as shown in Fig. 13-102, a reasonably consistent correlation (based on more than 350 distillation curves) exists between whole crude API gravity and the TBP distillation curve at 101.3 kPa (760 torr). Exceptions not correlated by Fig. 13-102 are highly paraffinic or naphthenic crude oils.

An alternative to TBP distillation is simulated distillation by gas chromatography. As described by Green, Schmauch, and Worman [*Anal. Chem.* **36:** 1512 (1965)] and Worman and Green [*Anal. Chem.* **37:** 1620 (1965)], the method is equivalent to a 100-theoretical-plate TBP distillation; is very rapid, reproducible, and easily automated; requires only a small microliter sample; and can better define initial and final boiling points. The ASTM D2887 standard test method is based on such a simulated distillation and is applicable to samples having a boiling range greater than 55°C (100°F) for temperature determinations as high as 538°C (1000°F). Typically, the test is conducted with a gas chromatograph having a thermal conductivity detector, a programmed temperature capability, helium or hydrogen carrier gas, and column packing of silicone gum rubber on a crushed firebrick or diatomaceous earth support.

It is important to note that simulated distillation does not always separate hydrocarbons in the order of their boiling points. For example, high-boiling multiple-ring-type compounds may be eluted earlier than normal paraffins (used as the calibration standard) of the same boiling point. Gas chromatography is also used in the ASTM D2427 test method to determine quantitatively ethane through pentane hydrocarbons.

A third fundamental type of laboratory distillation, which is the most tedious to perform of the three types of laboratory distillations, is equilibrium flash vaporization (EFV), for which no standard test exists. The sample is heated in such a manner that the total vapor produced remains in contact with the total remaining liquid until the desired temperature is reached at a set pressure. The volume percent vaporized at these conditions is recorded. To determine the complete flash curve, a series of runs at a fixed pressure is conducted over a range of temperatures sufficient to cover the range of vaporization from 0 to 100 percent. As seen in Fig. 13-101, the component separation achieved by an EFV distillation is much less than that achieved by the ASTM or TBP distillation tests. The initial and final EFV points are the bubble point and the dew point, respectively, of the sample. If desired, EFV curves can be established at a series of pressures.

Because of the time and expense involved in conducting laboratory distillation tests of all three basic types, it has become increasingly common to use empirical correlations to estimate the other two distillation curves when the ASTM, TBP, or EFV curve is available. Preferred correlations given in the API *Technical Data Book—Petroleum Refining* (1966) are based on the work of Edmister and Pollock [*Chem. Eng. Prog.* **44:** 905 (1948)], Edmister and Okamoto [*Pet. Refiner* **38**(8): 117 (1959); **38**(9): 271 (1959)], Maxwell (*Data Book on Hydrocarbons,* Van Nostrand, Princeton, N.J., 1950), and Chu and Staffel [*J. Inst. Pet.* **41:** 92 (1955)]. Because of the lack of sufficiently precise and consistent data on which to develop the correlations, they are, at best, first approximations and should be used with caution. Also, they do not apply to mixtures containing only a few components of widely different boiling points. Perhaps the most useful correlation of the group is Fig. 13-103 for converting between ASTM D86 and TBP distillations of petroleum fractions at 101.3 kPa (760 torr). The ASTM D2889 test method, which presents a standard method for calculating EFV curves from the results of an ASTM D86 test for a petroleum fraction having a 10 to 90 vol% boiling range of less than 55°C (100°F), is also quite useful.

## APPLICATIONS OF PETROLEUM DISTILLATION

Typical equipment configurations for the distillation of crude oil and other complex hydrocarbon mixtures in a crude unit, a catalytic cracking unit, and a delayed coking unit of a petroleum refinery are shown in Figs. 13-104, 13-105, and 13-106. The initial separation of crude oil into fractions is conducted in two main columns, shown in Fig. 13-104. In the first column, called the atmospheric tower or topping still, partially vaporized crude oil, from which water, sediment, and salt have been removed, is mainly rectified, at a feed tray pressure of no more than about

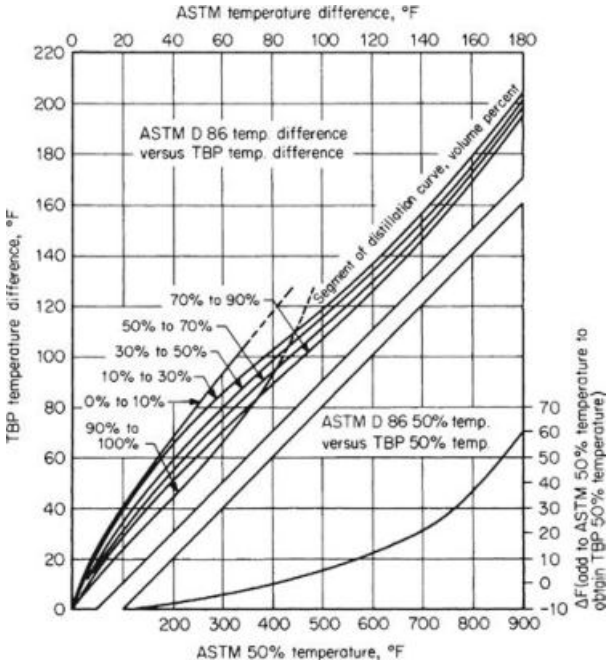

**FIG. 13-103** Relationship between ASTM and TBP distillation curves. *(From W. C. Edmister,* Applied Hydrocarbon Thermodynamics, *vol. 1, 1st ed., 1961 Gulf Publishing Company, Houston, Tex. Used with permission. All rights reserved.)*

276 kPa (40 psia), to yield a noncondensable light-hydrocarbon gas, a light naphtha, a heavy naphtha, a light distillate (kerosine), a heavy distillate (diesel oil), and a bottoms residual of components whose TBP exceeds approximately 427°C (800°F). Alternatively, other fractions, shown in Fig. 13-99, may be withdrawn. To control the IBP of the ASTM D86 curves, each of the sidestreams of the atmospheric tower and the vacuum and main fractionators of Figs. 13-104, 13-105, and 13-106 may be sent to side-cut strippers, which use a partial reboiler or steam stripping. Additional stripping by steam is commonly used in the bottom of the atmospheric tower as well as in the vacuum tower and other main fractionators.

Additional distillate in the TBP range of approximately 427°C to 593°C (800°F to 1100°F) is recovered from bottoms residuum of the atmospheric tower by rectification in a vacuum tower, also shown in Fig. 13-104, at the minimum practical overhead condenser pressure, which is typically 1.3 kPa (10 torr). The use of special low-pressure-drop trays or column packing permits the feed tray pressure to be approximately 5.3 to 6.7 kPa (40 to 50 torr) to obtain the maximum degree of vaporization. Vacuum towers may be designed or operated to produce several different products, including heavy distillates, gas-oil feedstocks for catalytic cracking, lubricating oils, bunker fuel, and bottoms residua of asphalt (5 to 8 API gravity) or pitch (0 to 5 API gravity). The catalytic cracking process of Fig. 13-105 produces a superheated vapor at approximately 538°C (1000°F) and 172 to 207 kPa (25 to 30 psia) of a TBP range that covers hydrogen to compounds with normal boiling points above 482°C (900°F). This gas is sent directly to a main fractionator for rectification to obtain products that are typically gas and naphtha [204°C (400°F) ASTM EP approximately], which are often fractionated further to produce relatively pure light hydrocarbons and gasoline; a light cycle oil [typically 204°C to 371°C (400°F to 700°F) ASTM D86 range], which may be used for heating oil, hydrocracked, or recycled to the catalytic cracker; an intermediate cycle oil [typically 371°C to 482°C (700°F to 900°F) ASTM D86 range], which is generally recycled to the catalytic cracker to extinction; and a heavy gas oil or bottom slurry oil.

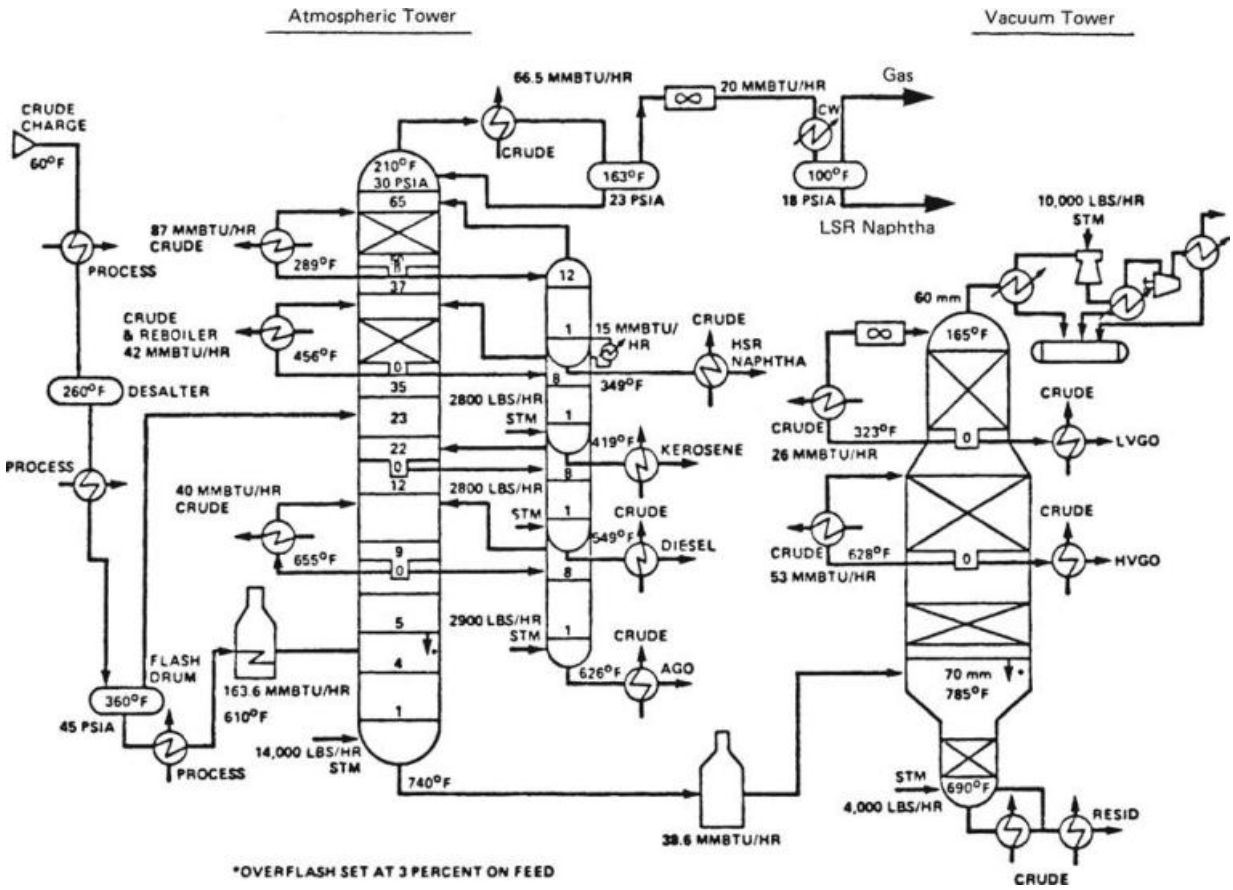

**FIG. 13-104** Crude unit with atmospheric and vacuum towers. [*Kleinschrodt and Hammer,* Chem. Eng. Prog. 79*(7): 33 (1983).*]

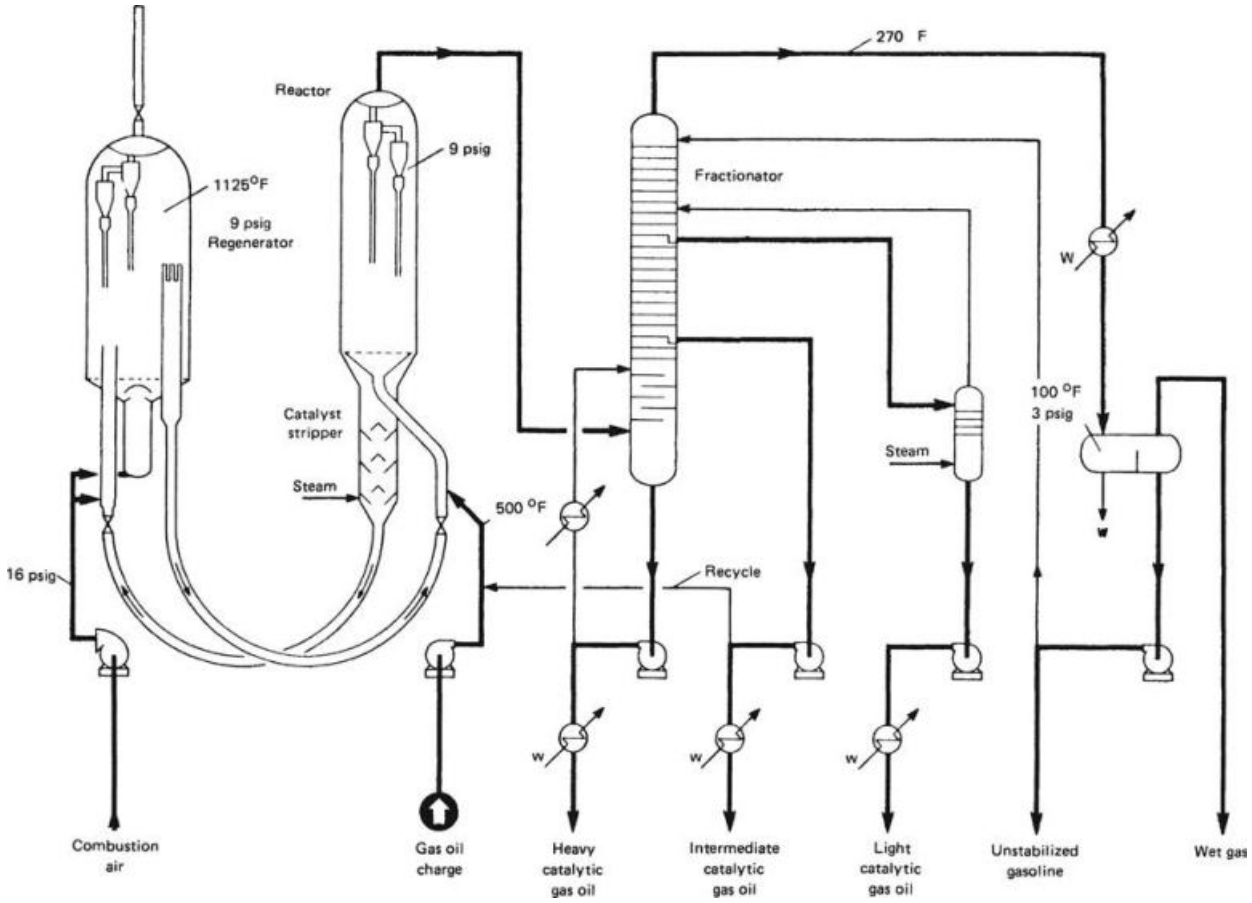

**FIG. 13-105** Catalytic cracking unit. [*New Horizons*, Lummus Co., New York (1954)].

Vacuum-column bottoms, bottoms residuum from the main fractionation of a catalytic cracker, and other residua can be further processed at approximately 510°C (950°F) and 448 kPa (65 psia) in a delayed-coker unit, as shown in Fig. 13-106, to produce petroleum coke and gas of TBP range that covers methane (with perhaps a small amount of hydrogen) to compounds with normal boiling points that may exceed 649°C (1200°F). The gas is sent directly to a main fractionator that is similar to the type used in conjunction with a catalytic cracker, except that in the delayed-coking operation the liquid to be coked first enters into and passes down through the bottom trays of the main fractionator to be preheated by

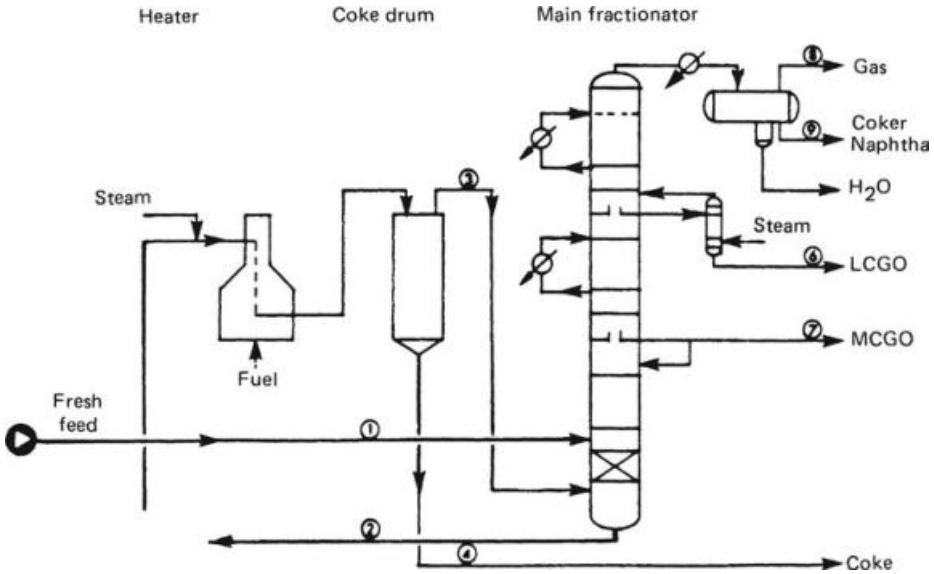

**FIG. 13-106** Delayed-coking unit. (Watkins, *Petroleum Refinery Distillation*, 2d ed., Gulf, Houston, Tex., 1979).

and to scrub coker vapor of entrained coke particles and condensables for recycling to the delayed coker. Products produced from the main fractionator are similar to those produced in a catalytic cracking unit, except for more unsaturated cyclic compounds, and include gas and coker naphtha, which are further processed to separate out light hydrocarbons and a coker naphtha that generally needs hydrotreating, and light and heavy coker gas oils, both of which may require hydrocracking to become suitable blending stocks.

## DESIGN PROCEDURES

Two general procedures are available for designing fractionators that process petroleum, synthetic crude oils, and complex mixtures. The first, which was originally developed for crude units by Packie [*Trans. Am. Inst. Chem. Eng. J.* **37:** 51 (1941)], extended to main fractionators by Houghland, Lemieux, and Schreiner [*Proc. API,* sec. III, *Refining,* 385 (1954)], and further elaborated and described in great detail by Watkins (*Petroleum Refinery Distillation,* 2d ed., Gulf, Houston, 1979), uses material and energy balances, with empirical correlations to establish tray requirements, and is essentially a hand calculation procedure that is a valuable learning experience and is suitable for preliminary designs. Also, when backed by sufficient experience from previous designs, this procedure is adequate for final design.

In the second procedure, which is best applied with a digital computer, the complex mixture being distilled is represented by actual components at the light end and by perhaps 30 pseudocomponents (e.g., petroleum fractions) over the remaining portion of the TBP distillation curve for the column feed. Each of the pseudocomponents is characterized by a TBP range, an average normal boiling point, an average API gravity, and an average molecular weight. Rigorous material balance, energy balance, and phase equilibrium calculations are then made by an appropriate equation-tearing method, as shown by Cecchetti et al. [*Hydrocarbon Process.* **42**(9): 159 (1963)] or a simultaneous-correction procedure as shown, for example, by Goldstein and Stanfield [*Ind. Eng. Chem. Process Des. Dev.* **9:** 78 (1970)] and Hess et al. [*Hydrocarbon Process.* **56**(5): 241 (1977)]. Highly developed procedures of the latter type, suitable for preliminary or final design, are included in most computer-aided steady-state process design and simulation programs as a special case of interlinked distillation, wherein the crude tower or fractionator is converged simultaneously with the sidecut stripper columns.

Regardless of the procedure used, certain initial steps must be taken for the determination or specification of certain product properties and yields based on the TBP distillation curve of the column feed, the method of providing column reflux, the column-operating pressure, the type of condenser, and the type of sidecut stripper and stripping requirements. These steps are developed and illustrated with several detailed examples by Watkins (1979). Only one example, modified from one given by Watkins, is considered briefly here to indicate the approach taken during the initial steps.

For the atmospheric tower shown in Fig. 13-107, suppose distillation specifications are as follows:

- Feed: 50,000 bbl (at 42 U.S. gal each) per stream day (BPSD) of 31.6 API crude oil.
- Measured light-ends analysis of feed:

| Component | Volume percent of crude oil |
|---|---|
| Ethane | 0.04 |
| Propane | 0.37 |
| Isobutane | 0.27 |
| *n*-Butane | 0.89 |
| Isopentane | 0.77 |
| *n*-Pentane | 1.13 |
| | 3.47 |

- Measured TBP and API gravity of feed, computed atmospheric pressure EFV ( from API *Technical Data Book*), and molecular weight of feed:

| Volume percent vaporized | TBP, °F | EFV, °F | °API | Molecular weight |
|---|---|---|---|---|
| 0 | −130 | 179 | | |
| 5 | 148 | 275 | 75.0 | 91 |
| 10 | 213 | 317 | 61.3 | 106 |
| 20 | 327 | 394 | 50.0 | 137 |
| 30 | 430 | 468 | 41.8 | 177 |
| 40 | 534 | 544 | 36.9 | 223 |
| 50 | 639 | 619 | 30.7 | 273 |
| 60 | 747 | 696 | 26.3 | 327 |
| 70 | 867 | 777 | 22.7 | 392 |
| 80 | 1013 | 866 | 19.1 | 480 |

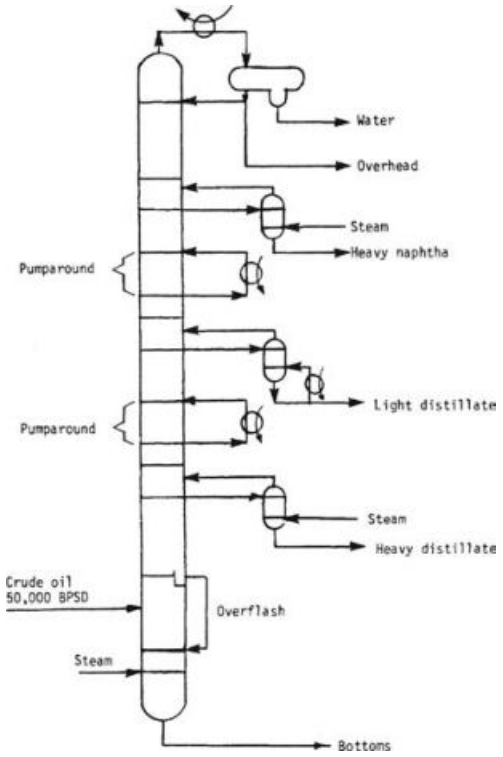

**FIG. 13-107** Crude atmospheric tower.

- Product specifications:

| | ASTM D86, °F | | |
|---|---|---|---|
| Desired cut | 5% | 50% | 95% |
| Overhead (OV) | | | 253 |
| Heavy naphtha (HN) | 278 | 314 | 363 |
| Light distillate (LD) | 398 | 453 | 536 |
| Heavy distillate (HD) | 546 | 589 | |
| Bottoms (B) | | | |

NOTE: To convert degrees Fahrenheit to degrees Celsius, °C = (°F − 32)/1.8.

- TBP cut point between the heavy distillate and the bottoms = 650°F
- Percent overflash = 2 vol% of feed
- Furnace outlet temperature = 343°C (650°F) maximum
- Overhead temperature in reflux drum = 49°C (120°F) minimum

From the product specifications, distillate yields are computed as follows: From Fig. 13-103 and the ASTM D86 50 percent temperatures, TBP 50 percent temperatures of the three intermediate cuts are obtained as 155°C, 236°C, and 316°C (311°F, 456°F, and 600°F) for the HN, LD, and HD, respectively. The TBP cut points, corresponding volume fractions of crude oil, and flow rates of the four distillates are readily obtained by starting from the specified 343°C (650°F) cut point as follows, where CP is the cut point and $T$ is the TBP temperature (°F):

$$\mathrm{CP}_{\mathrm{HD,B}} = 650°\mathrm{F}$$
$$\mathrm{CP}_{\mathrm{HD,B}} - T_{\mathrm{HD50}} = 650 - 600 = 50°\mathrm{F}$$
$$\mathrm{CP}_{\mathrm{LD,HD}} = T_{\mathrm{HD50}} - 50 = 600 - 50 = 550°\mathrm{F}$$
$$\mathrm{CP}_{\mathrm{LD,HD}} - T_{\mathrm{LD50}} = 550 - 456 = 94°\mathrm{F}$$
$$\mathrm{CP}_{\mathrm{HN,LD}} = T_{\mathrm{LD50}} - 94 = 456 - 94 = 362°\mathrm{F}$$
$$\mathrm{CP}_{\mathrm{HN,LD}} - T_{\mathrm{HN50}} = 362 - 311 = 51°\mathrm{F}$$
$$\mathrm{CP}_{\mathrm{OV,HN}} = T_{\mathrm{HN50}} - 51 = 311 - 51 = 260°\mathrm{F}$$

These cut points are shown as vertical lines on the crude oil TBP plot of Fig. 13-108, from which the following volume fractions and flow rates of product cuts are readily obtained:

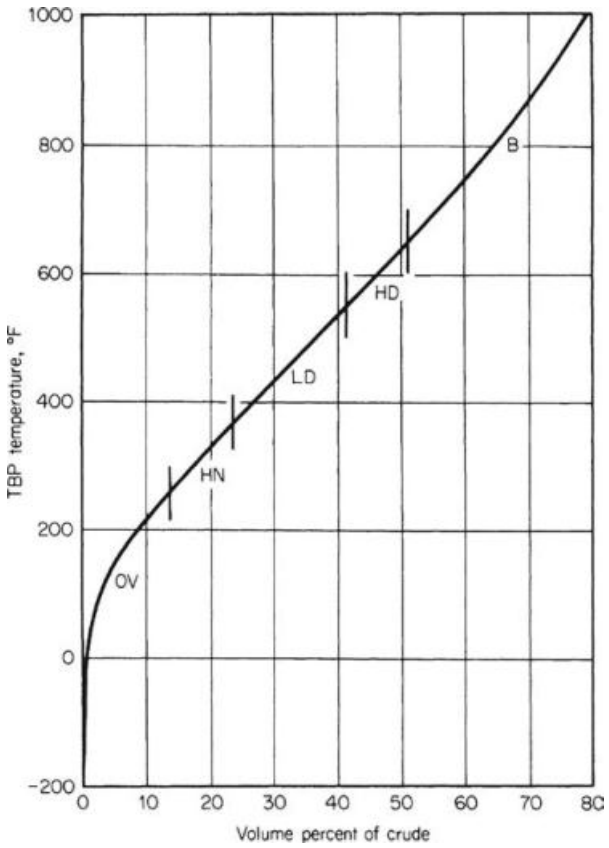

**FIG. 13-108** Example of crude oil TBP cut points.

| Desired cut | Volume percent of crude oil | BPSD |
|---|---|---|
| Overhead (OV) | 13.4 | 6,700 |
| Heavy naphtha (HN) | 10.3 | 5,150 |
| Light distillate (LD) | 17.4 | 8,700 |
| Heavy distillate (HD) | 10.0 | 5,000 |
| Bottoms (B) | 48.9 | 24,450 |
| | 100.0 | 50,000 |

As shown in Fig. 13-109, methods of providing column reflux include *(a)* conventional top-tray reflux, *(b)* pump-back reflux from sidecut strippers, and *(c)* pump-around reflux. The latter two methods essentially function as intercondenser schemes that reduce the top-tray reflux requirement. As shown in Fig. 13-110 for the example being considered, the internal-reflux flow rate decreases rapidly from the top tray to the feed-flash zone for case *a*. The other two cases, particularly case *c*, result in better balancing of the column-reflux traffic. Because of this and the opportunity provided to recover energy at a moderate- to high-temperature level, pump-around reflux is the most commonly used technique. However, not indicated in Fig. 13-110 is the fact that in cases *b* and *c* the smaller quantity of reflux present in the upper portion of the column increases the tray requirements. Furthermore, the pump-around circuits, which extend over three trays each, are believed to be equivalent for mass-transfer purposes to only one tray each. Representative tray requirements for the three cases are included in Fig. 13-109. In case *c*, heat-transfer rates associated with the two pump-around circuits account for approximately 40 percent of the total heat removed in the overhead condenser and from the two pump-around circuits combined.

Bottoms and three sidecut strippers remove light ends from products and may use steam or reboilers. In Fig. 13-109 a reboiled stripper is used on the light distillate, which is the largest sidecut withdrawn. Steam-stripping rates in sidecut strippers and at the bottom of the atmospheric column may vary from 0.45 to 4.5 kg (1 to 10 lb) of steam per barrel of stripped liquid, depending on the fraction of stripper feed liquid that is vaporized.

Column pressure at the reflux drum is established to totally condense the overhead vapor or some fraction thereof. Flash-zone pressure is approximately 69 kPa (10 psia) higher. Crude oil feed temperature at flash-zone pressure must be sufficient to vaporize the total distillates plus the overflash, which is necessary to provide reflux between the lowest sidestream-product

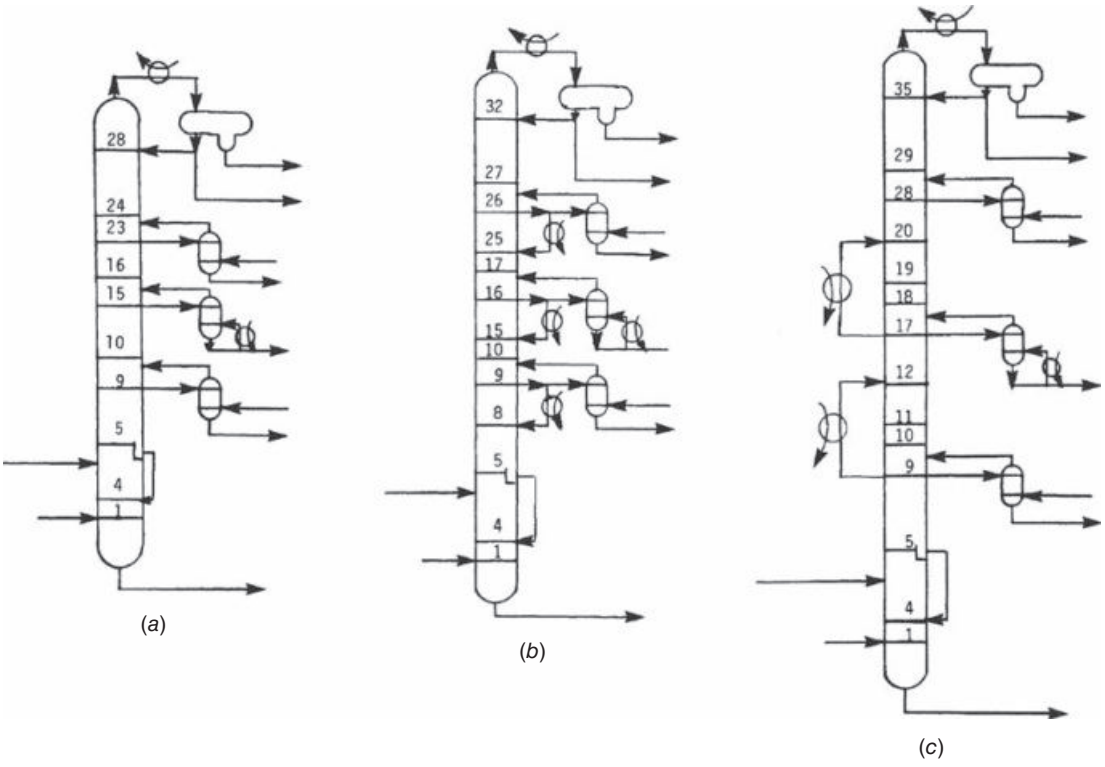

**FIG. 13-109** Methods of providing reflux to crude units. (*a*) Top reflux. (*b*) Pump-back reflux. (*c*) Pump-around reflux.

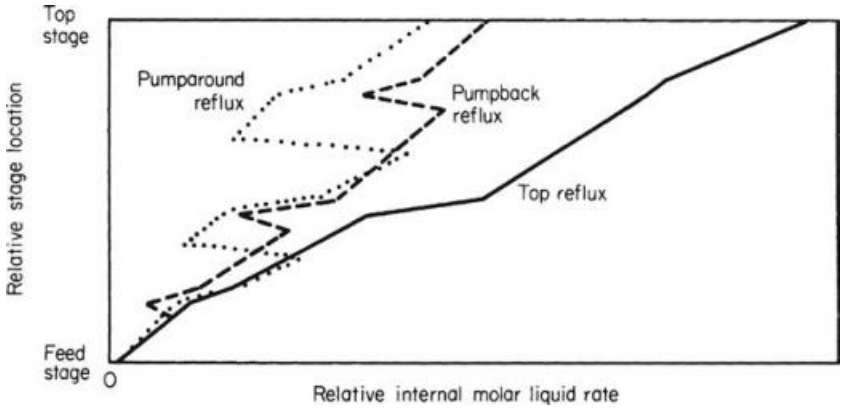

**FIG. 13-110** Comparison of internal reflux rates for three methods of providing reflux.

drawoff tray and the flash zone. Calculations are made by using the crude oil EFV curve corrected for pressure. For the example being considered, percent vaporized at the flash zone must be 53.1 percent of the feed.

Tray requirements depend on internal reflux ratios and ASTM 5-95 gaps or overlaps and may be estimated by the correlation of Packie [*Trans. Am. Inst. Chem. Eng. J.* **37:** 51 (1941)] for crude units and the correlation of Houghland, Lemieux, and Schreiner [*Proc. API,* sec. III, *Refining,* 385 (1954)] for main fractionators.

***Example 13-15 Simulation Calculation of an Atmospheric Tower*** The ability of a rigorous calculation procedure to simulate the operation of an atmospheric tower with its accompanying sidecut strippers may be illustrated by comparing commercial-test data from an actual operation with results computed with the REFINE program of ChemShare Corporation, Houston, Texas. (See also the DESIGN II program from WinSim, Inc., Sugar Land, Texas; http://www.winsim.com.) The tower configuration and plant operating conditions are shown in Fig. 13-111.

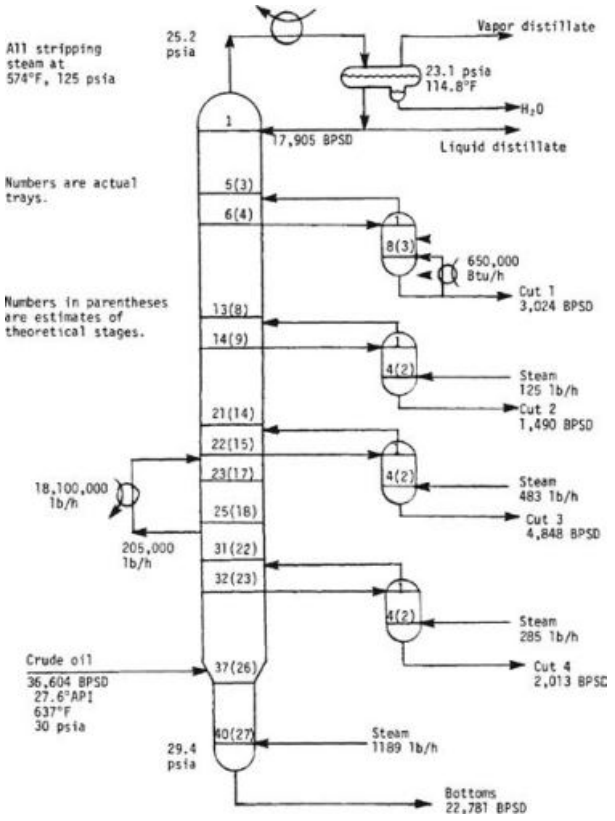

**FIG. 13-111** Configuration and conditions for the simulation of the atmospheric tower of crude unit.

Light-component analysis and the TBP and API gravity for the feed are given in Table 13-25. Representation of this feed by pseudocomponents is given in Table 13-26 based on 16.7°C (30°F) cuts from 82°C to 366°C (180°F to 690°F), followed by 41.7°C (75°F) and then 55.6°C (100°F) cuts. Actual tray numbers are shown in Fig. 13-111. Corresponding theoretical-stage numbers, which were determined by trial and error to obtain a reasonable match of computed- and measured-product TBP distillation curves, are shown in parentheses. Overall tray efficiency appears to be approximately 70 percent for the tower and 25 to 50 percent for the sidecut strippers.

Results of rigorous calculations and comparison to plant data, when possible, are shown in Figs. 13-112, 13-113, and 13-114. Plant temperatures are in good agreement with computed values in Fig. 13-112. Computed sidestream-product TBP distillation curves are in reasonably good agreement with values converted from plant ASTM distillations, as shown in Fig. 13-113. Exceptions are the initial points of all four cuts and the higher-boiling end of the heavy-distillate curve. This would seem to indicate that more theoretical stripping stages should be added and that either the percent vaporization of the tower feed in the simulation is too high or the internal reflux rate at the lower drawoff tray is too low. The liquid-rate profile in the tower is shown in Fig. 13-114. The use of two or three pump-around circuits instead of one would result in a better traffic pattern than that shown.

**TABLE 13-25 Light-Component Analysis and TBP Distillation of Feed for the Atmospheric Crude Tower of Fig. 13-114**

| Light-component analysis | |
|---|---|
| Component | Volume percent |

# BATCH DISTILLATION

Batch distillation, which is the process of separating a specific quantity (the charge) of a liquid mixture into products, is used extensively in the laboratory and in small production units that may have to serve for many mixtures. When there are $c$ components in the feed, one batch column will often suffice where $c-1$ simple continuous distillation columns would be required.

Many larger installations also feature a batch still. The material to be separated may be high in solids content, or it might contain tars or resins that would plug or foul a continuous unit. The use of a batch unit can keep solids separated and permit convenient removal at the termination of the process.

## SIMPLE BATCH DISTILLATION

The simplest form of batch distillation consists of a heated vessel (pot or boiler), a condenser, and one or more receiving tanks. No trays or packing is provided. Feed is charged into the vessel and brought to boiling. Vapors are condensed and collected in a receiver. No reflux is returned. The rate of vaporization is sometimes limited to prevent "bumping" the charge and to avoid overloading the condenser, but other controls are minimal. This process is often referred to as a Rayleigh distillation.

If we represent the moles of vapor with $V$, the moles of liquid in the pot with $H$, the mole fraction of the more volatile component in this liquid with $x$, and the mole fraction of the same component in the vapor with $y$, a material balance yields

$$-y\,dV = d(Hx) \tag{13-122}$$

Since $dV = -dH$, substitution and expansion give

$$y\,dH = H\,dx + x\,dH \tag{13-123}$$

Rearranging and integrating give

$$\ln\frac{H_i}{H_f} = \int_{x_f}^{x_i}\frac{dx}{y-x} \tag{13-124}$$

where subscript $i$ represents the initial condition and $f$ the final condition of the liquid in the pot. The integration limits have been reversed to obtain a positive integral. Equation (13-124) is equivalent to an integrated form of the defining expression for residue curves in Eq. (13-114), with appropriate substitutions for the variable $\xi$ (see below).

If phase equilibrium is assumed between liquid and vapor, the right-hand side of Eq. (13-124) may be evaluated from the area under a curve of $1/(y-x)$ versus $x$ between the limits $x_i$ and $x_f$. If the mixture is a binary system for which the relative volatility $\alpha$ can be approximated as a constant over the range considered, then the VLE relationship

$$y = \frac{\alpha x}{1+(\alpha-1)x} \tag{13-125}$$

can be substituted into Eq. (13-124) and a direct integration can be made:

$$\ln\left(\frac{H_f}{H_i}\right) = \frac{1}{\alpha-1}\ln\left[\frac{x_f/(1-x_f)}{x_i/(1-x_i)}\right] + \ln\left(\frac{1-x_i}{1-x_f}\right) \tag{13-126}$$

For any two components $A$ and $B$ of a multicomponent mixture, if constant $\alpha$ values can be assumed for all pairs of components, then $dH_A/dH_B = y_A/y_B = \alpha_{A,B}(x_A/x_B)$. When this is integrated, we obtain

$$\ln\left(\frac{H_{A,f}}{H_{A,i}}\right) = \alpha_{A,B}\ln\left(\frac{H_{B,f}}{H_{B,i}}\right) \tag{13-127}$$

where $H_{A,i}$ and $H_{A,f}$ are the moles of component $A$ in the pot before and after distillation and $H_{B,i}$ and $H_{B,f}$ are the corresponding moles of component $B$. Mixtures that cannot be accurately described by using a constant relative volatility require some form of numerical or graphical integration for the solution of Eq. (13-124).

As an example, consider the distillation of an ethanol-water mixture at 101.3 kPa (1 atm). The initial charge is 100 mol of liquid containing 18 mol% ethanol, and the mixture must be reduced to a maximum ethanol concentration in the still of 6 mol%. By using equilibrium data interpolated from Gmehling and Onken [*Vapor-Liquid Equilibrium Data Collection*, DECHEMA Chemistry Data Ser., vol. 1, Part 1, Frankfurt (1977)], we get the following:

| $x$ | $y$ | $y-x$ | $1/(y-x)$ |
|---|---|---|---|
| 0.18 | 0.517 | 0.337 | 2.97 |
| 0.16 | 0.502 | 0.342 | 2.91 |
| 0.14 | 0.485 | 0.345 | 2.90 |
| 0.12 | 0.464 | 0.344 | 2.90 |
| 0.10 | 0.438 | 0.338 | 2.97 |
| 0.08 | 0.405 | 0.325 | 3.08 |
| 0.06 | 0.353 | 0.293 | 3.41 |

The area under a curve of $1/(y-x)$ versus $x$ between $x = 0.06$ and 0.18 is $0.358 = \ln(H_i/H_f)$, so that $H_f = 100/1.43 = 70.0$ mol. The liquid remaining consists of $(70.0)(0.06) = 4.2$ mol of ethanol and 65.8 mol of water. By material balance, the total accumulated distillate must contain $18.0 - 4.2 = 13.8$ mol of alcohol and $82.0 - 65.8 = 16.2$ mol of water. The total distillate is 30 mol, and the average distillate composition is $13.8/30 = 0.46$ mole fraction ethanol. The time, rate of heating, and vapor rate required to carry out the process are related by the energy balance and operating policy, which can be considered separately.

Graphical solutions of models lend significant insight, but there are many cases where such solutions are not possible or where repeated solutions are desired for different conditions. Progress in computer-based models, ranging from specialized simulation software to more general-purpose tools, now permits rapid solutions for most models. It is a simple matter to find a numerical solution to this model using a general-purpose computational tool such as Matlab or Mathematica.

The simple batch still provides only one theoretical plate of separation. Its use is usually restricted to laboratory work or preliminary manufacturing in which the products will be held for additional separation at a later time, when most of the volatile component must be removed from the batch before it is processed further, for separation of the batch from heavy undesired components.

## BATCH DISTILLATION WITH RECTIFICATION

To obtain products with a narrow composition range, a batch rectifying still is commonly used. The *batch rectifier* consists of a pot (or reboiler) as in simple distillation, plus a rectifying column, a condenser, some means of accumulating and splitting off a portion of the condensed vapor (distillate) for reflux, and one or more product receivers (Fig. 13-115).

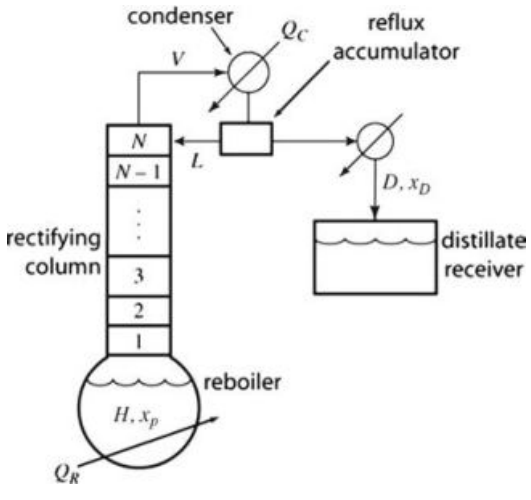

**FIG. 13-115** Schematic of a batch rectifier.

The temperature of the distillate is controlled near the bubble point, and reflux is returned at or near the upper column temperature to permit a true indication of reflux quantity and to improve the column operation. A heat exchanger is used to subcool the remainder of the distillate, which is sent to a product receiver. The column may operate at an elevated pressure or at vacuum, in which case appropriate additional devices must be included to obtain the desired pressure. Equipment design methods for batch still components, except for the pot, typically follow the same principles as those presented for continuous distillation under the assumption of conditions close to a steady state (but see the comments below on the effects of holdup). The design should be checked for each mixture if several mixtures are to be processed. The design should be checked at more than one point for each mixture, since the compositions in the pot and in the column change as the distillation proceeds. The pot design is based on the batch size and the vaporization rate, which are related to the time and rate of heating and cooling available. For existing equipment, the pot size will determine the size of the batch or at least a range of feasible sizes $H_i$.

In operation, a batch of liquid is charged to the pot, and the system is first brought to steady state under total reflux. A portion of the overhead condensate is then continuously withdrawn in accordance with the established reflux policy. "Cuts" are made by switching to alternate receivers, at which time the operating conditions, such as reflux rate, may also be changed. The entire column operates as an enriching or rectifying section. As time proceeds, the composition of the liquid in the pot becomes less rich in the more volatile components, and distillation of a cut is stopped when the accumulated distillate attains the desired average composition or temperature.

## OPERATING METHODS

A batch distillation can be operated in several ways:

1. *Constant reflux ratio, varying overhead composition.* The reflux ratio is set at a predetermined value at which it is maintained for the entire run. Since the pot liquid composition is changing, the instantaneous composition of the distillate also changes. The progress of the distillate and pot compositions in a particular binary separation is illustrated in Fig. 13-116. The variation of the distillate composition for a multicomponent batch distillation is shown in Fig. 13-117 (these distillate product cuts have relatively low purity). The shapes of the curves are functions of volatility, reflux ratio, and number of theoretical plates. The distillation is continued until the average distillate composition is at the desired value. In the case of a binary mixture, the overhead is then typically diverted to another receiver, and an intermediate or "slop" cut is withdrawn until the remaining pot liquid meets the required specification. The intermediate cut is usually added to the next batch, which can therefore have a somewhat different composition from the previous batch. For a multicomponent mixture, two or more intermediate cuts may be taken between the product cuts. It is preferable to limit the size of the intermediate cuts as far as is practical because they reduce the total amount of fresh feed that can be processed.

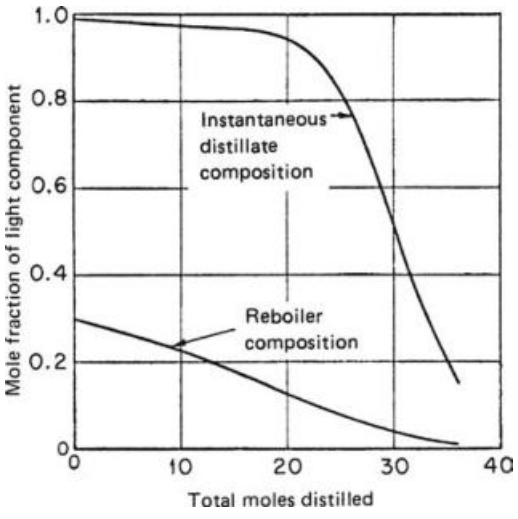

**FIG. 13-116** Variation in distillate and reboiler compositions with the amount distilled in binary batch distillation at a constant reflux ratio.

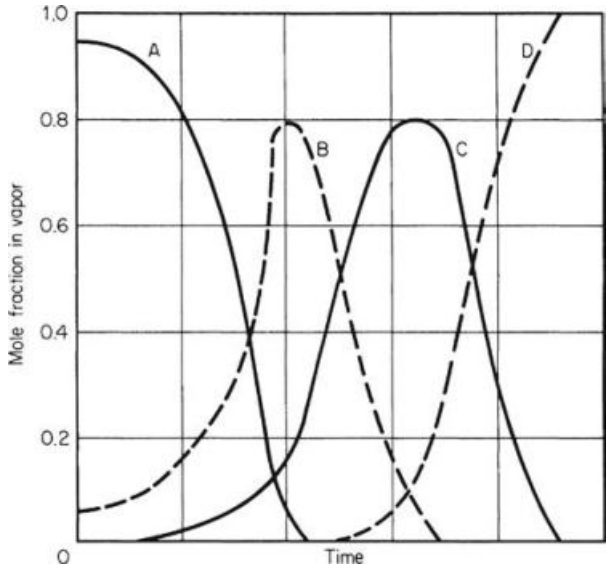

**FIG. 13-117** Distillate composition for a batch distillation of a four-component mixture at a constant reflux ratio.

2. *Constant overhead composition, varying reflux.* If we wish to maintain a constant overhead composition in the case of a binary mixture, the amount of reflux returned to the column must be constantly increased throughout the run. As time proceeds, the pot is gradually depleted of the lighter component. The increase in reflux is typically gradual at first and more rapid near the end of a cut. Finally, a point is reached at which there is little of the lighter component remaining in the pot, and the reflux ratio has attained a very high value. The receivers are then changed, the reflux is reduced, and an intermediate cut is taken as before. This technique can also be extended to a multicomponent mixture.

3. *Other methods.* Instead of fixing reflux ratio, distillation may be run at constant reflux flow, or constant takeoff flow. Since boil-up usually diminishes during a batch, fixing reflux flow results in gradually increasing reflux ratio, whereas fixing distillate flow would have the opposite effect. Operating at constant reflux flow ensures that the column receives sufficient reflux to keep it wet.

4. A cycling procedure can also be used for the column operation. The unit operates at total reflux until a steady state is established. The distillate is then taken as total drawoff for a short time, after which the column is returned to total reflux operation. This cycle is repeated throughout the course of distillation. An alternative scheme is to interrupt vapor flow to the column periodically by the use of a solenoid-operated butterfly valve in the vapor line from the pot. In both cases, the equations needed to describe the system are complex, as shown by Schrodt et al. [*Chem. Eng. Sci.* **22:** 759 (1967)]. Several investigators have also proposed that batch distillation be programmed to attain *time optimization* by proper variation of the reflux ratio. A comprehensive discussion was first presented by Coward [*Chem. Eng. Sci.* **22:** 503 (1967)] and reviewed and updated by Kim and Diwekar [*Rev. Chem. Eng.* **17:** 111 (2001)]. Typical control instrumentation is described by Block [*Chem. Eng.* **74:** 147 (Jan. 16, 1967)].

5. More complex operations may involve the withdrawal of sidestreams, provision for intercondensers, the addition of feeds to trays, and periodic feed additions to the pot.

## APPROXIMATE CALCULATION PROCEDURES FOR BINARY MIXTURES

Useful intuition is provided by an analysis for a binary mixture based on the McCabe-Thiele graphical method. In addition to the usual assumptions of an adiabatic column and constant molar overflow on the trays, the following procedure assumes that the holdup of liquid on the trays, in the column, and in the condenser is negligible compared to the holdup in the pot. (The effects of holdup can be significant and are discussed in a later subsection.)

As a first step, the minimum reflux ratio should be determined. Point $D$ in Fig. 13-118 represents the desired distillate composition and is located on the diagonal since a total condenser is assumed and $x_D = y_D$. Point $F$ represents the initial composition in the pot $x_{pi}$ and for the vapor entering the

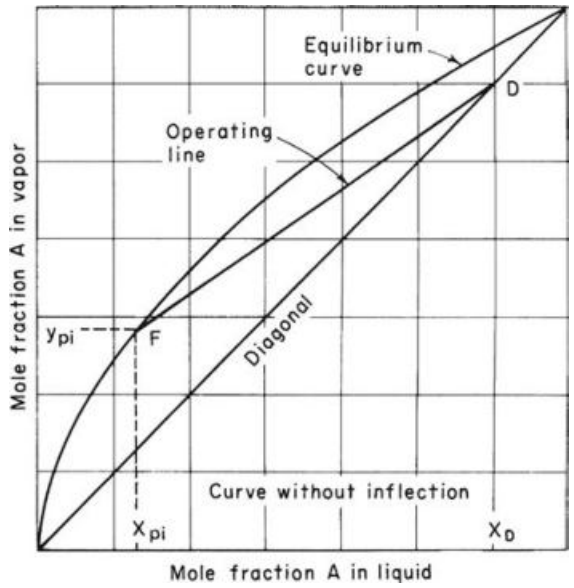

**FIG. 13-118** Determination of the minimum reflux for a relatively ideal equilibrium curve.

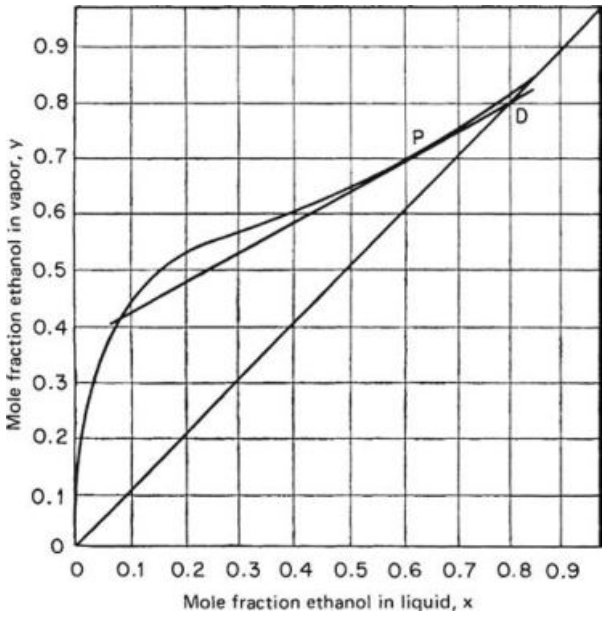

**FIG. 13-119** Determination of minimum reflux for an equilibrium curve with an inflection point.

bottom of the rectifying column $y_{pi}$. The minimum internal reflux is found from the slope of the line *DF*

$$\left(\frac{L}{V}\right)_{\min} = \frac{y_D - y_{pi}}{x_D - x_{pi}} \tag{13-128}$$

where $L$ is the liquid flow rate and $V$ is the vapor rate, both in moles per hour. Since $V = L + D$ (where $D$ is distillate rate) and the external reflux ratio $R$ is defined as $R = L/D$,

$$\frac{L}{V} = \frac{R}{R+1} \tag{13-129}$$

or

$$R_{\min} = \frac{(L/V)_{\min}}{1-(L/V)_{\min}} \tag{13-130}$$

The condition of minimum reflux for an equilibrium curve with an inflection point *P* is shown in Fig. 13-119. In this case the minimum internal reflux is

$$\left(\frac{L}{V}\right)_{\min} = \frac{y_D - y_P}{x_D - x_P} \tag{13-131}$$

The operating reflux ratio is usually 1.5 but may be as much as 10 times the minimum. By using the ethanol-water equilibrium curve for 101.3-kPa (1-atm) pressure shown in Fig. 13-119 but extending the line to a convenient point for readability, $(L/V)_{\min} = (0.800 - 0.695)/(0.800 - 0.600) = 0.52$ and $R_{\min} = 1.083$.

**Batch Rectification at Constant Reflux Ratio** Using an analysis similar to the simple batch still, Smoker and Rose [*Trans. Am. Inst. Chem. Eng.* **36:** 285 (1940)] developed the following equation:

$$\ln\frac{H_i}{H_f} = \int_{x_{pf}}^{x_{pi}} \frac{dx_p}{x_D - x_p} \tag{13-132}$$

An overall material balance on the light component gives the average or accumulated distillate composition $x_{D,\text{avg}}$.

$$x_{D,\text{avg}} = \frac{H_i x_{pi} - H_f x_{pf}}{H_i - H_f} \tag{13-133}$$

If the integral on the right side of Eq. (13-132) is denoted by $\xi$, the time $\theta$ for distillation can be found by

$$\theta = (R+1)\frac{H_i(e^{\xi}-1)}{Ve^{\xi}} \tag{13-134}$$

An alternative equation is

$$\theta = \frac{R+1}{V}(H_i - H_f) \tag{13-135}$$

Development of these equations is given by Block [*Chem. Eng.* **68:** 88 (Feb. 6, 1961)]. The calculation process is illustrated schematically in Fig. 13-120. Operating lines are drawn with the same slope but intersecting the 45° line at different points. The number of theoretical plates

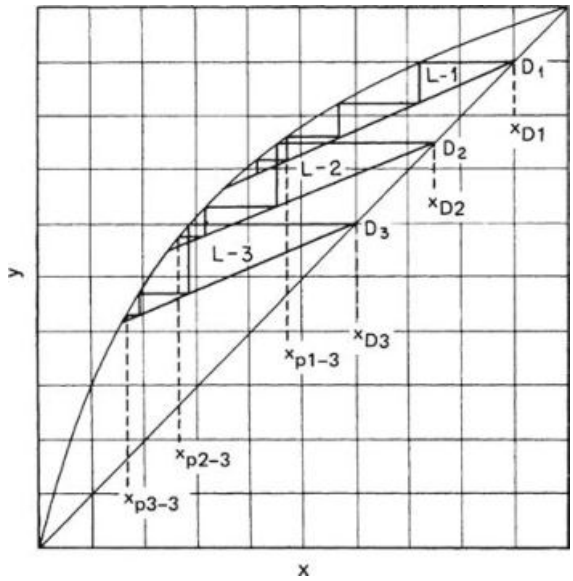

**FIG. 13-120** Graphical method for constant-reflux operation.

under consideration is stepped off to find the corresponding bottoms composition (i.e., still pot composition) for each distillate composition. In Fig. 13-120, operating line $L-1$ with slope $L/V$ drawn from point $D_1$ where the distillate composition is $x_{D1}$ and the pot composition is $x_{p1\text{-}3}$ for three theoretical plates, $x_{D2}$ has a corresponding pot composition of $x_{p2\text{-}3}$, etc. By using these pairs of distillate and pot compositions, the right-hand side of Eq. (13-132) can be evaluated, and $x_{D,\text{avg}}$ can be found from Eq. (13-133). An iterative calculation is required to find the value of $H_f$ that corresponds to a specified $x_{D,\text{avg}}$.

To illustrate the use of these equations, consider a charge of 520 mol of an ethanol-water mixture containing 18 mol% ethanol to be distilled at 101.3 kPa (1 atm). Suppose that the vaporization rate is 75 mol/h, and the product specification is 80 mol% ethanol. Let $L/V = 0.75$, corresponding to a reflux ratio $R = 3.0$. If the column section has six theoretical plates and the pot provides an additional seventh, find how many moles of product will be obtained, what the composition of the pot residue will be, and the amount of time that the distillation will take.

Using the vapor-liquid equilibrium data, plot a $y$-$x$ diagram. Draw a number of operating lines at a slope of 0.75. Note the composition at the 45° intersection, and step off seven stages on each to find the equilibrium value of the bottoms pot composition. Some of the results are tabulated in the following table:

| $x_D$ | $x_p$ | $x_D - x_p$ | $1/(x_D - x_p)$ |
|---|---|---|---|
| 0.800 | 0.323 | 0.477 | 2.097 |
| 0.795 | 0.245 | 0.550 | 1.820 |
| 0.790 | 0.210 | 0.580 | 1.725 |
| 0.785 | 0.180 | 0.605 | 1.654 |
| 0.780 | 0.107 | 0.673 | 1.487 |
| 0.775 | 0.041 | 0.734 | 1.362 |

By using an iterative procedure, integrating between $x_{pi}$ of 0.18 and various lower limits, we find that $x_{D,\text{avg}} = 0.80$ when $x_{pf} = 0.04$, at which time the value of the integral $= 0.205 = \ln(H_i/H_f)$, so that $H_f = 424$ mol. The product collected $= H_i - H_f = 520 - 424 = 96$ mol. From Eq. (13-134),

$$\theta = \frac{(4)(520)(e^{0.205}-1)}{75(e^{0.205})} = 5.2\,\text{h} \tag{13-136}$$

**Batch Rectification at Constant Distillate Composition** Bogart [*Trans. Am. Inst. Chem. Eng.* **33:** 139 (1937)] developed the following equation for constant distillate composition with the column holdup assumed to be negligible:

$$\theta = \frac{H_i(x_D - x_{pi})}{V} \int_{x_{pf}}^{x_{pi}} \frac{dx_p}{(1-L/V)(x_D - x_p)^2} \tag{13-137}$$

and where the terms are defined as before. The quantity distilled can then be found by material balance once the initial and final pot compositions are known.

$$H_i - H_f = \frac{H_i(x_{pi} - x_{pf})}{x_D - x_{pf}} \tag{13-138}$$

A schematic example is shown in Fig. 13-121. The distillate composition is held constant by increasing the reflux as the pot composition becomes more dilute. Operating lines with varying slopes ($= L/V$) are drawn from the known distillate composition, and the given number of stages is stepped off to find the corresponding bottoms (still pot) compositions.

As an example, consider the same ethanol-water mixture used previously to illustrate constant reflux, but now with a constant distillate composition of $x_D = 0.90$. The following table is compiled:

| $L/V$ | $R$ | $x_p$ | $x_D - x_p$ | $1/(1-L/V)(x_D - x_p)^2$ |
|---|---|---|---|---|
| 0.600 | 1.50 | 0.654 | 0.147 | 115.7 |
| 0.700 | 2.33 | 0.453 | 0.348 | 27.5 |
| 0.750 | 3.00 | 0.318 | 0.483 | 17.2 |
| 0.800 | 4.00 | 0.143 | 0.658 | 11.5 |
| 0.850 | 5.67 | 0.054 | 0.747 | 11.9 |
| 0.900 | 9.00 | 0.021 | 0.780 | 16.4 |

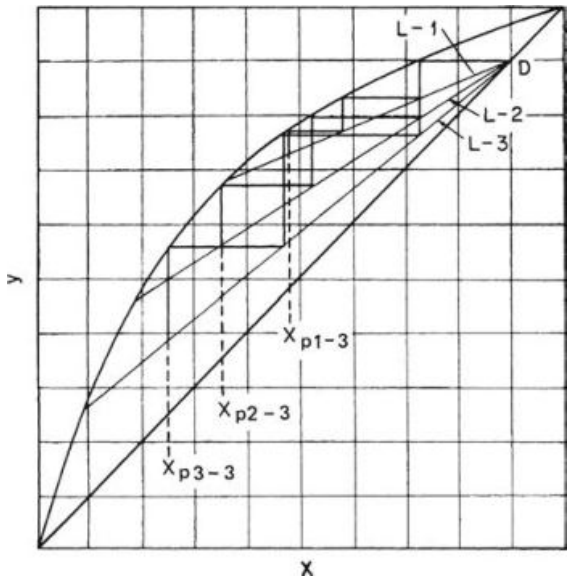

**FIG. 13-121** Schematic of constant distillate composition operation.

If the right-hand side of Eq. (13-137) is integrated by using a limit for $x_{pf}$ of 0.04, the value of the integral is 1.615, and the time is

$$\theta = \frac{(520)(0.800-0.180)(1.615)}{75} = 7.0\,\text{h} \tag{13-139}$$

The quantity distilled can be found from Eq. (13-140):

$$H_i - H_f = \frac{(520)(0.180-0.040)}{0.800-0.040} = 96\,\text{mol} \tag{13-140}$$

## EFFECTS OF COLUMN HOLDUP

When the holdup of liquid on the trays and in the condenser and reflux accumulator is significant compared with the holdup in the pot, the distillate composition at constant reflux ratio changes with time at a different rate than when the column holdup is negligible because of two separate effects.

First, with an appreciable column holdup, the composition of the charge to the pot will be higher in the light component than the pot composition at the start of the distillation. The reason is that before product takeoff begins, the column holdup must be supplied, and due to the rectification, its average composition is higher in the lighter component than that of the liquid charged as feed to the pot. Thus, when overhead takeoff begins, the pot composition is lower than it would be if there were negligible column holdup, and the separation is more difficult than expected based on the composition of the feed. The second effect of column holdup is to slow the rate of exchange of the components; the holdup exerts an inertial effect, which prevents compositions from changing as rapidly as they would otherwise, and the degree of separation is usually improved.

Both these effects occur at the same time and change in importance during the course of distillation. Although a number of studies were made and approximate methods developed for predicting the effect of liquid holdup during the 1950s and 1960s (summarized in the 6th edition of *Perry's Chemical Engineers' Handbook*), it is now simpler to use simulation methods to determine the effect of holdup on a case-by-case basis.

As an example, consider a batch rectifier fed with a 1 to 1 mixture of ethanol and *n*-propanol. The rectifier has eight theoretical stages in the column and is operated at a reflux ratio of 19. The distillate and pot compositions are shown in Fig. 13-122 for various values of the holdups.

In Fig. 13-122*a*, the holdup on each stage is 0.01 percent of the initial pot holdup, and in the reflux accumulator it is 0.1 percent of the initial pot holdup ( for a total of 0.108 percent). Because this model calculation does not begin with a total reflux period, there is a very small initial distillate cut

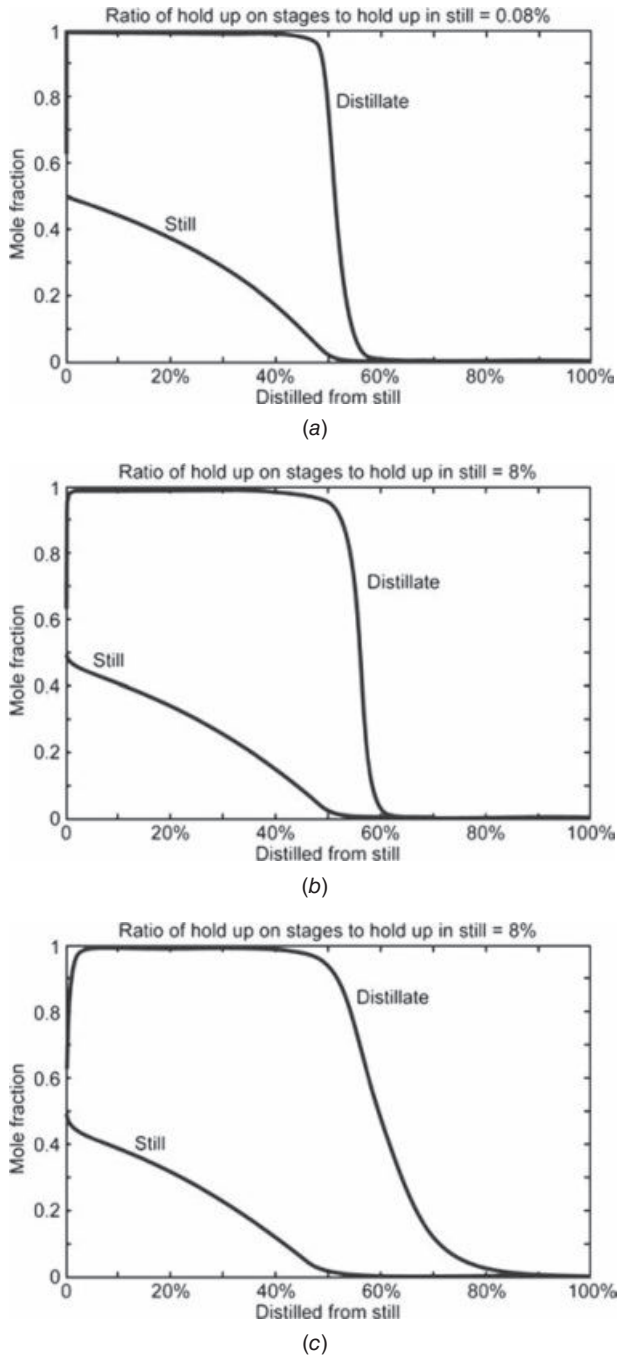

**FIG. 13-122** Effects of holdup on batch rectifier.

with relatively low ethanol purity. This is followed by a high-purity distillate cut. An intermediate cut of approximately 10 percent of the initial batch size can be collected, leaving the pot with a high purity of *n*-propanol. The column holdup for the case shown in Fig. 13-122*b* is 1 percent of the initial batch size on each stage, while the reflux accumulator holdup remains small at 0.1 percent ( for a total of 8.1 percent). In this case, both the first low-purity cut and the intermediate cut are somewhat larger for the same purity specifications. These effects are substantially larger when the reflux accumulator has a more significant holdup, as shown in Fig. 13-122*c,* corresponding to a holdup of 1 percent on each stage and 5 percent in the reflux accumulator ( for a total of 13 percent). Similar effects are found for multicomponent mixtures. The impact of column and condenser holdup is most important when a high-purity cut is desired for a component that is present in relatively small amounts in the feed.

## SHORTCUT METHODS FOR MULTICOMPONENT BATCH RECTIFICATION

For preliminary studies of batch rectification of multicomponent mixtures, shortcut methods that assume constant molar overflow and negligible vapor and liquid holdup are useful in some cases (see the preceding discussion about the effects of holdup). The method of Diwekar and Madhaven [*Ind. Eng. Chem. Res.* **30:** 713 (1991)] can be used for constant reflux or constant overhead rate. The method of Sundaram and Evans [*Ind. Eng. Chem. Res.* **32:** 511 (1993)] applies only to the case of constant reflux, but it is easy to implement. Both methods employ the Fenske-Underwood-Gilliland (FUG) shortcut procedure at successive time steps. Thus, batch rectification is treated as a sequence of continuous, steady-state rectifications.

## CALCULATION METHODS AND SIMULATION

Model predictions such as those shown in Fig. 13-122 are relatively straightforward to obtain by using modern simulation models and software tools. As discussed in earlier editions of this handbook, such models and algorithms for their solutions have been the subject of study since the early 1960s. Detailed calculation procedures for binary and multicomponent batch distillation were initially focused on binary mixtures of constant relative volatility. For example, Huckaba and Danly [*AIChE J.* **6:** 335 (1960)] developed a simulation model that incorporated more details than can be included in the simple analytical models we have described. They assumed constant-mass tray holdups, adiabatic tray operation, and linear enthalpy relationships, but they did include energy balances around each tray, and they incorporated the use of nonequilibrium trays by means of specified tray efficiencies. Experimental data were provided to validate the simulation. Meadows ["Multicomponent Batch-Distillation Calculations on a Digital Computer," *Chem. Eng. Prog. Symp. Ser.* **46**(59): 48–55 (1963)] presented a multicomponent batch distillation model that included equations for energy, material, and volume balances around theoretical trays. The assumptions made were perfect mixing on each tray, negligible vapor holdup, adiabatic operation, and constant-volume tray holdup. Distefano [*AIChE. J.* **14:** 190 (1968)] extended the model and developed a procedure that was used to simulate several commercial batch distillation columns successfully. Boston et al. (in *Foundations of Computer-Aided Chemical Process Design,* vol. 2, ed. Mah and Seider, American Institute of Chemical Engineers, New York, 1981, p. 203) further extended the model, provided a variety of practical sets of specifications, and used modern numerical procedures and equation formulations to efficiently handle the nonlinear and often stiff nature of the multicomponent batch distillation problem.

It is important to note that in using computer-aided models for batch distillation, the various assumptions of the model can have a significant impact on the accuracy of the results; for example, see the previous discussion of the effects of holdup. Uncertainties in the physical and chemical parameters in the models can be addressed most effectively by a combination of sensitivity calculations using simulation tools, along with comparison to data. The mathematical treatment of stiffness in the model equations can also be very important, and there is often a substantial advantage in using simulation tools that take special account of this stiffness. (See the 7th edition of *Perry's Chemical Engineers' Handbook* for a more detailed discussion of this aspect.)

The availability of detailed models and solution methods has enabled many new studies of complex, mixtures, configurations, and operating and control strategies for batch distillation.

## SEMIBATCH DISTILLATION

A typical example of this process is a distillation in which feed is supplied continuously and distillate is withdrawn continuously. This is applicable for mixtures with significant amounts of volatile component. At first, a small portion of the pot is charged and heated. Then the feed is supplied at such a rate that the low-boiling component instantaneously flashes off and is withdrawn as distillate. At the end of charging, there is a full pot containing mostly the less volatile component (usually the product). This component may be withdrawn as bottom product, or it may be distilled to purify it from heavier contaminants.

Another example of a semibatch process is constant-level distillation. In this application, one solvent is replaced with another in the presence of a heavy nonvolatile product, as may be encountered in pharmaceutical production. One option for switching solvents is to use simple distillation repeatedly. Initially, a portion of the first solvent is removed by boiling. Then the second solvent is added, and a simple distillation removes more of the first solvent along with some of the second. Repetition of the latter

step can be used to reduce the concentration of the first solvent to very small levels.

Gentilcore [*Chem. Eng. Progr.* **98**(1): 56 (2002)] describes an alternative strategy of "constant-level" batch distillation, where the replacement solvent is added at a rate to keep the volume of liquid in the pot constant. For simple distillation without rectification, the analog of Eq. (13-124) is

$$\frac{S}{H} = \int_{x_f}^{x_i} \frac{dx}{y} \tag{13-141}$$

and the analog of Eq. (13-126) is

$$\frac{S}{H} = \frac{1}{\alpha} \ln \frac{x_i}{x_f} + \frac{\alpha - 1}{\alpha}(x_i - x_f) \tag{13-142}$$

where the mole fractions refer to the compositions of the original solvent, and $S$ is the amount of the second solvent added to the batch. The amount of solute, a nonvolatile heavy product, is small compared to the size of the batch (alternatively, the analysis can be done on a solute-free basis). The second solvent is assumed to be pure, and the rate of addition is manipulated to keep a constant level in the pot. Compared to the repeated application of simple distillation, this semibatch operation can typically reduce solvent use by one-half or more, depending on the volatility and the desired compositions. This is also a more efficient use of equipment at the expense of a somewhat more complex operation.

An example provided by Gentilcore shows a 60 percent savings in the use of replacement solvent.

## INDUSTRIAL OPERATING PRACTICES

Batch columns often purify products coming out of a reactor. The reactor and column usually work in campaigns. A campaign is devoted to making one product (although sometimes two products are made simultaneously, such as isomers), and a campaign may last from a few days to several weeks. After the campaign is over, the equipment is cleaned and another campaign to make different products begins.

The objective of industrial batch distillation is normally to maximize the production rate, provided that purity and yield constraints are satisfied. Usually one or two products are separated from a multicomponent mixture. A product can be obtained as a distillate or as a bottom product.

The simplest batch distillation is the removal of volatile impurities from the final (bottom) product. This can be treated as pseudobinary distillation, with the light impurities being the first pseudocomponent (in reality, the impurities are always multicomponent mixtures) and the product being the second component.

Another typical case (pseudoternary system) is a separation of a desired product from light (more volatile) impurities and heavy (less volatile) impurities. The process involves the following steps: charging the column, heating and degassing, establishing reflux, low-boils cut, front cut, product cut, after-cut, pumping out heavies, and possibly washing the pot. These steps will be discussed next.

Charging must be as fast as possible to maximize the production rate. Therefore, the batch must be charged as soon as possible after the previous batch is finished (if it is safe to do so). We need to ensure that the feed pump works at a sufficiently high rate. If not, the pump rotor or the entire pump may need to be replaced. The piping should be inspected and understood; for example, there may be a manual valve left partially closed on the way to the pot. Also, we may consider feeding the column that is under vacuum, to increase the feeding rate. Finally, we should be charging as much as possible, but without overcharging. Partial charge is a waste of equipment capacity, but charging too much may result in damaging column internals when distillation starts.

One should not wait until charging is complete to start the heating step. The heat exchanger may be internal to the pot (a submerged tube bundle) or external ( forced circulation reboiler or thermosyphon). The heat should be turned on as soon as the internal bundle is covered with liquid or as soon as it is possible to continuously operate a circulation pump without it going dry. To reduce heating time, the heat to the reboiler should be maximized.

After reflux is established, the column is usually kept at total reflux for some time. The objective of this step is to establish a concentration profile in the column, with more volatile components closer to the top and heavier components situated lower in the column. What often interferes with establishing the desired column profile is material that may be left from the previous batch in the top accumulator. This material is usually the heavy component. It will be washed down by total reflux, but it will take time for it to travel down the column. Heat duty for the total reflux step should be lowered, and column pressure drop must be kept below maximum, to keep the column away from the flood point.

After the steady state in the column is reached, we may begin taking off distillate. The purity of the distillate will be changing during the process, so the material will be directed to various tanks as so-called cuts. First, the most volatile components will be taken off as the "low-boils cut." This material is usually disposed of as waste. When the product starts to appear in the distillate, but it is still below the purity specification, we switch the distillate to a different tank. This material is referred to as "front cut" or "slop cut." This cut will have to be reprocessed. When the purity of the product in the distillate is high enough, we may start collecting the "product cut." However, if this is the first distillation in the campaign, we need to make sure that the line to the pure tank and the tank itself are clean and dry (they are usually cleaned with water before the campaign). So part of the first product cut is used to flash the line and the tank, and then it is pumped away to the front-cut tank, to be reprocessed. Sometimes the flash needs to be repeated. Then we begin taking the product cut and continue until the purity of the distillate starts decreasing (thus taking the product purity out of specification). So distillate purity needs to be either measured or inferred from the temperature at the top of the column or inferred from the distillate amount. That is usually determined empirically by trial and error.

If the purity of the distillate is below the specification and it can no longer be blended with the existing product taken so far, the material is switched to the "after-cut tank." If there are no more tanks available, it can be directed to the front-cut tank, although mixing materials of different compositions is never thermodynamically efficient. This material should be reprocessed.

Finally, product content in the distillate is very small or boil-up stops because the pot becomes almost empty or the residual heavy material does not boil anymore. That is the end of distillation. The pot may need to be pumped out or (to save time) new material is charged on top of the left-over residue of heavy impurities. This practice cannot be continued over too many batches because eventually, when the amount of heavy impurities increases, distillation time and yield losses will increase. Therefore, from time to time the pot needs to be cleaned—usually washed with water.

To maximize the yield of the batch, the column holdup (containing valuable product) should be recovered. A part of this holdup resides in the top accumulator. Therefore, at the end of the batch, this accumulator should be emptied, if possible into the product tank. It is a very simple step, but it is often overlooked in industrial practice. Also, the piping from the accumulator to the tank should be blown, e.g., with nitrogen, to recover the product.

The second part of the holdup is the liquid that resides on the packing or trays. After heat is turned off, boil-up vanishes, and this liquid falls down to the pot and mixes with the heavy residue. If the pot needs to be washed, the column holdup is lost, which may be a significant amount. A simple valve on the liquid return to the pot, closed after the batch is over, prevents these losses.

Slop cuts need to be reprocessed, at extra expense of time and energy. Common strategies are either to mix the slop cuts with the next-batch charge or to collect them and distill separately. In some cases, when separation is very easy or purity specification is not stringent or the amount of impurity is small, some slop cuts may not be needed.

Parameters used to optimize the column are: reflux ratio, heat duty, column pressure, and switch points between cuts. These parameters may change between cuts or even during a single cut. Typically, computer recipes contain all this detailed information.

The reflux ratio for slop cuts should be optimized. High reflux ratios reduce the sizes of slop cuts, which give less material to reprocess. However, high reflux ratios also increase the time of the cuts.

For the product cut, the reflux ratio should have the smallest value that still provides the desired purity of the cut. Certain cuts, with easily separable components, may proceed at total takeoff (zero reflux); at other times, total reflux is used intermittently with total takeoff.

Heat duty should be maximized to maximize distillation rate, provided that the column does not flood (the column pressure drop needs to be monitored).

The column pressure is chosen so that we could easily boil the mixture in the pot and condense the distillate. Lower pressure usually makes separation easier. However, too low a pressure may cause column flooding. It is not uncommon to reduce the pressure as distillation proceeds and heavier components need to be boiled off.

To summarize, batch distillation is one of the oldest, most widely approved chemical engineering processes. It seems to be quite simple because there is only one column to control. It provides great flexibility

because many different materials can be distilled in the same equipment. However, there are many disadvantages of batch distillation compared to continuous distillation. One is that cleaning between campaigns or even in one campaign (blowing the lines) takes time and energy and creates waste streams. Another disadvantage is related to slop cuts: these are cuts that need to be reprocessed using additional time and energy. Thermodynamic inefficiencies are also related to holdups; for example, the top accumulator collects liquid from the condenser. This liquid (at constant reflux) changes its composition in time, so condensates of various compositions are mixed together over time. Finally, the batch nature of the process creates additional problems, either in the form of mistakes (product inadvertently sent to a wrong tank) or idle times when one process has to wait for another.

## ALTERNATIVE EQUIPMENT CONFIGURATIONS

The batch rectifier shown schematically in Fig. 13-115 is by far the most common configuration of equipment. Several alternative special-purpose configurations have been studied and offer potential advantages in particular applications. Also see Doherty and Malone (*Conceptual Design of Distillation Systems,* McGraw-Hill, 2001, pp. 407–409, 417–419).

For instance, a simple batch distillation can be combined with a stripping column to give the batch stripper shown in Fig. 13-123. The pot holds the batch charge and provides liquid reflux to the stripping section. The reboiler provides vapor to the column and has relatively small holdup. The product stream $B$ in the bottom is concentrated in the higher-boiling compound, and the pot gradually becomes more concentrated in the lighter component. Multiple "cuts" can be taken as products, and the reboil rate either can be constant or can be adjusted by analogy with the reflux ratio in the batch rectifier.

For mixtures containing large concentrations of a heavy component, the batch stripper can be advantageous.

The more complex "middle vessel" column combines aspects of both the batch rectifier and the batch stripper, as shown in Fig. 13-124. The middle vessel arrangement was described qualitatively by Robinson and Gilliland (*Elements of Fractional Distillation,* McGraw-Hill, New York, 1950, p. 388) and analyzed by Bortolini and Guirase [*Quad. Ing. Chim. Ital.* **6:** 150 (1970)]. This configuration requires more equipment and is more complex, but it can produce both distillate and bottoms product cuts simultaneously. Barolo and Botteon [*AIChE J.* **43:** 2601 (1997)] pointed out that the middle vessel configuration at total reflux and reboil and with the appropriate collection equipment for distillate and bottoms products (not shown in Fig. 13-124) can concentrate a ternary mixture into its three pure fractions. This and analogous configurations for mixtures with more components have been studied by Hasebe et al. [*J. Chem. Eng. Japan* **29:** 1000 (1996); *Computers Chem. Eng.* **23:** 523 (1999)] and experimentally by Wittgens and Skogestad [*IChemE Symp Ser.* **142:** 239 (1997).]

The batch stripper and the middle vessel configurations offer the ability to make separations for certain azeotropic mixtures that are not possible or that cannot be done efficiently in the batch rectifier.

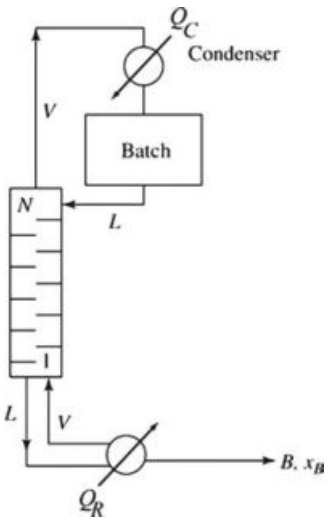

**FIG. 13-123** Schematic of a batch stripper.

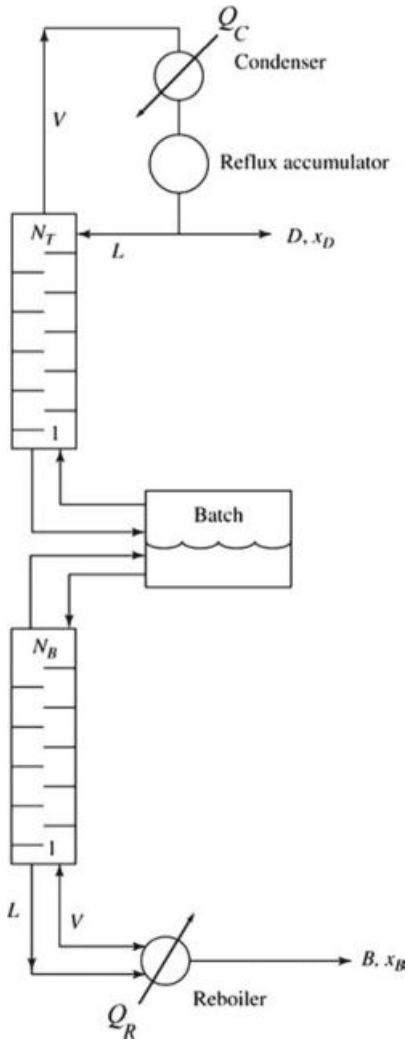

**FIG. 13-124** Middle vessel batch distillation.

## BATCH DISTILLATION OF AZEOTROPIC MIXTURES

Although azeotropic distillation is covered in an earlier subsection, it is appropriate to consider the application of residue curve maps to batch distillation here. (See the subsection Enhanced Distillation for a discussion of residue curve maps.) An essential point is that the sequence, number, and limiting composition of each cut from a batch distillation depend on the form of the residue curve map and the composition of the initial charge to the still. As with continuous distillation operation, the set of reachable products (cuts) for a given charge to a batch distillation is constrained by the residue curve–map distillation boundaries. Furthermore, some pure components can be produced as products from the batch stripper but not the batch rectifier, and vice versa. Doherty and Malone (*Conceptual Design of Distillation Systems,* chap. 9, McGraw-Hill, New York, 2001) give more details, but the main points are the following.

In the batch rectifier, the limiting cuts, obtainable with a sufficiently large number of stages and reflux, begin with the low-boiling node that defines the distillation region containing the feed composition. For the batch stripper, the first limiting cut is the high-boiling node. In either case, the subsequent cuts depend on the structure of the residue curve map.

For the batch rectifier, as the low-boiling component or azeotrope is removed, the still composition moves along a straight material balance line through the initial feed composition and the low-boiling node, and away from the initial composition, until it reaches the edge of the composition triangle or a distillation boundary. The path then follows the edge or distillation boundary to the high-boiling node of the region.

As an example, consider the residue curve map structure shown in Fig. 13-125 for a mixture of methanol, methyl propionate, and water at a

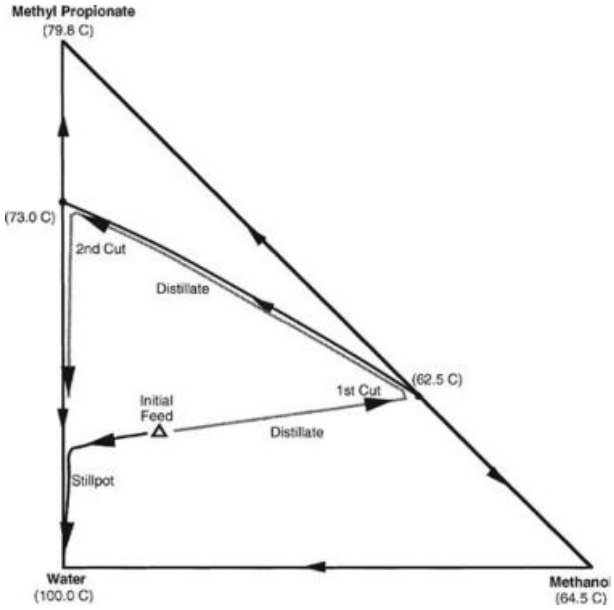

**FIG. 13-125** Residue curve map and batch rectifier paths for methanol, methyl propionate, and water.

pressure of 1 atm. There are two minimum-boiling binary azeotropes joined by a distillation boundary that separates the compositions into two distillation regions. Feeds in the upper and lower regions will have different distillate products. For the sample feed shown, and with a sufficient number of theoretical stages and reflux, the distillate will approach the low-boiling azeotrope of methanol and methyl propionate at 62.5°C. The still pot composition changes along the straight-line segment as shown until it is nearly free of methanol. At that point, the distillate composition changes along the distillation boundary to a composition for the second cut at or near the methyl propionate–water azeotrope. The still pot composition eventually approaches pure water.

For the same feed, a batch stripper can be used to remove a bottoms product that approaches pure water. The pot composition (overhead) will contain all three components near the point of intersection of the distillation boundary with a straight line extended from the water vertex through the feed composition.

For this mixture, it is not possible to isolate the pure components in a batch rectifier or batch stripper. The use of additional equipment such as a decanter to exploit liquid-liquid phase behavior or the addition of a fourth component or chemical reactions can sometimes be used to effect the separation.

The product cuts for azeotropic mixtures are also sensitive to the curvature of the distillation boundaries; see Doherty and Malone (*Conceptual Design of Distillation Systems,* McGraw-Hill, New York, 2001; pp. 403–404) and additional references there.

Foam Prevention ..... 14-118
Automatic Foam Control ..... 14-118

## Nomenclature

| Symbol | Definition | SI units | U.S. Customary System units |
|---|---|---|---|
| $a, a_e$ | Effective interfacial area | $m^2/m^3$ | $ft^2/ft^3$ |
| $a_p$ | Packing surface area per unit volume | $m^2/m^3$ | $ft^2/ft^3$ |
| $A$ | Absorption factor $L_M/(mG_M)$ | -/- | -/- |
| $A$ | Cross-sectional area | $m^2$ | $ft^2$ |
| $A_a$ | Active area, same as bubbling area | $m^2$ | $ft^2$ |
| $A_B$ | Bubbling (active) area | $m^2$ | $ft^2$ |
| $A_D$ | Downcomer area (straight vertical downcomer) | $m^2$ | $ft^2$ |
| $A_{da}$ | Downcomer apron area | $m^2$ | $ft^2$ |
| $A_{DB}$ | Area at bottom of downcomer | $m^2$ | $ft^2$ |
| $A_{DT}$ | Area at top of downcomer | $m^2$ | $ft^2$ |
| $A_e$, $A'$ | Effective absorption factor (Edmister) | -/- | -/- |
| $A_f$ | Fractional hole area | -/- | -/- |
| $A_h$ | Hole area | $m^2$ | $ft^2$ |
| $A_N$ | Net ( free) area | $m^2$ | $ft^2$ |
| $A_S$ | Slot area | $m^2$ | $ft^2$ |
| $A_{SO}$ | Open slot area | $m^2$ | $ft^2$ |
| $A_T$ | Tower cross-sectional area | $m^2$ | $ft^2$ |
| $c$ | Concentration | $kg \cdot mol/m^3$ | $lb \cdot mol/ft^3$ |
| $c'$ | Stokes-Cunningham correction factor for terminal settling velocity | -/- | -/- |
| $C$ | $C$-factor for gas loading, Eq. (14-77) | m/s | ft/s |
| $C_1$, $C_2$ | Parameters in system limit equation | m/s | ft/s |
| $C_3$, $C_4$ | Constants in Robbins' packing pressure drop correlation | -/- | -/- |
| CAF | Flood $C$-factor, Eq. (14-88) | m/s | ft/s |
| $CAF_0$ | Uncorrected flood C-factor, Fig. 14-31 | — | ft/s |
| $C_d$ | Coefficient in clear liquid height correlation, Eq. (14-116) | -/- | -/- |
| $C_G$ | Gas $C$-factor; same as C | m/s | ft/s |
| $C_L$ | Liquid loading factor, Eq. (14-144) | m/s | ft/s |
| $C_{LG}$ | A constant in packing pressure drop correlation, Eq. (14-143) | $(m/s)^{0.5}$ | $(ft/s)^{0.5}$ |
| CP | Capacity parameter (packed towers), Eq. (14-140) | | |
| $C_{SB}$, $C_{sb}$ | $C$-factor at entrainment flood, Eq. (14-80) | m/s | ft/s |
| $C_{sbf}$ | Capacity parameter corrected for surface tension | m/s | ft/s |
| $C_v$, $C_V$ | Discharge coefficient, Fig. 14-36 | -/- | -/- |
| $C_w$ | A constant in weep rate equation, Eq. (14-123) | -/- | -/- |
| $C_{XY}$ | Coefficient in Eq. (14-159) reflecting angle of inclination | -/- | -/- |
| $d$ | Diameter | m | ft |
| $d_b$ | Bubble diameter | m | ft |
| $d_h$, $d_H$ | Hole diameter | mm | in |
| $d_o$ | Orifice diameter | m | ft |
| $d_{pc}$ | Cut size of a particle collected in a device, 50% mass efficiency | μm | ft |
| $d_{psd}$ | Mass median size particle in the pollutant gas | μm | ft |
| $d_{pa50}$ | Aerodynamic diameter of a real median size particle | μm | ft |
| $d_w$ | Weir diameter, circular weirs | mm | in |
| $D$ | Diffusion coefficient | $m^2/s$ | $ft^2/s$ |
| $D$ | Tube diameter (wetted-wall columns) | m | ft |
| $D_{32}$ | Sauter mean diameter | m | ft |
| $D_g$ | Diffusion coefficient | $m^2/s$ | $ft^2/h$ |
| $D_p$ | Packing particle diameter | m | ft |
| $D_T$ | Tower diameter | m | ft |
| $D_{tube}$ | Tube inside diameter | m | ft |
| $D_{vm}$ | Volume mean diameter | m | ft |
| $e$ | Absolute entrainment of liquid | $kg \cdot mol/h$ | $lb \cdot mol/h$ |
| $e$ | Entrainment, mass liquid/mass gas | kg/kg | lb/lb |
| $E$ | Plate or stage efficiency, fractional | -/- | -/- |
| $E$ | Power dissipation per mass | W | Btu/lb |
| $E_a$ | Murphree tray efficiency, with entrainment, gas concentrations, fractional | -/- | -/- |
| $E_g$ | Point efficiency, gas phase only, fractional | -/- | -/- |
| $E_{OC}$ | Overall column efficiency, fractional | -/- | -/- |
| $E_{OG}$ | Overall point efficiency, gas concentrations, fractional | -/- | -/- |
| $E_{mv}$, $E_{MV}$ | Murphree tray efficiency, gas concentrations, fractional | -/- | -/- |

| Symbol | Definition | SI units | U.S. Customary System units |
|---|---|---|---|
| $E_s$ | Entrainment, kg entrained liquid per kg gas upflow | kg/kg | lb/lb |
| $f$ | Fractional approach to flood | -/- | -/- |
| $f$ | Liquid maldistribution fraction | -/- | -/- |
| $f_{max}$ | Maximum value of $f$ above which separation cannot be achieved | -/- | -/- |
| $f_w$ | Weep fraction, Eq. (14-121) | -/- | -/- |
| $F$ | Fraction of volume occupied by liquid phase, system limit correlation, Eq. (14-171) | -/- | -/- |
| $F$ | $F$-factor for gas loading Eq. (14-76) | $m/s(kg/m^3)^{0.5}$ | $ft/s(lb/ft^3)^{0.5}$ |
| $F_{LG}$ | Flow parameter, Eq. (14-89) and Eq. (14-141) | -/- | -/- |
| $F_p$ | Packing factor | $m^{-1}$ | $ft^{-1}$ |
| $F_{pd}$ | Dry packing factor | $m^{-1}$ | $ft^{-1}$ |
| FPL | Flow path length | m | ft |
| Fr | Froude number, clear liquid height correlation, Eq. (14-120) | -/- | -/- |
| $Fr_h$ | Hole Froude number, Eq. (14-114) | -/- | -/- |
| $F_w$ | Weir constriction correction factor, Fig. 14-39 | -/- | -/- |
| $g$ | Gravitational constant | $m/s^2$ | $ft/s^2$ |
| $g_c$ | Conversion factor | $1.0\ kg \cdot m/(N \cdot s^2)$ | $32.2\ lb \cdot ft/(lbf \cdot s^2)$ |
| $G$ | Gas phase mass velocity | $kg/(s \cdot m^2)$ | $lb/(hr \cdot ft^2)$ |
| $G_f$ | Gas loading factor in Robbins' packing pressure drop correlation | $kg/(s \cdot m^2)$ | $lb/(h \cdot ft^2)$ |
| $G_M$ | Gas phase molar velocity | $kg \cdot mol/(s \cdot m^2)$ | $lb \cdot mol/(h \cdot ft^2)$ |
| GPM | Liquid flow rate | — | gpm |
| $h$ | Pressure head | mm | in |
| $h'_{dc}$ | Froth height in downcomer | mm | in |
| $h'_L$ | Pressure drop through aerated mass on tray | mm | in |
| $h_c$, $h_C$ | Clear liquid height on tray | mm | in |
| $h_{cl}$ | Clearance under downcomer | mm | in |
| $h_{ct}$ | Clear liquid height at spray to froth transition | mm | in |
| $h_d$ | Dry pressure drop across tray | mm | in |
| $h_{da}$ | Head loss due to liquid flow under downcomer apron | mm | in |
| $h_{dc}$ | Clear liquid height in downcomer | mm | in |
| $h_{ds}$ | Calculated clear liquid height, Eq. (14-108) | mm | in |
| $h_f$ | Height of froth | mm | in |
| $h_{fow}$ | Froth height over the weir, Eq. (14-117) | mm | in |
| $h_{hg}$ | Hydraulic gradient | mm | in |
| $h_{Lo}$ | Packing holdup in preloading regime, fractional | -/- | -/- |
| $h_{Lt}$ | Clear liquid height at froth to spray transition, corrected for effect of weir height, Eq. (14-96) | mm | in |
| $h_{ow}$ | Height of crest over weir | mm | in |
| $h_T$ | Height of contacting | m | ft |
| $h_t$ | Total pressure drop across tray | mm | in |
| $h_w$, $h_W$ | Weir height | mm | in |
| $H$ | Height of a transfer unit | m | ft |
| $H$ | Henry's law constant | kPa/mol fraction | atm/mol fraction |
| $H'$ | Henry's law constant | $kPa/(kmol \cdot m^3)$ | $psi/(lb \cdot mol \cdot ft^3)$ |
| $H_G$ | Height of a gas phase transfer unit | m | ft |
| $H_L$ | Height of a liquid phase transfer unit | m | ft |
| $H_{OG}$ | Height of an overall transfer unit, gas phase concentrations | m | ft |
| $H_{OL}$ | Height of an overall transfer unit, liquid phase concentrations | m | ft |
| $H'$ | Henry's law coefficient | kPa/mol frac | atm/mol frac |
| HETP | Height equivalent to a theoretical plate or stage | m | ft |
| $J_G^*$ | Dimensionless gas velocity, weep correlation, Eq. (14-124) | -/- | -/- |
| $J_L^*$ | Dimensionless liquid velocity, weep correlation, Eq. (14-125) | -/- | -/- |
| $k$ | Individual phase mass transfer coefficient | $kmol/(s \cdot m^2 \cdot$ mol frac) | $lb \cdot mol/(s \cdot ft^2 \cdot$ mol frac) |
| $k_1$ | First order reaction velocity constant | 1/s | 1/s |
| $k_2$ | Second-order reaction velocity constant | $m^3/(s \cdot kmol)$ | $ft^3/(h \cdot lb \cdot mol)$ |
| $k_g$ | Gas mass-transfer coefficient, wetted-wall columns [see Eq. (14-172) for unique units] | | |

**Nomenclature** (*Continued*)

| Symbol | Definition | SI units | U.S. Customary System units |
|---|---|---|---|
| $k_G$ | Gas phase mass-transfer coefficient | kmol/(s·m²·mol frac) | lb·mol/(s·ft²·mol frac) |
| $k_L$ | Liquid phase mass-transfer coefficient | kmol/(s·m²·mol mol frac) | lb·mol/(s·ft²·mol frac) |
| $K$ | Constant in trays dry pressure drop equation | mm·s²/m² | in·s²/ft² |
| $K$ | Vapor–liquid equilibrium ratio | -/- | -/- |
| $K_C$ | Dry pressure drop constant, all valves closed | mm·s²/m² | in·s²/ft² |
| $K_D$ | Orifice discharge coefficient, liquid distributor | -/- | -/- |
| $K_g$ | Overall mass-transfer coefficient | kg·mol/(s·m²·atm) | lb·mol/(h·ft²·atm) |
| $K_O$ | Dry pressure drop constant, all valves open | mm·s²/m² | in·s²/ft² |
| $K_{OG}$, $K_G$ | Overall mass-transfer coefficient, gas concentrations | kmol/(s·m²·mol) | lb·mol/(s·ft²·mol frac) |
| $K_{OL}$ | Overall mass-transfer coefficient, liquid concentrations | kmol/(s·m²·mol frac) | lb.mol/(s·ft²·mol frac) |
| $L$ | Liquid mass velocity | kg/(m²·s) | lb/ft²·h |
| $L_f$ | Liquid loading factor in Robbins' packing pressure drop correlation | kg/(s·m²) | lb/(h·ft²) |
| $L_m$ | Molar liquid downflow rate | kg·mol/h | lb·mol/h |
| $L_M$ | Liquid molar mass velocity | kmol/(m²·s) | lb·mol/(ft²·h) |
| $L_S$ | Liquid velocity, based on superficial tower area | m/s | ft/s |
| $L_w$ | Weir length | m | in |
| $m$ | An empirical constant based on Wallis' countercurrent flow limitation equation, Eqs. (14-123) and (14-143) | -/- | -/- |
| $m$ | Slope of equilibrium curve = $dy^*/dx$ | -/- | -/- |
| $M$ | Molecular weight | kg/kmol | lb/(lb·mol) |
| $n$ | Parameter in spray regime clear liquid height correlation, Eq. (14-84) | mm | In |
| $n_A$ | Rate of solute transfer | kmol/s | lb·mol/s |
| $n_D$ | Number of holes in orifice distributor | -/- | -/- |
| $N_a$ | Number of actual trays | -/- | -/- |
| $N_A$, $N_t$ | Number of theoretical stages | -/- | -/- |
| $N_{OG}$ | Number of overall gas-transfer units | -/- | -/- |
| $N_p$ | Number of tray passes | -/- | -/- |
| $p$ | Hole pitch (center-to-center hole spacing) | mm | in |
| $p$ | Partial pressure | kPa | atm |
| $P_{BM}$ | Logarithmic mean partial pressure of inert gas | kPa | atm |
| $P$, $p_T$ | Total pressure | kPa | atm |
| $P^0$ | Vapor pressure | kpa | atm |
| $Q$, $q$ | Volumetric flow rate of liquid | m³/s | ft³/s |
| $Q'$ | Liquid flow per serration of serrated weir | m·³/s | ft³/s |
| $Q_D$ | Downcomer liquid load, Eq. (14-79) | m/s | ft/s |
| $Q_L$ | Weir load, Eq. (14-78) | m³/(h·m) | gpm/in |
| $Q_{MW}$ | Minimum wetting rate | m³/(h·m²) | gpm/ft² |
| $R$ | Reflux flow rate | kg·mol/h | lb·mol/h |
| $R$ | Gas constant | | |
| $R_h$ | Hydraulic radius | m | ft |
| $R_{vw}$ | Ratio of valve weight with legs to valve weight without legs, Table (14-11) | -/- | -/- |
| $Re_G$ | Gas Reynolds number (defined on page 14-63) | -/- | -/- |
| $Re_L$ | Liquid Reynolds number, Eq. 14-165 | -/- | -/- |
| $S$ | Length of corrugation side, structured packing | m | ft |
| $S$ | Stripping factor $mG_M/L_M$ | -/- | -/- |
| $S$ | Tray spacing | mm | in |
| $S_e$, $S'$ | Effective stripping factor (Edmister) | -/- | -/- |
| SF | Derating (system) factor, Table 14-9 | -/- | -/- |
| $t_t$ | Tray thickness | mm | in |
| $t_v$ | Valve thickness | mm | in |
| $T$ | Absolute temperature | K | °R |
| TS | Tray spacing; same as $S$ | mm | in |
| $U$,$u$ | Linear velocity of gas | m/s | ft/s |
| $U_a$ | Velocity of gas through active area | m/s | ft/s |
| $U_a^*$ | Gas velocity through active area at froth to spray transition | m/s | ft/s |
| $U_h$, $u_h$ | Gas hole velocity | m/s | ft/s |
| $U_L$, $u_L$ | Liquid superficial velocity based on tower cross-sectional area | m/s | ft/s |
| $U_n$ | Velocity of gas through net area | m/s | ft/s |
| $U_{nf}$ | Gas velocity through net area at flood | -/- | -/- |
| $U_t$ | Superficial velocity of gas | m/s | ft/s |
| $v_H$ | Horizontal velocity in trough | m/s | ft/s |
| $V$ | Linear velocity | m/s | ft/s |
| $V$ | Molar vapor flow rate | kg·mol/s | lb·mol/h |
| $W$ | Weep rate | m³/s | gpm |
| $x$ | Mole fraction, liquid phase (note 1) | -/- | -/- |
| $x'$ | Mole fraction, liquid phase, column 1 (note 1) | | |
| $x''$ | Mole fraction, liquid phase, column 2 (note 1) | | |
| $x^*$, $x^\circ$ | Liquid mole fraction at equilibrium (note 1) | -/- | -/- |
| $y$ | Mole fraction, gas or vapor phase (note 1) | -/- | -/- |
| $y'$ | Mole fraction, vapor phase, column 1 (note 1) | | |
| $y''$ | Mole fraction, vapor phase, column 2 (note 1) | | |
| $y^*$, $y^\circ$ | Gas mole fraction at equilibrium (note 1) | | |
| $Z$ | Characteristic length in weep rate equation, Eq. (14-126) | m | ft |
| $Z_p$ | Total packed height | m | ft |

Greek symbols

| | | | |
|---|---|---|---|
| α | Relative volatility | -/- | -/- |
| β | Tray aeration factor, Fig. 14-38 | -/- | -/- |
| ε | Void fraction | -/- | -/- |
| ϕ | Contact angle | deg | deg |
| ϕ | Relative froth density | -/- | -/- |
| γ | Activity coefficient | -/- | -/- |
| Γ | Flow rate per length | kg/(s·m) | lb/(s·ft) |
| δ | Effective film thickness | m | ft |
| η | Collection eficiency, fractional | -/- | -/- |
| η | Factor used in froth density correlation, Eq. (14-118) | -/- | -/- |
| λ | Stripping factor = $m/(L_M/G_M)$ | -/- | -/- |
| μ | Absolute viscosity | Pa·s | cP or lb/(ft·s) |
| μm | Micrometers | m | -/- |
| ν | Kinematic viscosity | m²/s | cS |
| π | 3.1416. . . . | -/- | -/- |
| θ | Residence time | s | s |
| θ | Angle of serration in serrated weir | deg | deg |
| ρ | Density | kg/m³ | lb/ft³ |
| $\rho_M$ | Valve metal density | kg/m³ | lb/ft³ |
| σ | Surface tension | mN/m | dyn/cm |
| χ | Parameter used in entrainment correlation, Eq. (14-95) | -/- | -/- |
| ψ | Fractional entrainment, moles liquid entrained per mole liquid downflow | k·mol/k·mol | lb·mol/lb·mol |
| Φ | Fractional approach to entrainment flood | -/- | -/- |
| $\Delta P$ | Pressure drop per length of packed bed | mm$H_2O$/m | in$H_2O$/ft |
| Δρ | $\rho_L - \rho_G$ | kg/m³ | lb/ft³ |

Subscripts

| | |
|---|---|
| *A* | Species A |
| *AB* | Species A diffusing through species B |
| *B* | Species B |
| *B* | Based on the bubbling area |
| *d* | Dry |
| *da* | Downcomer apron |
| *dc* | Downcomer |
| dry | Uncorrected for entrainment and weeping |
| *e* | Effective value |
| *f* | Froth |
| *Fl* | Flood |
| flood | At flood |
| *G*, *g* | Gas or vapor |
| *h* | Based on hole area (or slot area) |
| $H_2O$ | Water |
| *i* | Interface value |
| *L*, *l* | Liquid |
| *m* | Mean |

**Nomenclature** (*Continued*)

| Symbol | Definition | SI units | U.S. Customary System units |
|---|---|---|---|
| min | Minimum | | |
| MOC | At maximum operational capacity | | |
| | Subscripts | | |
| *n, N* | On stage *n* | | |
| *N* | At the inlet nozzle | | |
| *NF, nf* | Based on net area at flood | | |
| *p* | Particle | | |
| *S* | Superficial | | |
| *t* | Total | | |
| ult | At system limit (ultimate capacity) | | |
| *V, v* | Vapor | | |
| *w* | Water | | |
| 1 | Tower bottom | | |
| 2 | Tower top | | |
| | Dimensionless groups | | |
| $N_{Fr}$ | Froude number = $(U_L^2)/(Sg)$ | | |
| $N_{Re}$ | Reynolds number = $(D_{tube}U_{ge}\rho_G)/(\mu_G)$ | | |
| $N_{Sc}$ | Schmidt number = $\mu/(\rho D)$ | | |
| $N_{We}$ | Weber number = $(U_L^2\rho_L S)/(\sigma g_c)$ | | |

NOTE: 1. Unless otherwise specified, refers to concentration of more volatile component (distillation) or solute (absorption).

# INTRODUCTION

## DEFINITIONS

Gas absorption is a unit operation in which soluble components of a gas mixture are dissolved in a liquid. The inverse operation, called stripping or desorption, is used when we wish to transfer volatile components from a liquid mixture into a gas. Both absorption and stripping, in common with distillation (Sec. 13), make use of special equipment for bringing gas and liquid phases into intimate contact. This section is concerned with the design of gas–liquid contacting equipment, as well as with the design of absorption and stripping processes.

## EQUIPMENT

Absorption, stripping, and distillation operations are usually carried out in vertical, cylindrical columns or towers in which devices such as plates or packing elements are placed. The gas and liquid normally flow countercurrently, and the devices serve to provide the contacting and development of interfacial surface through which mass transfer takes place. Background material on this mass transfer process is given in Sec. 5.

## DESIGN PROCEDURES

The procedures to be followed in specifying the principal dimensions of gas absorption and distillation equipment are described in this section and are supported by several worked-out examples. The experimental data required for executing the designs are keyed to appropriate references or to other sections of this handbook.

For absorption, stripping, and distillation, there are three main steps involved in design:

1. *Data on the gas–liquid or vapor–liquid equilibrium for the system at hand.* If absorption, stripping, and distillation operations are considered equilibrium-limited processes, which was the usual approach in the past but is less so now due to the availability of commercial software, these data are critical for determining the maximum possible separation. In some cases, the operations are considered rate-based (see later in this section and also Sec. 13), but they require knowledge of equilibrium at the phase interface. Other data required include physical properties such as viscosity and density and thermodynamic properties such as enthalpy. Section 2 deals with sources of such data.

2. *Information on the liquid- and gas-handling capacity of the contacting device chosen for the particular separation problem.* Such information includes pressure drop characteristics of the device, in order that an optimum balance between capital cost (column cross section and height) and energy requirements might be achieved. Capacity and pressure drop characteristics of the available devices are covered later in Sec. 14.

3. *Determination of the required height of contacting zone for the separation to be made as a function of properties of the fluid mixtures and mass-transfer efficiency of the contacting device.* This determination involves the calculation of mass-transfer parameters such as heights of transfer units and tray efficiencies as well as equilibrium or rate parameters such as theoretical stages or numbers of transfer units. An additional consideration for systems in which chemical reaction occurs is the provision of adequate residence time for desired reactions to occur, or minimal residence time to prevent undesired reactions from occurring. For equilibrium-based operations, the parameters for required height are covered in the present section, but guidance is also provided for the use of commercial software.

## DATA SOURCES IN THE HANDBOOK

Sources of data for the analysis or design of absorbers, strippers, and distillation columns are manifold, and a detailed listing of them is outside the scope of this section. Some key sources within the handbook are shown in Table 14-1.

## EQUILIBRIUM DATA

Finding reliable gas–liquid and vapor–liquid equilibrium data usually is the most time-consuming task associated with the design of absorbers and other gas–liquid contactors, and yet it may be the most important task at hand. For gas solubility, an important data source is the set of volumes edited by Kertes et al., *Solubility Data Series,* published by Pergamon Press (1979 ff.). In the introduction to each volume, there is an excellent discussion and definition of the various methods by which gas solubility data have been reported, such as the Bunsen coefficient, the Kuenen coefficient, the Ostwalt coefficient, the absorption coefficient, and the Henry's law coefficient. The fifth edition of *The Properties of Gases and Liquids* by Poling, Prausnitz, and O'Connell (McGraw-Hill, New York, 2000) provides data and recommended estimation methods for gas solubility as well as the broader area of vapor–liquid equilibrium. Online databases for vapor–liquid equilibrium are increasingly available, but they may entail a fee. DETHERM on the web (http://i-systems.dechema.de/detherm/) is a comprehensive source of data. NIST-TDE [Frenkel et al., *J. Chem. Inf. Model* **45:** 816–838 (2005); http://trc.nist.gov/tde.html] also provides a comprehensive source of data, and in addition it is available in process-simulation software tools, such as those from Aspen Technology, Inc.

# DESIGN OF GAS ABSORPTION SYSTEMS

## GENERAL DESIGN PROCEDURE

The design engineer usually must determine (1) the best solvent; (2) the best gas velocity through the absorber, or, equivalently, the vessel diameter; (3) the height of the vessel and its internal members, which is the height and type of packing or the number of contacting trays; (4) the optimum solvent circulation rate through the absorber and stripper; (5) temperatures of streams entering and leaving the absorber and stripper, and the quantity of heat to be removed to account for the heat of solution and other thermal effects; (6) pressures at which the absorber and stripper will operate; and (7) the mechanical design of the absorber and stripper vessels (predominantly columns or towers), including flow distributors and packing supports. This subsection covers these aspects.

The problem presented to the designer of a gas absorption system usually specifies the following quantities: (1) gas flow rate; (2) gas composition of the component or components to be absorbed; (3) operating pressure and allowable pressure drop across the absorber; (4) minimum recovery of one or more of the solutes; and, possibly, (5) the solvent to be employed. Items 3, 4, and 5 may be subject to economic considerations and therefore may be left to the designer. For a determination of the number of variables that must be specified to fix a unique solution for the absorber design, one may use the same phase-rule approach described in Sec. 13 for distillation systems.

Recovery and recycle of the solvent, occasionally by chemical means but more often by stripping, is almost always required and is considered an integral part of the absorption system process design. A more complete solvent-stripping operation normally will result in a less costly absorber because of a lower concentration of residual solute in the regenerated (lean) solvent, but this may increase the overall cost of the entire absorption system. A more detailed discussion of these and other economic considerations is presented later in this section.

The design calculations presented in this subsection are relatively simple and usually can be done by using a calculator or spreadsheet. In many cases, the calculations are explained through design diagrams. Most engineers today will perform rigorous, detailed calculations using process simulators. The design procedures presented here are intended to complement the rigorous computerized calculations by presenting approximate estimates and insight into the essential elements of absorption and stripping operations. These relatively simple design procedures are especially useful for understanding trends and for checking the results from commercial simulators.

## SELECTION OF SOLVENT AND NATURE OF SOLVENTS

When a choice is possible, preference is given to solvents with high solubilities for the target solute and high selectivity for the target solute over the other species in the gas mixture. A high solubility reduces the flow rate of liquid to be circulated. The solvent should have the advantages of low volatility, low cost, low corrosive tendencies, high stability, low viscosity, low tendency to foam, and low flammability. Since the exit gas normally leaves saturated with solvent, solvent loss can be costly and can cause environmental problems. The choice of the solvent is a key factor in the economic analysis of the process and in its compliance with environmental regulations.

Typically, a solvent that is chemically similar to the target solute or that reacts with it will provide high solubility. Water is often used for polar and acidic solutes (e.g., HCl), oils for light hydrocarbons, and special chemical solvents for acid gases such as $CO_2$, $SO_2$, and $H_2S$. Solvents are classified as physical and chemical. A chemical solvent forms complexes or chemical compounds with the solute, while physical solvents have only weaker interactions with the solute. Physical and chemical solvents are compared by examining the solubility of $CO_2$ in propylene carbonate (representative physical solvent) and aqueous monoethanolamine (MEA; representative chemical solvent).

Figures 14-1 and 14-2 present correlations (based on data) for the solubility of $CO_2$ in the two representative physical and chemical solvents, each at two temperatures: 40°C and 100°C. The propylene carbonate data are from Zubchenko et al. [*Zhur. Priklad. Khim.* **44:** 2044–2047 (1971)], and the MEA data are from Jou, Mather, and Otto [*Can. J. Chem. Eng.* **73:** 140–147 (1995)]. The two figures have the same content, but Fig. 14-2 focuses on the low-pressure region by converting both composition and pressure to the logarithm scale. Examination of the two sets of data reveals the differences between physical and chemical solvents, which are summarized in the following table:

| Characteristic | Physical solvent | Chemical solvent |
|---|---|---|
| Solubility variation with pressure | Relatively linear | Highly nonlinear |
| Low-pressure solubility | Low | High |
| High-pressure solubility | Continues to increase | Levels off |
| Heat of solution—related to variation of solubility with temperature at fixed pressure | Relatively low and approximately constant with solute loading | Relatively high and decreases somewhat with increased solute loading |
| Typical value for heat of solution | 12 kJ/gmol for $CO_2$ in propylene carbonate 40°C | 85 kJ/gmol for $CO_2$ in 30 wt% MEA at 40°C and low $CO_2$ loading |

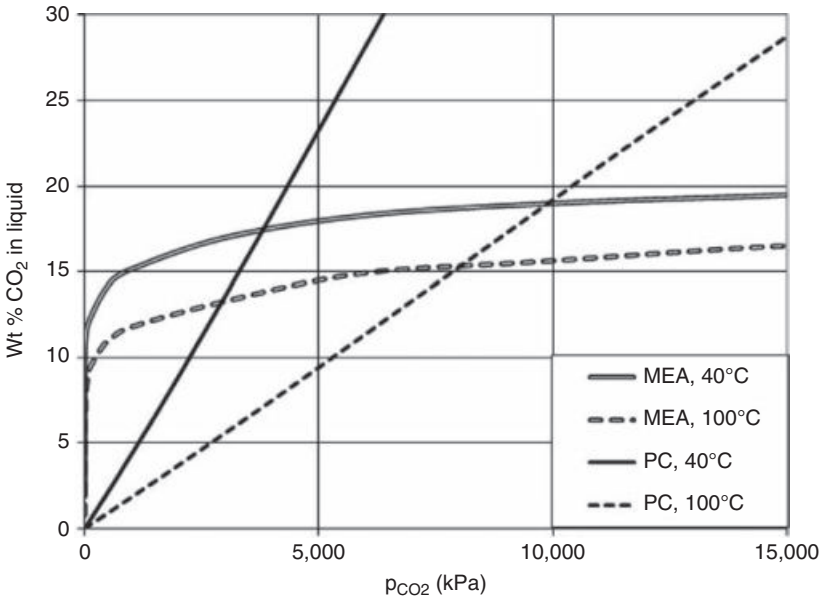

**FIG. 14-1** Solubility of $CO_2$ in 30 wt% MEA and propylene carbonate. Linear scale.

Chemical solvents are usually preferred when the solute must be reduced to very low levels, when high selectivity is needed, and when the solute partial pressure is low. However, the strong absorption at low solute partial pressures and the high heat of solution are disadvantages for stripping. For chemical solvents, the strong nonlinearity of the absorption makes it necessary that accurate absorption data for the conditions of interest be available.

## SELECTION OF SOLUBILITY DATA

Solubility values are necessary for design because they determine the liquid rate necessary for complete or economical solute recovery. Equilibrium data generally will be found in one of three forms: (1) solubility data expressed either as weight or mole percent or as Henry's law coefficients, (2) pure-component vapor pressures, or (3) equilibrium distribution coefficients ($K$ values). Data for specific systems may be found in Sec. 2, and Sec. 4 provides a discussion of Henry's law coefficients; additional references to sources of data are presented in this section.

To define completely the solubility of gas in a liquid, it is generally necessary to state the temperature, equilibrium partial pressure of the solute gas in the gas phase, and the concentration of the solute gas in the liquid phase. Strictly speaking, the total pressure of the system should also be identified, but for low pressures (less than about 507 kPa or 5 atm), the solubility for a particular partial pressure of the solute will be relatively independent of the total pressure.

For many physical systems, the equilibrium relationship between solute partial pressure and liquid-phase concentration is given by Henry's law:

$$p_A = Hx_A \tag{14-1}$$

or

$$p_A = H' c_A \tag{14-2}$$

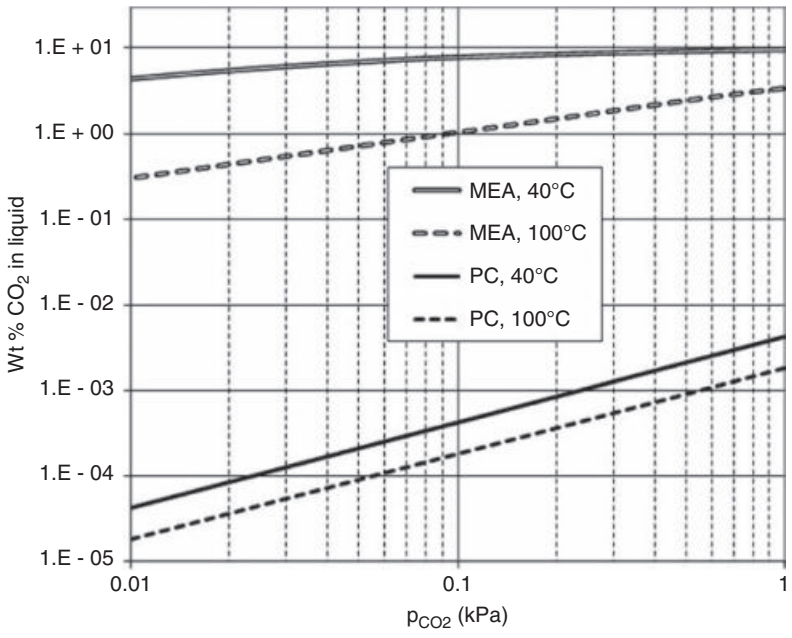

**FIG. 14-2** Solubility of $CO_2$ in 30 wt% MEA and propylene carbonate. Logarithm scale and focus on low-pressure region.

where $H$ is the Henry's law coefficient expressed in kPa per mole fraction solute in liquid and $H'$ is the Henry's law coefficient expressed in kPa · m$^3$/kmol. Section 4 discusses conversions between $H$ and $H'$ and other variants of Henry's law coefficients.

Figure 14-1 indicates that Henry's law is valid to a good approximation for the solubility of $CO_2$ in propylene carbonate. In general, Henry's law is a reasonable approximation for physical solvents. If Henry's law holds, the solubility is defined by knowing (or estimating) the value of the constant $H$ (or $H'$).

Note that the assumption of Henry's law will lead to incorrect results for the solubility of chemical systems such as $CO_2$-MEA (Figs. 14-1 and 14-2) and HCl-$H_2O$. Solubility modeling for chemical systems requires the use of a *speciation model,* as described later in this section and also in Sec. 4.

For quite a number of physically absorbed gases, Henry's law holds very well when the partial pressure of the solute is less than about 101 kPa (1 atm). For partial pressures above 101 kPa, $H$ may be independent of the partial pressure (Fig. 14-1), but this needs to be verified for the system of interest. The variation of $H$ with temperature is a strongly nonlinear function of temperature, as discussed by Poling, Prausnitz, and O'Connell (*The Properties of Gases and Liquids,* 5th ed., McGraw-Hill, New York, 2000) and Smith and Harvey [*Chem. Eng. Progress* **103:** 33 (2007)]. One should consult these references and the discussion in Sec. 4 when temperature and pressure extrapolations of Henry's law data are needed. Further discussion of Henry's law is presented in Sec. 4.

The use of Henry's law constants is illustrated by the following example.

***Example 14-1 Gas Solubility*** We wish to find out how much hydrogen can be dissolved in 100 weights of water from a gas mixture when the total pressure is 101.3 kPa (760 torr; 1 atm), the partial pressure of the $H_2$ is 26.7 kPa (200 torr), and the temperature is 25°C. For partial pressures up to about 100 kPa, the value of $H$ is given in Sec. 3 as $7.17 \times 10^6$ kPa ($7.08 \times 10^4$ atm) at 25°C. According to Henry's law,

$$x_{H2} = p_{H2}/H_{H2} = 26.7/7.08 \times 10^6 = 3.72 \times 10^{-6}$$

The mole fraction $x$ is the ratio of the number of moles of $H_2$ in solution to the total moles of all constituents contained. To calculate the weights of $H_2$ per 100 weights of $H_2O$, one can use the following formula, where the subscripts $A$ and $w$ correspond to the solute (hydrogen) and solvent (water):

$$\left(\frac{x_A}{1-x_A}\right)\frac{M_A}{M_W}100 = \left(\frac{3.72 \times 10^{-6}}{1-3.72 \times 10^{-6}}\right)\frac{2.02}{18.02}100$$

$$= 4.17 \times 10^{-5} \text{ weights } H_2/100 \text{ weights } H_2O$$

$$= 0.42 \text{ parts per million weight or } 0.42 \text{ ppmw}$$

Pure-component vapor pressure can be used for predicting solubilities for systems in which *Raoult's law* is valid. For such systems, $p_A = p_A^0 x_A$, where $p_A^0$ is the pure-component vapor pressure of the solute and $p_A$ is its partial pressure. Extreme care should be exercised when using pure-component vapor pressures to predict gas absorption behavior. Both vapor-phase and liquid-phase nonidealities can cause significant deviations from Raoult's law, and this is often the reason particular solvents are used, that is, because they have special affinity for particular solutes. Poling, Prausnitz, and O'Connell (*The Properties of Gases and Liquids,* 5th ed., McGraw-Hill, New York, 2000) provide an excellent discussion of the conditions where Raoult's law is valid. Vapor-pressure data are available in Sec. 2 for a variety of materials.

Whenever data are available for a given system under similar conditions of temperature, pressure, and composition, *equilibrium distribution coefficients* ($K = y/x$) provide a much more reliable tool for predicting vapor–liquid distributions. Detailed discussions of equilibrium $K$ values are presented in Secs. 4 and 13.

## CALCULATION OF LIQUID-TO-GAS RATIO

The minimum possible liquid rate is readily calculated from the composition of the entering gas and the solubility of the solute in the exit liquor, with equilibrium being assumed. It may be necessary to estimate the temperature of the exit liquid based on the heat of solution of the solute gas. Values of latent heat and specific heat and values of heats of solution (at infinite dilution) are given in Sec. 2.

The actual liquid-to-gas ratio (solvent circulation rate) normally will be greater than the minimum by as much as 25 to 100 percent, and the estimated factor may be arrived at by economic considerations as well as judgment and experience. For example, in some packed-tower applications involving very soluble gases or vacuum operation, the minimum quantity of solvent needed to dissolve the solute may be insufficient to keep the packing surface thoroughly wet, leading to poor distribution of the liquid stream.

When the solute concentration in the inlet gas is low and when a significant fraction of the solute is absorbed (this often the case), the approximation

$$y_1 G_M = x_1 L_M = (y_1^\circ/m)L_M \tag{14-3}$$

leads to the conclusion that the ratio $mG_M/L_M$ represents the fractional approach of the exit liquid to saturation with the inlet gas,

$$mG_M/L_M = y_1^\circ/y_1 \tag{14-4}$$

Optimization of the liquid-to-gas ratio in terms of total annual costs often suggests that the molar liquid-to-gas ratio $L_M/G_M$ should be about 1.2 to 1.5 times the theoretical minimum corresponding to equilibrium at the rich end of the tower (infinite height or number of trays), provided flooding is not a problem. This, for example, would be an alternative to assuming that $L_M/G_M \approx m/0.7$.

When the exit-liquor temperature rises because of the heat of absorption of the solute, the value of $m$ changes through the tower, and the liquid-to-gas ratio must be chosen to give reasonable values of $m_1G_M/L_M$ and $m_2G_M/L_M$, where the subscripts 1 and 2 refer to the bottom and top of the absorber, respectively. For this case, the value of $m_2G_M/L_M$ will be taken to be somewhat less than 0.7, so the value of $m_1G_M/L_M$ will not approach unity too closely. This rule-of-thumb approach is useful only when the solute concentration is low and heat effects are negligible.

When the solute has a large heat of solution or when the feed gas contains high concentrations of the solute, one should consider the use of internal cooling coils or intermediate liquid withdrawal and cooling to remove the heat of absorption.

## SELECTION OF EQUIPMENT

Trays and packings (both random and structured) have been extensively used for gas absorption; structured packings are seeing increasing usage, particularly for applications requiring low pressure drop and high surface area. Compared to trays, packings have the advantages of availability in low-cost, corrosion-resistant materials (such as plastics and ceramics), low pressure drop (which can be an advantage when the tower is in the suction of a fan or compressor), easy and economic adaptability to small-diameter (less than 0.6-m or 2-ft) columns, and excellent handling of foams. Trays are much better for handling solids and fouling applications, offer greater residence time for slow absorption reactions, can better handle high $L/G$ ratios and intermediate cooling, give better liquid turndown, and are more robust and less prone to reliability issues such as those resulting from poor distribution. Details on the operating characteristics of tray and packed towers are given later in this subsection.

## COLUMN DIAMETER AND PRESSURE DROP

Flooding determines the minimum possible diameter of the absorber column, and the usual design is for 60 to 80 percent of the flooding velocity. In near-atmospheric applications, pressure drop usually needs to be minimized to reduce the cost of energy for compression of the feed gas. For systems having a significant tendency to foam, the maximum allowable velocity will be lower than the estimated flooding velocity. Methods for predicting flooding velocities and pressure drops are given later in this section.

## COMPUTATION OF TOWER HEIGHT

The required height of a gas absorption or stripping tower for physical solvents depends on (1) the phase equilibria involved; (2) the specified degree of removal of the solute from the gas; and (3) the mass-transfer efficiency of the device. These three considerations apply to both tray and packed towers. Items 1 and 2 dictate the required number of theoretical stages (tray tower) or transfer units (packed tower). Item 3 is derived from the tray efficiency and spacing (tray tower) or from the height of one transfer unit (packed tower). Solute removal specifications are usually derived from economic considerations.

For tray towers, the approximate design methods described in this subsection may be used in estimating the number of theoretical stages, and the tray efficiencies and spacings for the tower can be specified on the basis of the information given later. Considerations involved in the rigorous design of theoretical stages for tray towers are treated in Sec. 13.

For packed towers, the continuous differential nature of the contact between gas and liquid leads to a design procedure involving the solution of differential equations, as described in the next subsection. Note that the design procedures discussed in this section are not applicable to reboiled absorbers, which should be designed according to the procedures described in Sec. 13.

Caution is advised in distinguishing between systems involving pure physical absorption and those in which chemical reactions can significantly affect design procedures. Chemical systems require additional procedures, as described later in this section.

## SELECTION OF STRIPPER OPERATING CONDITIONS

Stripping involves the removal of one or more components from the solvent through the application of heat or contacting it with a gas such as steam, nitrogen, or air. The operating conditions chosen for stripping normally result in a low solubility of solute (i.e., a high value of $m$), so the ratio $mG_M/L_M$ will be larger than unity. A value of 1.4 may be used for rule-of-thumb calculations involving pure physical absorption. For tray-tower calculations, the stripping factor $S = KG_M/L_M$, where $K = y^0/x$ usually is specified for each tray.

When the solvent from an absorption operation must be regenerated for recycling to the absorber, one may employ a "pressure-swing" or "temperature-swing" concept, or a combination of the two, in specifying the stripping operation. In pressure-swing operation, the temperature of the stripper is about the same as that of the absorber, but the stripping pressure is much lower. In temperature-swing operation, the pressures are about equal, but the stripping temperature is much higher than the absorption temperature.

In pressure-swing operation, a portion of the gas may be "sprung" from the liquid by the use of a flash drum upstream of the stripper feed point. This type of operation has been discussed by Burrows and Preece [*Trans. Inst. Chem. Eng.* **32:** 99 (1954)] and by Langley and Haselden [*Inst. Chem. Eng. Symp. Ser. (London)*, no. 28 (1968)]. If the flashing of the liquid takes place inside the stripping tower, this effect must be accounted for in the design of the upper section in order to avoid overloading and flooding near the top of the tower.

Often the rate at which residual absorbed gas can be driven from the liquid in a stripping tower is limited by the rate of a chemical reaction, in which case the liquid-phase residence time (and hence the tower liquid holdup) becomes the most important design factor. Thus, many stripper regenerators are designed on the basis of liquid holdup rather than on the basis of mass-transfer rate.

Approximate design equations applicable only to the case of pure physical desorption are developed later in this subsection for both packed and tray stripping towers. A more rigorous approach using distillation concepts may be found in Sec. 13. A brief discussion of desorption with chemical reaction is given in the subsection Absorption with Chemical Reaction.

## DESIGN OF ABSORBER-STRIPPER SYSTEMS

The solute-rich liquor leaving a gas absorber normally is distilled or stripped to regenerate the solvent for recirculation back to the absorber, as depicted in Fig. 14-3. The conditions selected for the absorption step (e.g., temperature, pressure, $L_M/G_M$) will affect the design of the stripping tower, and conversely, a selection of stripping conditions will affect the absorber design. The choice of optimum operating conditions for an absorber-stripper system therefore involves a combination of economic factors and practical judgments as to the operability of the system within the context of the overall process flow sheet. In Fig. 14-3, the stripping vapor is provided by a reboiler; alternately, an extraneous stripping gas may be used.

An appropriate procedure for executing the design of an absorber-stripper system is to set up a carefully selected series of design cases and then evaluate the equipment costs, the operating costs, and the operability of each case. Equipment costs are discussed briefly in the subsection Column Costs later in this chapter.

## IMPORTANCE OF DESIGN DIAGRAMS

One of the first things a designer should do is to lay out a carefully constructed equilibrium curve $y^0 = F(x)$ on an $xy$ diagram, as shown in Fig. 14-4. A horizontal line corresponding to the inlet-gas composition $y_1$ is then the locus of feasible outlet-liquor compositions, and a vertical line corresponding to the inlet-solvent-liquor composition $x_2$ is the locus of outlet-gas compositions. These lines are indicated as $y = y_1$ and $x = x_2$, respectively, on Fig. 14-4.

For gas absorption, the region of feasible operating lines lies above the equilibrium curve; for stripping, the feasible region for operating lines lies below the equilibrium curve. These feasible regions are bounded by the equilibrium curve and by the lines $x = x_2$ and $y = y_1$. By inspection, one should be able to visualize those operating lines that are feasible and those that would lead to "pinch points" within the tower. Also, it is possible to determine if a particular proposed design for solute recovery falls within the feasible envelope.

Once the design recovery for an absorber has been established, the operating line can be constructed by first locating the point $x_2$, $y_2$ on the diagram. The intersection of the horizontal line corresponding to the inlet gas composition $y_1$ with the equilibrium curve $y^0 = F(x)$ defines the theoretical minimum liquid-to-gas ratio for systems in which there are no intermediate pinch points. This operating line that connects this point with the point $x_2$, $y_2$ corresponds to the minimum value of $L_M/G_M$. The actual design value of $L_M/G_M$ should normally be around 1.2 to 1.5 times this minimum value. Thus, the actual design operating line for a gas absorber will pass through the point $x_2$, $y_2$ and will intersect the line $y = y_1$ to the left of the equilibrium curve.

For stripping, one begins by using the design specification to locate the point $x_1$, $y_1$; then the intersection of the vertical line $x = x_2$ with the equilibrium curve $y^0 = F(x)$ defines the theoretical minimum gas-to-liquid ratio. The actual value of $G_M/L_M$ is chosen to be about 20 to 50 percent higher than this minimum, so the actual design operating line will intersect the line $x = x_2$ at a point somewhat below the equilibrium curve.

## PACKED-TOWER DESIGN

Methods for estimating the height of the active section of counterflow differential contactors such as packed towers, spray towers, and falling-film absorbers are based on rate expressions representing mass transfer at a

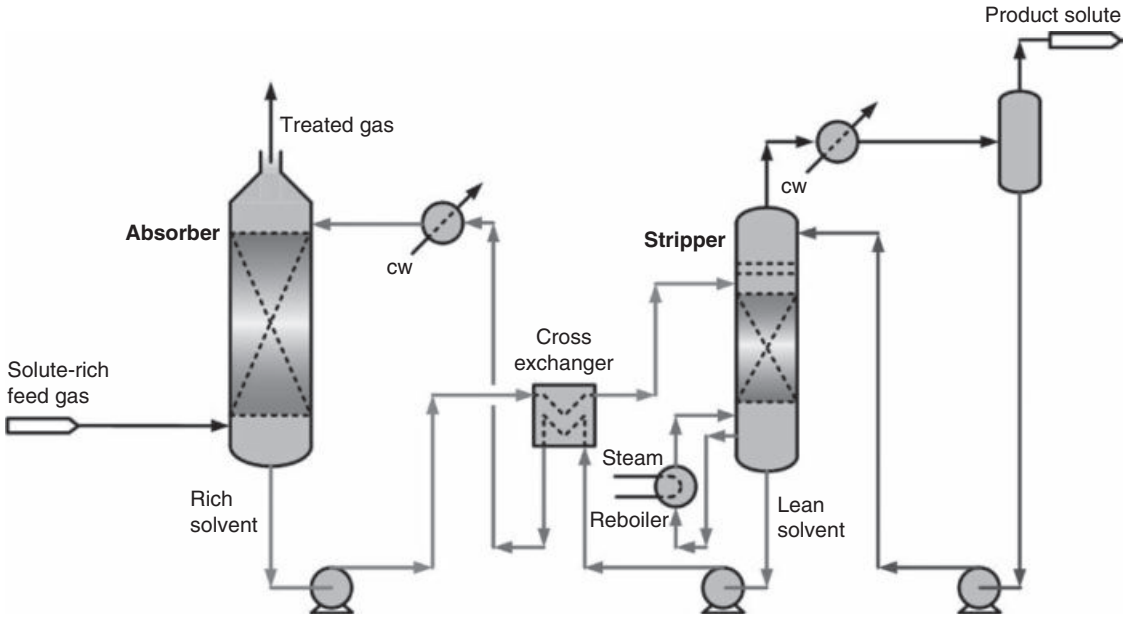

**FIG. 14-3** Gas absorber-stripper in which the solute-laden rich solvent is regenerated by stripping.

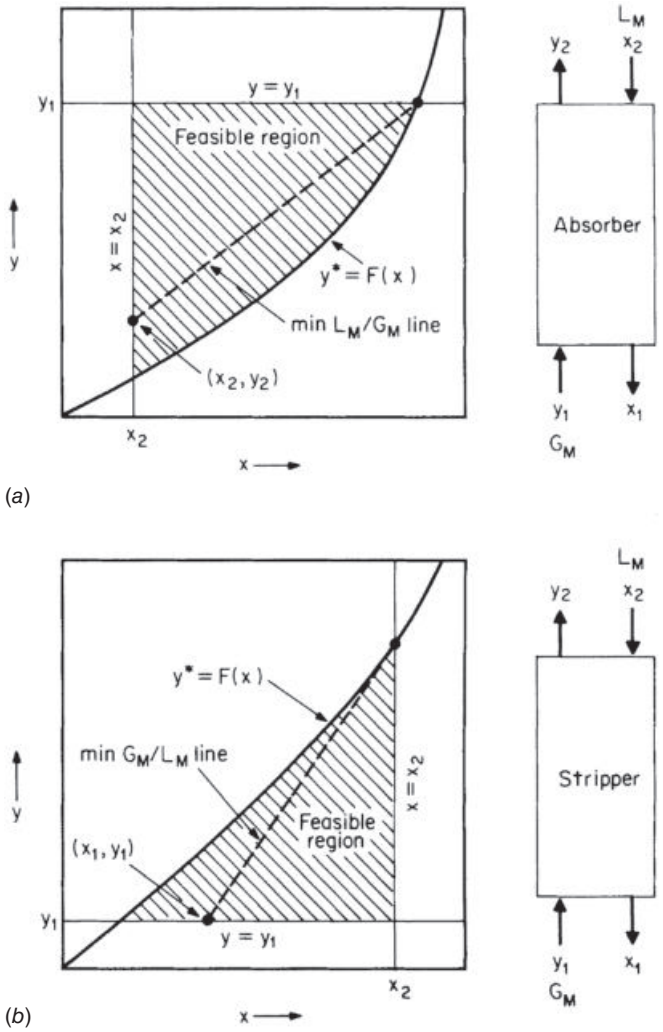

**FIG. 14-4** Design diagrams for (*a*) absorption and (*b*) stripping.

point on the gas–liquid interface and on material balances representing the changes in bulk composition in the two phases that flow past each other. The rate expressions are based on the interphase mass-transfer principles described in Sec. 5. A combination of such expressions leads to an integral expression for the number of transfer units or to equations related closely to the number of theoretical stages. The paragraphs that follow set forth convenient methods for using such equations, first in a general case and then for cases in which simplifying assumptions are valid.

**Use of Mass-Transfer-Rate Expression** Figure 14-5 shows a section of a packed absorption tower together with the nomenclature that will be used in developing the equations that follow. In a differential section *dh*, we can equate the rate at which solute is lost from the gas phase to the rate at which it is transferred through the gas phase to the interface as follows:

$$-d(G_M y) = -G_M\,dy - y\,dG_M = N_A a\,dh \tag{14-5}$$

In Eq. (14-5), $G_M$ is the gas-phase molar velocity [kmol/(s · m²)], $N_A$ is the mass-transfer flux [kmol/(s · m²)], and $a$ is the effective interfacial area (m²/m³).

When only one component is transferred,

$$dG_M = -N_A a\,dh \tag{14-6}$$

Substitution of this relation into Eq. (14-5) and rearranging yield

$$dh = -\frac{G_M\,d_y}{N_A a(1-y)} \tag{14-7}$$

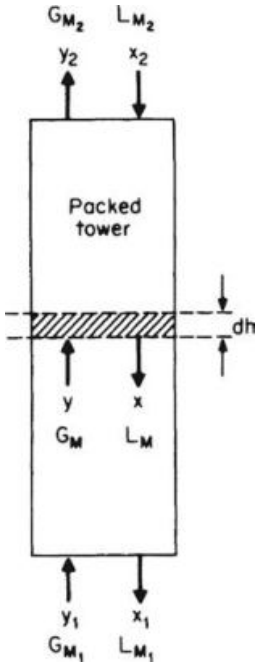

**FIG. 14-5** Nomenclature for material balances in a packed-tower absorber or stripper.

For this derivation we use the gas-phase rate expression $N_A = k_G(y - y_i)$ and integrate over the tower to obtain

$$h_{Tl} = \int_{y_2}^{y_1} \frac{G_M dy}{k_G a(1-y)(y-y_i)} \tag{14-8}$$

Multiplying and dividing by $y_{BM}$ place Eq. (14-8) into the $H_G N_G$ format

$$h_T = \int_{y_2}^{y_1} \left(\frac{G_M}{k_G a y_{BM}}\right) \frac{y_{BM}\,dy}{(1-y)(y-y_i)}$$

$$= H_{G,\text{av}} \int_{y_2}^{y_1} \frac{y_{BM}\,dy}{(1-y)(y-y_i)} = H_{G\text{av}}\,N_G \tag{14-9}$$

The general expression given by Eq. (14-8) is more complex than normally is required, but it must be used when the mass-transfer coefficient varies from point to point, as may be the case when the gas is not dilute or when the gas velocity varies as the gas dissolves. The values of $y_i$ to be used in Eq. (14-8) depend on the local liquid composition $x_i$ and on the temperature. This dependency is best represented by using the operating and equilibrium lines as discussed later.

Example 14-2 illustrates the use of Eq. (14-8) for scrubbing chlorine from air with aqueous caustic solution. For this case, one can make the simplifying assumption that $y_i$, the interfacial partial pressure of chlorine over the caustic solution, is zero due to the rapid and complete reaction of the chlorine after it dissolves. We note that the feed gas is not dilute.

***Example 14-2 Packed Height Requirement*** Let us compute the height of packing needed to reduce the chlorine concentration of a chlorine–air mixture containing 0.503 mole-fraction chlorine to 0.0403 mole fraction. The inlet gas flow rate is of 0.537 kg/(s · m²), or 396 lb/(h · ft²). On the basis of test data described by Sherwood and Pigford (*Absorption and Extraction*, McGraw-Hill, 1952, p. 121) the value of $k_G a y_{BM}$ at a gas velocity equal to that at the bottom of the packing is equal to 0.1175 kmol/(s · m³), or 26.4 lb · mol/(h · ft³). The equilibrium back pressure $y_i$ can be assumed to be negligible.

*Solution.* By assuming that the mass-transfer coefficient varies as the 0.8 power of the local gas mass velocity, we can derive the following relation:

$$\hat{K}_G a = k_G a y_{BM} = 0.1175\left[\frac{71y + 29(1-y)}{71y_1 + 29(1-y_1)}\left(\frac{1-y_1}{1-y}\right)\right]^{0.8}$$

where 71 and 29 are the molecular weights of chlorine and air, respectively. Noting that the inert-gas (air) mass velocity is given by $G'_M = G_M(1-y) = 5.34 \times 10^{-3}$ kmol/(s · m²), or 3.94 lb · mol/(h · ft²), and introducing these expressions into the integral gives

$$h_T = 1.82 \int_{0.0403}^{0.503} \left[\frac{1-y}{29.+42y}\right]^{0.8} \frac{dy}{(1-y)^2 \ln[1/(1-y)]}$$

This definite integral can be evaluated numerically by the use of Simpson's rule to obtain $h_T = 0.303$ m (0.99 ft).

Note that if the exit mole fraction of chlorine is lowered to 0.0203, the required column height will rise by about 28 percent.

**Use of Operating Curve** Often it is not possible to assume that $y_i = 0$ as in Example 14-2, due to diffusional resistance in the liquid phase or to the accumulation of solute in the liquid stream. When the backpressure cannot be neglected, it is necessary to supplement the equations with a material balance representing the operating line or curve. In view of the countercurrent flows into and from the differential section of packing shown in Fig. 14-5, a steady-state material balance leads to the following equivalent relations:

$$d(G_M y) = d(L_M x) \tag{14-10}$$

$$G'_M \frac{dy}{(1-y)^2} = L'_M \frac{dx}{(1-x)^2} \tag{14-11}$$

where $L'_M$ = molar mass velocity of the inert-liquid component and $G'_M$ = molar mass velocity of the inert gas; $L_M$, $L'_M$, $G_M$, and $G'_M$ are superficial velocities based on the total tower cross section.

Equation (14-11) is the differential equation of the operating curve, and its integral around the upper portion of the packing is the equation for the operating curve.

$$G'_M\left[\frac{y}{1-y} - \frac{y_2}{1-y_2}\right] = L'_M\left[\frac{x}{1-x} - \frac{x_2}{1-x_2}\right] \tag{14-12}$$

For dilute solutions in which the mole fractions of $x$ and $y$ are small, the total molar flows $G_M$ and $L_M$ will be nearly constant, and the operating-curve equation is

$$G_M(y - y_2) = L_M(x - x_2) \tag{14-13}$$

This equation gives the relation between the bulk compositions of the gas and liquid streams at each height in the tower for conditions in which the operating curve can be approximated as a straight line.

Figure 14-6 shows the relationship between the operating curve and the equilibrium curve $y_i = F(x_i)$ for a typical example involving solvent recovery, where $y_i$ and $x_i$ are the interfacial compositions (assumed to be in equilibrium). Once $y$ is known as a function of $x$ along the operating curve, $y_i$ can be found at corresponding points on the equilibrium curve by

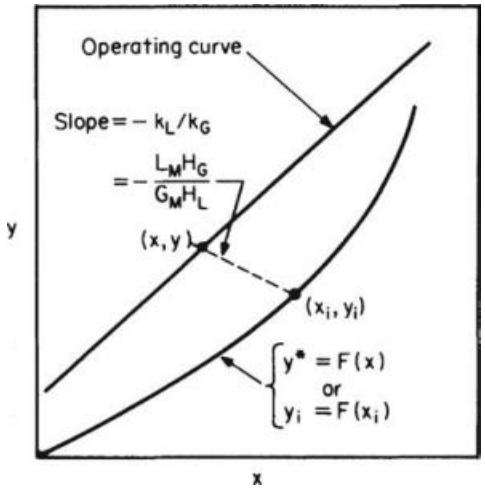

**FIG. 14-6** Relationship between equilibrium curve and operating curve in a packed absorber; computation of interfacial compositions.

$$(y - y_i)/(x_i - x) = k_L/k_G = L_M H_G / G_M H_L \tag{14-14}$$

where $L_M$ = molar liquid mass velocity, $G_M$ = molar gas mass velocity, $H_L$ = height of one transfer unit based on liquid-phase resistance, and $H_G$ = height of one transfer unit based on gas-phase resistance. Using this equation, the integral in Eq. (14-8) can be evaluated.

**Calculation of Transfer Units** In the general case, the equations described here must be used to calculate the height of packing required for a given separation. However, if the local mass-transfer coefficient $k_G a y_{BM}$ is approximately proportional to the first power of the local gas velocity $G_M$, then the height of one gas-phase transfer unit, defined as $H_G = G_M/k_G a y_{BM}$, will be constant in Eq. (14-9). Similar considerations lead to an assumption that the height of one overall gas-phase transfer unit $H_{OG}$ may be taken as constant. The height of packing required is then calculated according to the relation

$$h_T = H_G N_G = H_{OG} N_{OG} \tag{14-15}$$

where $N_G$ = number of gas-phase transfer units and $N_{OG}$ = number of overall gas-phase transfer units. When $H_G$ and $H_{OG}$ are not constant, it may be valid to use averaged values between the top and bottom of the tower and the relation

$$h_T = H_{G,av} N_G = H_{OG,av} N_{OG} \tag{14-16}$$

In these equations, the terms $N_G$ and $N_{OG}$ are defined by Eqs. (14-17) and (14-18).

$$N_G = \int_{y_2}^{y_1} \frac{y_{BM}\, dy}{(1-y)(y-y_i)} \tag{14-17}$$

$$N_G = \int_{y_0}^{y_1} \frac{y^0_{BM}\, dy}{(1-y)(y-y^0)} \tag{14-18}$$

Equation (14-18) is the more useful one in practice. It requires either actual experimental $H_{OG}$ data or values estimated by combining individual measurements of $H_G$ and $H_L$ by Eq. (14-19). Correlations for $H_G$, $H_L$, and $H_{OG}$ in nonreacting systems are presented in Sec. 5.

$$H_{OG} = \frac{y_{BM}}{y^0_{BM}} H_G + \frac{mG_M}{L_M}\frac{x_{BM}}{y^0_{BM}} H_L \tag{14-19a}$$

$$H_{OL} = \frac{x_{BM}}{x^0_{BM}} H_L + \frac{L_M}{mG_M}\frac{y_{BM}}{x^0_{BM}} H_G \tag{14-19b}$$

On occasion, the changes in gas flow and in the mole fraction of inert gas can be neglected so that inclusion of terms such as $1-y$ and $y^0_{BM}$ can be approximated, as is shown below.

One such simplification was suggested by Wiegand [*Trans. Am. Inst. Chem. Eng.* **36:** 679 (1940)], who pointed out that the logarithmic-mean mole fraction of inert gas $y^0_{BM}$ (or $y_{BM}$) is often very nearly equal to the arithmetic mean. Thus, substitution of the relation

$$\frac{y^0_{BM}}{(1-y)} = \frac{(1-y^0)+(1-y)}{2(1-y)} = \frac{y-y^0}{2(1-y)} + 1 \tag{14-20}$$

into the equations presented previously leads to the simplified forms

$$N_G = \frac{1}{2}\ln\left[\frac{1-y_2}{1-y_1}\right] + \int_{y_2}^{y_1} \frac{dy}{y-y_1} \tag{14-21}$$

$$N_{0G} = \frac{1}{2}\ln\frac{1-y_2}{1-y_1} + \int_{y^2}^{y1} \frac{dy}{y-y^0} \tag{14-22}$$

The second (integral) terms represent the numbers of transfer units for an infinitely dilute gas. The first terms, usually only a small correction, give the effect of a finite level of gas concentration.

The procedure for applying Eqs. (14-21) and (14-22) involves two steps: (1) evaluation of the integrals and (2) addition of the correction corresponding to the first (logarithmic) term. The discussion that follows deals only with the evaluation of the integral term ( first step).

The simplest possible case occurs when (1) both the operating and equilibrium lines are straight (i.e., the solutions are dilute); (2) Henry's law is valid ($y^0/x = y_i/x_i = m$); and (3) absorption heat effects are negligible. Under these conditions, the integral term in Eq. (14-21) may be computed by Colburn's equation [*Trans. Am. Inst. Chem. Eng.* **35:** 211 (1939)]:

$$N_{OG} = \frac{1}{1 - mG_M/L_M} \ln \left[ \left( 1 - \frac{mG_M}{L_M} \right) \left( \frac{y_1 - mx_2}{y_2 - mx_2} \right) + \frac{mG_M}{L_M} \right] \qquad (14\text{-}23)$$

Figure 14-7 is a plot of Eq. (14-23) from which the value of $N_{OG}$ can be read directly as a function of $mG_M/L_M$ and the ratio of concentrations. This plot and Eq. (14-23) are equivalent to the use of a logarithmic mean of terminal driving forces, but they are more convenient because one does not need to compute the exit-liquor concentration $x_1$.

In many practical situations involving nearly complete cleanup of the gas, an approximate result can be obtained from the equations just presented even when the simplifications are not valid, that is, solutions are concentrated and heat effects occur. In such cases the driving forces in the upper part of the tower are very much smaller than those at the bottom, and the value of $mG_M/L_M$ used in the equations should be the ratio of the operating line $L_M/G_M$ in the low-concentration region near the top of the tower.

Another approach is to divide the tower arbitrarily into a lean section (near the top) where approximate methods are valid, and to deal with the rich section separately. If the heat effects in the rich section are appreciable, consideration should be given to installing cooling units near the bottom of the tower. In any event, a design diagram showing the operating and equilibrium curves should be prepared to check the applicability of any simplified procedure. Figure 14-10, presented in Example 14-6, is one such diagram for an adiabatic absorption tower.

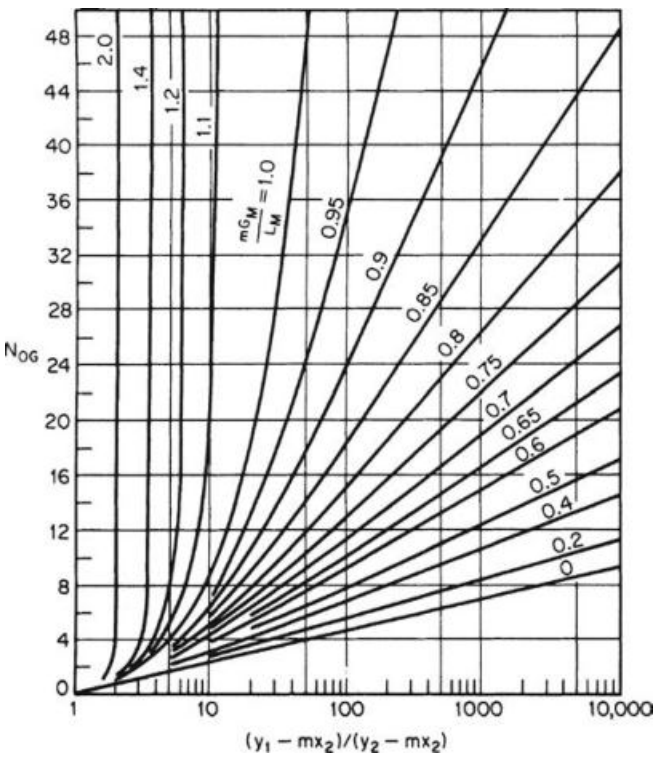

**FIG. 14-7** Number of overall gas-phase mass-transfer units in a packed absorption tower for constant $mG_M/L_M$; solution of Eq. (14-23). (*From Sherwood and Pigford,* Absorption and Extraction*, McGraw-Hill, New York, 1952.*)

**Stripping Equations** Stripping or desorption involves the removal of a volatile component from the liquid stream by contact with an inert gas such as nitrogen or steam or the application of heat. Here the change in concentration of the liquid stream is of prime importance, and it is more convenient to formulate the rate equation analogous to Eq. (14-6) in terms of the liquid composition $x$. This leads to the following equations defining the number of transfer units and the height of transfer units based on liquid-phase resistance:

$$h_T = H_L \int_{x_2}^{x_1} \frac{x_{BM}\,dx}{(1-x)(x_i - x)} = H_L N_L \qquad (14\text{-}24)$$

$$h_T = H_{OL} \int_{x_2}^{x_1} \frac{x^0_{BM}\,dx}{(1-x)(x^0 - x)} = H_{OL} N_{OL} \qquad (14\text{-}25)$$

where, as before, subscripts 1 and 2 refer to the bottom and top of the tower, respectively (see Fig. 14-5).

In situations where one cannot assume that $H_L$ and $H_{OL}$ are constant, these terms need to be incorporated inside the integrals in Eqs. (14-24) and (14-25), and the integrals must be evaluated numerically (using Simpson's rule, for example). In the normal case involving stripping without chemical reactions, the liquid-phase resistance will dominate, making it preferable to use Eq. (14-25) together with the approximation $H_L \approx H_{OL}$.

The Weigand approximations of these integrals, in which arithmetic means are substituted for the logarithmic means ($x_{BM}$ and $x^0_{BM}$), are

$$N_L = \frac{1}{2} \ln \frac{1-x_1}{1-x_2} + \int_{x_1}^{x_2} \frac{dx}{x - x_i} \qquad (14\text{-}26)$$

$$N_{OL} = \frac{1}{2} \ln \frac{1-x_1}{1-x_2} + \int_{x_1}^{x_2} \frac{dx}{x - x^\circ} \qquad (14\text{-}27)$$

In these equations, the first term is a correction for finite liquid-phase concentrations, and the integral term represents the numbers of transfer units required for dilute solutions. In most practical stripper applications, the first (logarithmic) term is relatively small.

For dilute solutions in which both the operating and the equilibrium lines are straight and in which heat effects can be neglected, the integral term in Eq. (14-27) is

$$N_{OL} = \frac{1}{1 - \dfrac{L_m}{mG_m}} \ln \left[ \left( 1 - \frac{L_m}{mG_m} \right) \left( \frac{x_2 - y_1/m}{x_1 - y_1/m} \right) + \frac{L_m}{mG_m} \right] \qquad (14\text{-}28)$$

This equation is analogous to Eq. (14-23). Thus, Fig. 14-7 is applicable if the concentration ratio $(x_2 - y_1/m)/(x_1 - y_1/m)$ is substituted for the abscissa and the parameter on the curves is identified as $L_M/mG_M$.

***Example 14-3 Air Stripping of VOCs from Water*** A 0.45-m-diameter packed column was used by Dvorak et al. [*Environ. Sci. Tech.* **20:** 945 (1996)] for removing trichloroethylene (TCE) from wastewater by stripping with atmospheric air. The column was packed with 25-mm Pall rings, fabricated from polypropylene, to a height of 3.0 m. The TCE concentration in the entering water was 38 parts per million by weight (ppmw). A molar ratio of entering water to entering air was kept at 23.7. What degree of removal was to be expected? The temperatures of water and air were 20°C. Pressure was atmospheric.

*Solution.* For TCE in water, the Henry's law coefficient may be taken as 417 atm/mf at 20°C; note that this value of 417 atm/mf at 20°C has a high uncertainty, about 20 to 30 percent. In this low-concentration region, the coefficient is constant and equal to the slope of the equilibrium line $m$. The solubility of TCE in water, based on $H = 417$ atm, is 2390 ppm. Because of this low solubility, the entire resistance to mass transfer resides in the liquid phase. Thus, Eq. (14-25) may be used to obtain $N_{OL}$, the number of overall liquid phase transfer units.

In the equation, the ratio $x^0_{BM}/(1 - x)$ is unity because of the very dilute solution. It is necessary to have a value of $H_L$ for the packing used, at given flow rates of liquid and gas. Methods for estimating $H_L$ may be found in Sec. 5. Dvorak et al. found $H_{OL} = 0.8$ m. Then, for $h_T = 3.0$ m, $N_L = N_{OL} = 3.0/0.8 = 3.75$ transfer units.

Transfer units may be calculated from Eq. (14-25), replacing mole fractions with ppm concentrations, and since the operating and equilibrium lines are straight,

$$N_{OL} = \ln \left( \frac{38}{(\text{ppm})_{\text{exit}}} \right) = 3.75$$

Solving, $(ppm)_{exit} = 0.9$. Thus, the stripped water would contain 0.9 parts per million of TCE. If the column height is doubled, to 4.5 m, the stripped water would contain 0.021 parts per million of TCE, a concentration reduction by a factor of 43.

**Use of HTU and $K_G a$ Data** In estimating the size of a commercial gas absorber or liquid stripper, it is desirable to have data on the overall mass-transfer coefficients (or heights of transfer units) for the system of interest and at the desired conditions of temperature, pressure, solute concentration, and fluid velocities. Such data is best obtained in an apparatus of pilot-plant or semiworks size to avoid the complexities of scale-up. Within the packing category, there are both random and ordered (structured) packing elements. Physical characteristics of these devices will be described later.

When no $K_G a$ or HTU data are available, their values may be estimated by means of a generalized model. A summary of useful models is given in Sec. 5. The values obtained may then be combined by the use of Eq. (14-19) to obtain values of $H_{OG}$ and $H_{OL}$. This simple procedure is not valid when the rate of absorption is limited by chemical reaction.

**Use of HETP Data for Absorber Design** Distillation design methods (see Sec. 13) normally involve determination of the number of theoretical equilibrium stages $N$. Thus, when packed towers are employed in distillation applications, it is common practice to rate the efficiency of tower packings in terms of the height of packing equivalent to one theoretical stage (HETP).

The HETP of a packed-tower section, valid for either distillation or dilute-gas absorption and stripping systems in which constant molal overflow can be assumed and in which no chemical reactions occur, is related to the height of one overall gas-phase mass-transfer unit $H_{OG}$ by the equation

$$\text{HETP} = H_{OG} \frac{\ln\left(\dfrac{mG_M}{L_M}\right)}{\left(\dfrac{mG_M}{L_M} - 1\right)} \tag{14-29}$$

For gas absorption systems in which the inlet gas is concentrated, the corrected equation is

$$\text{HETP} = \left(\frac{y^0_{BM}}{1-y}\right)_{\text{av}} H_{OG} \frac{\ln\left(\dfrac{mG_M}{L_M}\right)}{\left(\dfrac{mG_M}{L_M} - 1\right)} \tag{14-30}$$

where the correction term $y^0_{BM}/(1-y)$ is averaged over each individual theoretical stage. The equilibrium compositions corresponding to each theoretical stage may be estimated by the methods described in the next subsection, Tray-Tower Design. These compositions are used in conjunction with the local values of the gas and liquid flow rates and the equilibrium slope $m$ to obtain values for $H_G$, $H_L$, and $H_{OG}$ corresponding to the conditions on each theoretical stage, and the local values of the HETP are then computed by Eq. (14-30). The total height of packing required for the separation is the summation of the individual HETPs computed for each theoretical stage.

## TRAY-TOWER DESIGN

The design of a tray tower for gas absorption and gas-stripping operations involves many of the same principles employed in distillation calculations, such as the determination of the number of theoretical trays needed to achieve a specified composition change (see Sec. 13). Distillation differs from absorption because it involves the separation of components based on the distribution of the various substances between a vapor phase and a liquid phase when all components are present in both phases. In distillation, the new phase is generated from the original phase by the vaporization or condensation of the volatile components, and the separation is achieved by introducing reflux to the top of the tower.

In gas absorption, the new phase consists of a relatively nonvolatile solvent (absorption) or a relatively insoluble gas (stripping), and normally no reflux is involved. This section discusses some of the considerations peculiar to gas absorption calculations for tray towers and some of the approximate design methods that can be applied (when simplifying assumptions are valid).

**Graphical Design Procedure** Construction of design diagrams ($xy$ curves showing the equilibrium and operating curves) should be an integral part of any design involving the distribution of a single solute between a solvent and an inert gas. The number of theoretical trays can be stepped off rigorously, provided the curvatures of the operating and equilibrium lines are correctly represented in the diagram. The procedure is valid even though a solvent is present in the liquid phase and an inert gas is present in the vapor phase.

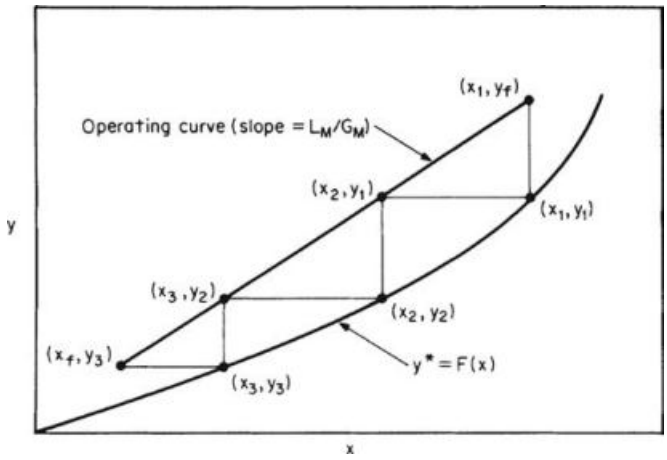

**FIG. 14-8** Graphical method for a three-theoretical-plate gas-absorption tower with inlet-liquor composition $x_f$ and inlet-gas composition $y_f$.

Figure 14-8 illustrates the graphical method for a three-theoretical-stage system. Note that in gas absorption the operating line is above the equilibrium curve, whereas in distillation this does not happen. In gas stripping, the operating line will be below the equilibrium curve.

On Fig. 14-8, note that the stepping-off procedure begins on the operating line. The starting point $x_f$, $y_3$ represents the compositions of the entering lean wash liquor and of the gas exiting from the top of the tower, as defined by the design specifications. After three steps, one reaches the point $x_1$, $y_f$ representing the compositions of the solute-rich feed gas $y_f$ and of the solute-rich liquor leaving the bottom of the tower $x_1$.

**Algebraic Method for Dilute Gases** By assuming that the operating and equilibrium curves are straight lines and that heat effects are negligible, Souders and Brown [*Ind. Eng. Chem.* **24:** 519 (1932)] developed the following equation:

$$(y_1 - y_2)/(y_1 - y^\circ_2) = (A^{N+1} - A)/(A^{N+1} - 1) \tag{14-31}$$

where $N$ = number of theoretical trays, $y_1$ = mole fraction of solute in the entering gas, $y_2$ = mole fraction of solute in the leaving gas, $y^\circ_2 = mx_2$ = mole fraction of solute in equilibrium with the incoming solvent (zero for a pure solvent), and $A$ = absorption factor = $L_M/mG_M$. Note that the absorption factor is the reciprocal of the expression given in Eq. (14-4) for packed columns.

Note that for the limiting case of $A = 1$, the solution is given by

$$(y_1 - y_2)/(y_1 - y^\circ_2) = N/(N+1) \tag{14-32}$$

Although Eq. (14-31) is convenient for computing the composition of the exit gas as a function of the number of theoretical stages, an alternative equation derived by Colburn [*Trans. Am. Inst. Chem. Eng.* **35:** 211 (1939)] is more useful when the number of theoretical plates is the unknown:

$$N = \frac{\ln[(1 - A^{-1})(y_1 - y^\circ_2)/(y_2 - y^\circ_2) + A^{-1}]}{\ln\,(A)} \tag{14-33}$$

The numerical results obtained by using either Eq. (14-31) or Eq. (14-33) are identical. Thus, the two equations may be used interchangeably as the need arises.

Comparison of Eqs. (14-33) and (14-23) shows that

$$N_{OG}/N = \ln(A)/(1 - A^{-1}) \tag{14-34}$$

thus revealing the close relationship between theoretical stages in a plate tower and mass-transfer units in a packed tower. Equations (14-23) and (14-33) are related to each other by virtue of the relation

$$h_T = H_{OG} N_{OG} = (\text{HETP})N \tag{14-35}$$

**Algebraic Method for Concentrated Gases** When the feed gas is concentrated, the absorption factor, which is defined in general as $A = L_M/KG_M$ and where $K = y^0/x$, can vary throughout the tower due to changes in temperature and composition. An approximate solution to this problem

can be obtained by substituting the "effective" adsorption factors $A_e$ and $A'$ derived by Edmister [*Ind. Eng. Chem.* **35:** 837 (1943)] into the equation

$$\frac{y_1-y_2}{y_1}=\left[1-\frac{1}{A'}\frac{(L_M x)_2}{(G_M y)_1}\right]\frac{A_e^{N+1}-A_e}{A_e^{N+1}-1} \tag{14-36}$$

where subscripts 1 and 2 refer to the bottom and top of the tower, respectively, and the absorption factors are defined by the equations

$$A_e=\sqrt{A_1(A_2+1)+0.25}-0.5 \tag{14-37}$$

$$A'=A_1(A_2+1)/(A_1+1) \tag{14-38}$$

This procedure has been applied to the absorption of $C_5$ and lighter hydrocarbon vapors into a lean oil, for example.

**Stripping Equations** When the liquid feed is dilute and the operating and equilibrium curves are straight lines, the stripping equations analogous to Eqs. (14-31) and (14-33) are

$$(x_2-x_1)/(x_2-x_1^0)=(S^{N+1}-S)/(S^{N+1}-1) \tag{14-39}$$

where $x_1^0=y_1/m$; $S=mG_M/L_M=A^{-1}$; and

$$N=\frac{\ln\left[(1-A)\dfrac{(x_2-x_1^0)}{(x_1-x_1^0)}+A\right]}{\ln(S)} \tag{14-40}$$

For systems in which the concentrations are large and the stripping factor $S$ may vary along the tower, the following Edmister equations [*Ind. Eng. Chem.* **35:** 837 (1943)] are applicable:

$$\frac{x_2-x_1}{x_2}=\left[1-\frac{1}{S'}\frac{(G_M y)_1}{(L_M x)_2}\right]\frac{S_e^{N+1}-S_e}{S_e^{N+1}-1} \tag{14-41}$$

where

$$S_e=\sqrt{S_2(S_1+1)+0.25}-0.5 \tag{14-42}$$

$$S'=S_2(S_1+1)/(S_2+1) \tag{14-43}$$

and the subscripts 1 and 2 refer to the bottom and top of the tower, respectively.

Equations (14-37) and (14-42) represent two different ways of obtaining an effective factor $S$, and a value of $A_e$ obtained by taking the reciprocal of $S_e$ from Eq. (14-42) will not check exactly with a value of $A_e$ derived by substituting $A_1=1/S_1$ and $A_2=1/S_2$ into Eq. (14-37). Regardless of this fact, the equations generally give reasonable results for approximate design calculations.

It should be noted that throughout this section the subscripts 1 and 2 refer to the bottom and to the top of the apparatus, respectively, regardless of whether it is an absorber or a stripper. This has been done to maintain internal consistency among all the equations and to prevent the confusion created in some derivations in which the numbering system for an absorber is different from the numbering system for a stripper.

**Tray Efficiencies in Tray Absorbers and Strippers** Computations of the theoretical trays $N$ assume that the liquid on each tray is completely mixed and that the vapor leaving the tray is in equilibrium with the liquid. In practice, complete equilibrium cannot exist since interphase mass transfer requires a finite driving force. This leads to the definition of an overall tray efficiency

$$E=N_{\text{theoretical}}/N_{\text{actual}} \tag{14-44}$$

which can be correlated with the system design variables.

Mass-transfer theory indicates that for trays of a given design, the factors that have the biggest influence on $E$ in absorption and stripping towers are the physical properties of the fluids and the dimensionless ratio $mG_M/L_M$. Systems in which mass transfer is gas-film-controlled may be expected to have efficiencies as high as 50 to 100 percent, whereas tray efficiencies as low as 1 percent have been reported for the absorption of low-solubility (large-$m$) gases into solvents of high viscosity.

The fluid properties of interest are represented by the Schmidt numbers of the gas and liquid phases. For gases, the Schmidt numbers are normally close to unity and independent of temperature and pressure. Thus, gas-phase mass-transfer coefficients are relatively independent of the system.

By contrast, the liquid-phase Schmidt numbers range from about $10^2$ to $10^4$ and depend strongly on temperature. The temperature dependence of the liquid-phase Schmidt number derives primarily from the strong dependence of the liquid viscosity on temperature.

Consideration of the preceding discussion in connection with the relationship between mass-transfer coefficients (see Sec. 5)

$$1/K_G=1/k_G+m/k_L \tag{14-45}$$

indicates that the variations in the overall resistance to mass transfer in absorbers and strippers are related primarily to variations in the liquid-phase viscosity $\mu$ and the slope $m$. O'Connell [*Trans. Am. Inst. Chem. Eng.* **42:** 741 (1946)] used the preceding findings and correlated the tray efficiency in terms of the liquid viscosity and the gas solubility. The O'Connell correlation for absorbers (Fig. 14-9) has Henry's law constant in lb·mol/(atm·ft$^3$), the pressure in atmospheres, and the liquid viscosity in centipoise.

The best procedure for making tray efficiency corrections (which can be quite significant, as seen in Fig. 14-9) is to use experimental data from a prototype system that is large enough to be representative of the actual commercial tower.

***Example 14-4 Actual Trays for Steam Stripping*** The number of actual trays required for steam-stripping an acetone-rich liquor containing 0.573 mol% acetone in water is to be estimated. The design overhead recovery of acetone is 99.88 percent, leaving 18.5 ppm weight of acetone in the stripper bottoms. The design operating temperature and pressure are 101.3 kPa and 94°C respectively, the average liquid-phase viscosity is 0.30 cP, and the average value of $K=y^\circ/x$ for these conditions is 33.

By choosing a value of $mG_M/L_M=S=A^{-1}=1.4$ and noting that the stripping medium is pure steam (i.e., $x_1^0=0$), the number of theoretical trays according to Eq. (14-40) is

$$N=\frac{\ln[(1-0.714)(1000)+0.714]}{\ln(1.4)}=16.8$$

The O'Connell parameter for gas absorbers is $\rho_L/KM\mu_L$, where $\rho_L$ is the liquid density, lb/ft$^3$; $\mu_L$ is the liquid viscosity, cP; $M$ is the molecular weight of the liquid; and $K=y^\circ/x$. For the present design

$$\rho_L/KM\mu_L=60.1/(33\times 18\times 0.30)=0.337$$

and according to the O'Connell graph for absorbers (Fig. 14-9), the overall tray efficiency for this case is estimated to be 30 percent. Thus, the required number of actual trays is 16.8/0.3 = 56 trays.

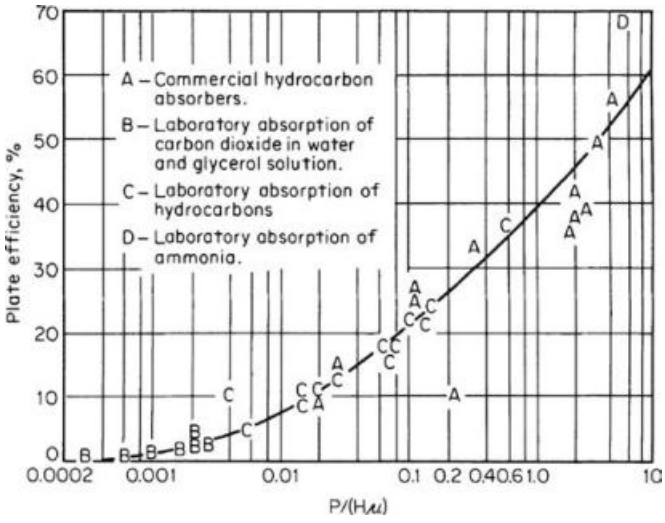

**FIG. 14-9** O'Connell correlation for overall column efficiency $E_{0c}$ for absorption. $H$ is in (atm·ft$^3$)/lb·mol, $P$ is in atm, $\mu$ is in cP. To convert $P/(H\mu)$ in lb·mol/(ft$^3$·cP) to kg·mol/(m$^3$·Pa·s), multiply by 1.60 * 10$^4$. [*O'Connell,* Trans. Am. Chem. Eng. ***42:*** *741 (1946).*]

## HEAT EFFECTS IN GAS ABSORPTION

**Overview** One of the most important considerations involved in designing gas absorption towers is to determine whether temperatures will vary along the height of the tower due to heat effects; note that the solute solubility often depends strongly on temperature. The simplified design procedures described earlier in this section become more complicated when heat effects cannot be neglected. Our purpose in this section is to help readers to understand and design gas absorption towers where heat effects are significant and cannot be ignored.

Heat effects that cause temperatures to vary from point to point in a gas absorber include (1) the heat of solution of the solute (including heat of condensation, heat of mixing, and heat of reaction); (2) the heat of vaporization or condensation of the solvent; (3) the exchange of sensible heat between the gas and liquid phases; and (4) the loss of sensible heat from the fluids to internal or external coils.

There are a number of systems where heat effects definitely cannot be ignored. Examples include the absorption of ammonia in water, dehumidification of air using concentrated $H_2SO_4$, absorption of HCl in water, absorption of $SO_3$ in $H_2SO_4$, and absorption of $CO_2$ in chemical solvents like alkanolamines. Even for systems where the heat effects are mild, they may not be negligible; an example is the absorption of acetone in water.

Thorough and knowledgeable discussions of the problems involved in gas absorption with significant heat effects have been presented by Coggan and Bourne [*Trans. Inst. Chem. Eng.* **47:** T96, T160 (1969)]; Bourn, von Stockar, and Coggan [*Ind. Eng. Chem. Proc. Des. Dev.* **13:** 115, 124 (1974)]; and von Stockar and Wilke [*Ind. Eng. Chem. Fundam.* **16:** 89 (1977)]. The first two of these references discuss tray-tower absorbers and include experimental studies of the absorption of ammonia in water. The third reference discusses the design of packed-tower absorbers and includes a shortcut design method based on a semitheoretical correlation of rigorous design calculations. All these authors demonstrate that when the solvent is volatile, the temperature inside an absorber can go through a maximum. They note that the least expensive and most common of solvents—water—is capable of exhibiting this "hot-spot" behavior.

Several approaches may be used in modeling absorption with heat effects, depending on the job at hand: (1) treat the process as isothermal by assuming a particular temperature, then add a safety factor; (2) employ the classical adiabatic method, which assumes that the heat of solution manifests itself only as sensible heat in the liquid phase and that the solvent vaporization is negligible; (3) use semitheoretical shortcut methods derived from rigorous calculations; and (4) employ rigorous methods available from a process simulator.

While simpler methods are useful for understanding the key effects involved, rigorous methods (usually using commercial software) are recommended for final designs. This subsection also discusses the range of safety factors that are required if simpler methods are used.

**Effects of Operating Variables** Conditions that give rise to significant heat effects are (1) an appreciable heat of solution and/or (2) absorption of large amounts of solute in the liquid phase. The second condition is favored when the solute concentration in the inlet gas is large, when the liquid flow rate is relatively low (small $L_M/G_M$), when the solubility of the solute in the liquid is high, and/or when the operating pressure is high.

If the solute-rich gas entering the bottom of an absorber tower is cold, the liquid phase may be cooled somewhat by transfer of sensible heat to the gas. A much stronger cooling effect can occur when the solute is volatile and the entering gas is not saturated with respect to the solvent. It is possible to experience a condition in which solvent is being evaporated near the bottom of the tower and condensed near the top. Under these conditions a pinch point may develop in which the operating and equilibrium curves approach each other at a point inside the tower.

In the references previously cited, the authors discuss the influence of operating variables upon the performance of towers when large heat effects are involved. Some key observations are as follows:

***Operating Pressure*** Raising the pressure may increase the separation effectiveness considerably. Calculations for the absorption of methanol in water from water-saturated air showed that doubling the pressure doubles the allowable concentration of methanol in the feed gas while still achieving the required concentration specification in the off gas.

***Temperature of Lean Solvent*** The temperature of the entering (lean) solvent has surprisingly little influence upon the temperature profile in an absorber since any temperature changes are usually caused by the heat of solution or the solvent vaporization. In these cases, the temperature profile in the liquid phase is usually dictated solely by the internal heat effects.

***Temperature and Humidity of the Rich Gas*** Cooling and consequent dehumidification of the feed gas to an absorption tower can be very beneficial. A high humidity (or relative saturation with the solvent) limits the capacity of the gas to take up latent heat and hence is unfavorable to absorption. Thus dehumidification of the inlet gas is worth considering in the design of absorbers with large heat effects.

***Liquid-to-Gas Ratio*** The $L/G$ ratio can have a significant influence on the development of temperature profiles in gas absorbers. High $L/G$ ratios tend to result in less strongly developed temperature profiles due to the increased heat capacity of the liquid phase. As the $L/G$ ratio is increased, the operating line moves away from the equilibrium line, and more solute is absorbed per stage or packing segment. However, there is a compensating effect; since more heat is liberated in each stage or packing segment, the temperatures will rise, which causes the equilibrium line to shift up. As the $L/G$ ratio is decreased, the concentration of solute tends to build up in the upper part of the absorber, and the point of highest temperature tends to move upward in the tower until finally the maximum temperature occurs at the top of the tower. Of course, the capacity of the liquid to absorb solute falls progressively as $L/G$ is reduced.

***Number of Stages or Packing Height*** When the heat effects combine to produce an extended zone in the tower where little absorption takes place (i.e., a pinch zone), the addition of trays or packing height will have no useful effect on separation efficiency. In this case, increases in absorption may be obtained by increasing solvent flow, introducing strategically placed coolers, cooling and dehumidifying the inlet gas, or raising the tower pressure.

**Equipment Considerations** When the solute has a large heat of solution and the feed gas contains a high concentration of solute, as in the absorption of HCl in water, the effects of heat release during absorption may be so pronounced that the installation of heat-transfer surface to remove the heat of absorption may be as important as providing sufficient interfacial area for the mass-transfer process itself. The added heat-transfer area may consist of internal cooling coils on the trays, or the liquid may be withdrawn from the tower, cooled in an external heat exchanger, and then returned to the tower.

In most cases the rate of heat liberation is largest near the bottom of the tower, where most of the solute absorption occurs, so cooling surfaces or intercoolers are required only at the lower part of the column. Coggan and Bourne [*Trans. Inst. Chem. Eng.* **47:** T96, T160 (1969)] found, however, that the optimal position for a single interstage cooler does not necessarily coincide with the position of the maximum temperature of the center of the pinch. They found that in a 12-tray tower, two strategically placed interstage coolers tripled the allowable ammonia feed concentration for a given off-gas specification. For a case involving methanol absorption, it was found that greater separation was possible in a 12-stage column with two intercoolers than in a simple column with 100 stages and no intercoolers.

In the case of HCl absorption, a shell-and-tube heat exchanger often is used as a cooled wetted-wall vertical-column absorber so that the exothermic heat of reaction can be removed continuously as it is released into a liquid film.

Installation of heat-exchange equipment to precool and dehumidify the feed gas to an absorber also deserves consideration, in order to take advantage of the cooling effects created by vaporization of solvent in the lower sections of the tower.

**Classical Isothermal Design Method** When the feed gas is sufficiently dilute, the exact design solution may be approximated by the isothermal one over the broad range of $L/G$ ratios, since heat effects are generally less important when washing dilute-gas mixtures. The problem, however, is one of defining the term *sufficiently dilute* for each case. For a new absorption duty, the assumption of isothermal operation must be subjected to verification by the use of a rigorous design procedure.

When heat-exchange surface is being provided in the design of an absorber, the isothermal design procedure can be rendered valid by virtue of the exchanger design specification. With ample surface area and a close approach, isothermal operation can be guaranteed.

For preliminary screening and feasibility studies or for rough estimates, one may wish to employ a version of the isothermal design method that assumes that the liquid temperatures in the tower are everywhere equal to the inlet-liquid temperature. In their analysis of packed-tower designs, von Stockar and Wilke [*Ind. Eng. Chem. Fundam.* **16:** 89 (1977)] showed that the isothermal method tended to underestimate the required height of packing by a factor of as much as 1.5 to 2. Thus, for rough estimates, one may wish to assume that the absorber temperature is equal to the inlet-liquid temperature and then apply a design factor to the result.

Another case in which the constant-temperature method is used involves the direct application of experimental $K_G a$ values obtained at the desired conditions of inlet temperatures, operating pressures, flow rates, and feed-stream compositions. The assumption here is that, regardless of any temperature profiles that may exist within the actual tower, the procedure of "working the problem in reverse" will yield a correct result. One should, however, be cautious about extrapolating such data from the original basis and take care to use compatible equilibrium data.

**Classical Adiabatic Design Method** The classical adiabatic design method assumes that the heat of solution serves only to heat up the liquid stream, and there is no vaporization of the solvent. This assumption makes it feasible to relate increases in the liquid-phase temperature to the solute concentration $x$ by a simple enthalpy balance. The equilibrium curve can then be adjusted to account for the corresponding temperature rise on an $xy$ diagram. The adjusted equilibrium curve will be concave upward as the concentration increases, tending to decrease the driving forces near the bottom of the tower, as illustrated in Fig. 14-10 in Example 14-6.

Colburn [*Trans. Am. Inst. Chem. Eng.* **35:** 211 (1939)] has shown that when the equilibrium line is straight near the origin but curved slightly at its upper end, $N_{OG}$ can be computed approximately by assuming that the equilibrium curve is a parabolic arc of slope $m_2$ near the origin and passing through the point $x_1$, $K_1x_1$ at the upper end. The Colburn equation for this case is

$$N_{OG} = \frac{1}{1-m_2G_M/L_M} \times \ln\left[\frac{(1-m_2G_M/L_M)^2}{1-K_1-G_M/L_M}\left(\frac{y_1-mx_2x_2}{y_2-m_2x_2}\right)+\frac{m_2G_M}{L_M}\right] \qquad (14\text{-}46)$$

Comparison by von Stockar and Wilke [*Ind. Eng. Chem. Fundam.* **16:** 89 (1977)] between the rigorous and the classical adiabatic design methods for packed towers indicates that the simple adiabatic design methods underestimate packing heights by as much as a factor of 1.25 to 1.5. Thus, when using the classical adiabatic method, one should probably apply a design safety factor.

A slight variation of the preceding method accounts for increases in the solvent content of the gas stream between the inlet and the outlet of the tower and assumes that the evaporation of solvent tends to cool the liquid. This procedure offsets a part of the temperature rise that would have been predicted with no solvent evaporation and leads to the prediction of a shorter tower.

**Rigorous Design Methods** A detailed discussion of rigorous methods for the design of packed and tray absorbers when large heat effects are involved is beyond the scope of this subsection. In principle, material and energy balances may be executed under the same constraints as for rigorous distillation calculations (see Sec. 13). Further discussion on this subject is given in the subsection Absorption with Chemical Reaction.

**Direct Comparison of Design Methods** The following problem, originally presented by Sherwood, Pigford, and Wilke (*Mass Transfer*, McGraw-Hill, New York, 1975, p. 616), was employed by von Stockar and Wilke [*Ind. Eng. Chem. Fundam.* **16:** 89 (1977)] as the basis for a direct comparison between the isothermal, adiabatic, semitheoretical shortcut, and rigorous design methods for estimating the height of packed towers.

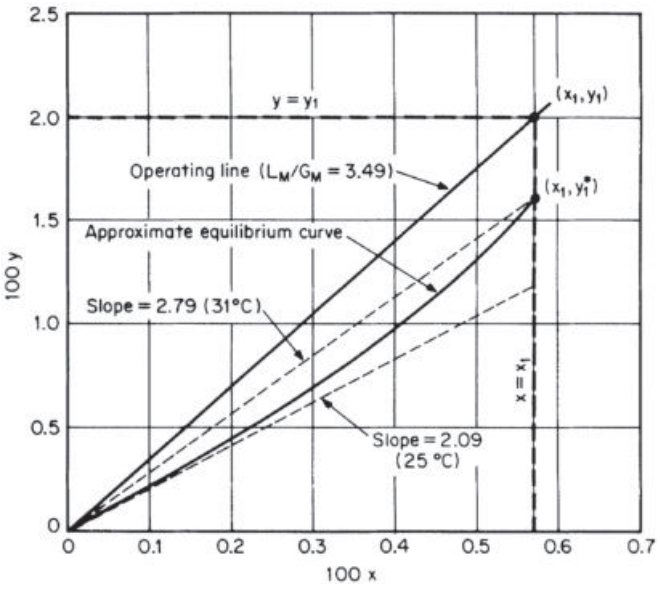

**FIG. 14-10** Design diagram for adiabatic absorption of acetone in water, Example 14-6.

***Example 14-5 Packed Absorber, Acetone into Water*** Inlet gas to an absorber consists of a mixture of 6 mol% acetone in air saturated with water vapor at 15°C and 101.3 kPa (1 atm). The scrubbing liquor is pure water at 15°C, and the inlet gas and liquid rates are given as 0.080 and 0.190 kmol/s, respectively. The liquid rate corresponds to 20 percent over the theoretical minimum as calculated by assuming a value of $x_1$ corresponding to complete equilibrium between the exit liquor and the incoming gas. $H_G$ and $H_L$ are given as 0.42 and 0.30 m, respectively, and the acetone equilibrium data at 15°C are $p_A^0 = 19.7$ kPa (147.4 torr), $\gamma_A = 6.46$, and $m_A = 6.46 \times 19.7/101.3 = 1.26$. The heat of solution of acetone is 7656 cal/gmol (32.05 kJ/gmol), and the heat of vaporization of solvent (water) is 10,755 cal/gmol (45.03 kJ/gmol). The problem calls for determining the height of packing required to achieve a 90 percent recovery of the acetone.

The following table compares the results obtained by von Stockar and Wilke [*Ind. Eng. Chem. Fundam.* **16:** 89 (1977)] for the various design methods:

| Design method used | $N_{OG}$ | Packed height, m | Design safety factor |
|---|---|---|---|
| Rigorous | 5.56 | 3.63 | 1.00 |
| Shortcut rigorous | 5.56 | 3.73 | 0.97 |
| Classical adiabatic | 4.01 | 2.38 | 1.53 |
| Classical isothermal | 3.30 | 1.96 | 1.85 |

It should be clear from this example that there is considerable room for error when approximate design methods are employed in situations involving large heat effects, even for a case in which the solute concentration in the inlet gas is only 6 mol%.

***Example 14-6 Solvent Rate for Absorption*** Let us consider the absorption of acetone from air at atmospheric pressure into a stream of pure water fed to the top of a packed absorber at 25°C. The inlet gas at 35°C contains 2 percent by volume of acetone and is 70 percent saturated with water vapor (4 percent $H_2O$ by volume). The mole-fraction acetone in the exit gas is to be reduced to 1/400 of the inlet value, or 50 ppmv. For 100 kmol of feed-gas mixture, how many kilomoles of freshwater should be fed to provide a positive-driving force throughout the packing? How many transfer units will be needed according to the classical adiabatic method? What is the estimated height of packing required if $H_{OG} = 0.70$ m?

The latent heats at 25°C are 7656 kcal/kmol for acetone and 10,490 kcal/kmol for water, and the differential heat of solution of acetone vapor in pure water is given as 2500 kcal/kmol. The specific heat of air is 7.0 kcal/(kmol·K).

Acetone solubilities are defined by the equation

$$K = y^\circ/x = \gamma_a p_a/p_T \qquad (14\text{-}47)$$

where the vapor pressure of pure acetone, $p_A^0$, in mm Hg (torr), with the temperature $T$ in Kelvin, is given by (Sherwood et al., *Mass Transfer,* McGraw-Hill, New York, 1975, p. 537):

$$p_A^0 = \exp\,(18.1594 - 3794.06/T) \qquad (14\text{–}48)$$

and the liquid-phase-activity coefficient may be approximated for low concentrations ($x \le 0.01$) by the equation

$$\gamma_a = 6.5 \exp\,(2.0803 - 601.2/T) \qquad (14\text{-}49)$$

Typical values of acetone solubility as a function of temperature at a total pressure of 760 mm Hg are shown in the following table:

| $t$, °C | 25 | 30 | 35 | 40 |
|---|---|---|---|---|
| $\gamma_a$ | 6.92 | 7.16 | 7.40 | 7.63 |
| $p_a$, mm Hg | 229 | 283 | 346 | 422 |
| $K = \gamma_a p_a^0/760$ | 2.09 | 2.66 | 3.37 | 4.23 |

For dry gas and liquid water at 25°C, the following enthalpies are computed for the inlet- and exit-gas streams (basis, 100 kmol of gas entering):

Entering gas:

| | |
|---|---|
| Acetone | $2(2500 + 7656) = 20{,}312$ kcal |
| Water vapor | $4(10{,}490) = 41{,}960$ |
| Sensible heat | $(100)(7.0)(35 - 25) = 7{,}000$ |
| | 69,272 kcal |

Exit gas (assumed saturated with water at 25°C):

| | |
|---|---|
| Acetone | $(2/400)(94/100)(2500) = 12$ kcal |
| Water vapor | $94\left(\frac{23.7}{760-23.7}\right)(10{,}490) = 31{,}600$ |
| | 31,612 kcal |

Enthalpy change of liquid = 69,272 − 31,612 = 37,660 kcal/100 kmol gas. Thus, $\Delta t = t_1 - t_2 = 37{,}660/18L_M$, and the relation between $L_M/G_M$ and the liquid-phase temperature rise is

$$L_M/G_M = (37{,}660)/(18)(100)\,\Delta t = 20.92/\Delta t$$

The following table summarizes the critical values for various assumed temperature rises:

| $\Delta t$, °C | $L_M/G_M$ | $K_1$ | $K_1G_M/L_M$ | $m_2G_M/L_M$ |
|---|---|---|---|---|
| 0 | | 2.09 | 0. | 0. |
| 2 | 10.46 | 2.31 | 0.221 | 0.200 |
| 3 | 6.97 | 2.42 | 0.347 | 0.300 |
| 4 | 5.23 | 2.54 | 0.486 | 0.400 |
| 5 | 4.18 | 2.66 | 0.636 | 0.500 |
| 6 | 3.49 | 2.79 | 0.799 | 0.599 |
| 7 | 2.99 | 2.93 | 0.980 | 0.699 |

Evidently a temperature rise of 7°C would not be a safe design because the equilibrium line nearly touches the operating line near the bottom of the tower, creating a pinch. A temperature rise of 6°C appears to give an operable design, and for this case $L_M = 349$ kmol per 100 kmol of feed gas.

The design diagram for this case is shown in Fig. 14-10, in which the equilibrium curve is drawn so that the slope at the origin $m_2$ is equal to 2.09 and passes through the point $x_1 = 0.02/3.49 = 0.00573$ at $y_1^\circ = 0.00573 \times 2.79 = 0.0160$.

The number of transfer units can be calculated from the adiabatic design equation, Eq. (14-46):

$$N_{OG} = \frac{1}{1-0.599} \ln \left[ \frac{(1-0.599)^2}{(1-0.799)} (400) + 0.599 \right] = 14.4$$

The estimated height of tower packing by assuming $H_{OG} = 0.70$ m and a design safety factor of 1.5 is

$$h_T = (14.4)(0.7)(1.5) = 15.1 \text{ m } (49.6 \text{ ft})$$

For this tower, one should consider the use of two or more shorter packed sections instead of one long section.

Another point to be noted is that this calculation can be done more easily today by using a process simulator. However, the details are presented here to help the reader gain familiarity with the key assumptions and results. The results of the approximate calculation in Example 14-6 are remarkably accurate. A rigorous simulation by a modern simulator using 14 theoretical stages results in a temperature change of about 6°C and an acetone concentration in the exit air of 6 ppm by volume.

## MULTICOMPONENT SYSTEMS

When no chemical reactions are involved in the absorption of more than one soluble component from an insoluble gas, the design conditions (temperature, pressure, liquid-to-gas ratio) are normally determined by the volatility or physical solubility of the least soluble component for which the recovery is specified.

The more volatile (i.e., less soluble) components will only be partially absorbed even for an infinite number of trays or transfer units. This can be seen in Fig. 14-11, in which the asymptotes become vertical for values of $mG_M/L_M$ greater than unity. If the amount of volatile component in the fresh solvent is negligible, then the limiting value of $y_1/y_2$ for each of the highly volatile components is

$$y_1/y_2 = S/(S-1) \tag{14-50}$$

where $S = mG_M/L_M$ and the subscripts 1 and 2 refer to the bottom and top of the tower, respectively.

When the gas stream is dilute, absorption of each constituent can be considered separately as if the other components were absent. The following example illustrates the use of this principle.

***Example 14-7 Multicomponent Absorption, Dilute Case*** Air entering a tower contains 1 percent acetaldehyde and 2 percent acetone. The liquid-to-gas ratio for optimum acetone recovery is $L_M/G_M = 3.1$ mol/mol when the fresh-solvent temperature is 31.5°C. The value of $y^o/x$ for acetaldehyde has been measured as 50 at the boiling point of a dilute solution, 93.5°C. What will the percentage recovery of acetaldehyde be under conditions of optimal acetone recovery?

*Solution.* If the heat of solution is neglected, $y^o/x$ at 31.5°C is equal to 50(1200/7300) = 8.2, where the factor in parentheses is the ratio of pure-acetaldehyde vapor pressures at 31.5 and 93.5°C, respectively. Since $L_M/G_M$ is equal to 3.1, the value of $S$ for the aldehyde is $S = mG_M/L_M = 8.2/3.1 = 2.64$, and $y_1/y_2 = S/(S-1) = 2.64/1.64 = 1.61$. The acetaldehyde recovery is therefore equal to $100 \times 0.61/1.61 = 38$ percent recovery.

In concentrated systems the change in gas and liquid flow rates within the tower and the heat effects accompanying the absorption of all components must be considered. A trial-and-error calculation from one theoretical stage to the next usually is required if accurate results are to be obtained, and in such cases calculation procedures similar to those described in Sec. 13 normally are used. A computer procedure for multicomponent adiabatic absorber design has been described by Feintuch and Treybal [*Ind. Eng. Chem. Process Des. Dev.* **17:** 505 (1978)]. Also see Holland, *Fundamentals and Modeling of Separation Processes,* Prentice Hall, Englewood Cliffs, N.J., 1975.

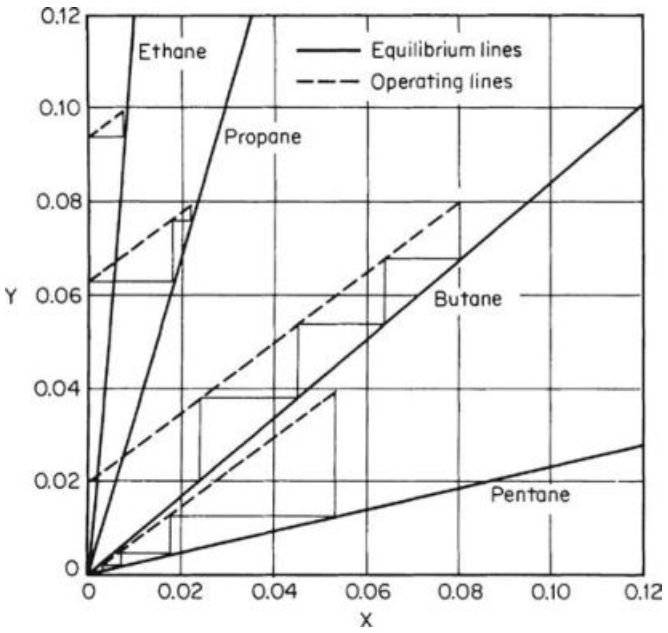

**FIG. 14-11** Graphical design method for multicomponent systems; absorption of butane and heavier components in a solute-free lean oil.

In concentrated systems, the changes in the gas and liquid flow rates within the tower and the heat effects accompanying the absorption of all components must be considered. A trial-and-error calculation from one theoretical stage to the next is usually required if accurate and reliable results are to be obtained, and in such cases calculation procedures similar to those described in Sec. 13 must be used.

When two or more gases are absorbed in systems involving chemical reactions, the system is much more complex. This topic is discussed later in the subsection Absorption with Chemical Reaction.

**Graphical Design Method for Dilute Systems** The following notation for multicomponent absorption systems has been adapted from Sherwood, Pigford, and Wilke (*Mass Transfer*, McGraw-Hill, New York, 1975, p. 415):

$L_M^S$ = moles of solvent per unit time
$G_M^0$ = moles of rich feed gas to be treated per unit time
$X$ = moles of one solute per mole of solute-free solvent fed to top of tower
$Y$ = moles of one solute in gas phase per mole of rich feed gas

Subscripts 1 and 2 refer to the bottom and the top of the tower, respectively, and the material balance for any one component may be written as

$$L_M^S (X - X_2) = G_M^0 (Y - Y_2) \tag{14-51}$$

or else as

$$L_M^S (X_1 - X) = G_M^0 (Y_1 - Y) \tag{14-52}$$

For the special case of absorption from lean gases with relatively large amounts of solvent, the equilibrium lines are defined for each component by the relation

$$Y^0 = K'X \tag{14-53}$$

Thus, the equilibrium line for each component passes through the origin with slope $K'$, where

$$K' = K(G_M/G_M^0)/(L_M/L_M^S) \tag{14-54}$$

and $K = y^o/x$. When the system is sufficiently dilute, $K' = K$.

The liquid-to-gas ratio is chosen on the basis of the least soluble component in the feed gas that must be absorbed completely. Each component will then have its own operating line with slope equal to $L_M^s/G_M^0$ (i.e., the operating lines for the various components will be parallel).

A typical diagram for the complete absorption of pentane and heavier components is shown in Fig. 14-11. The oil used as solvent is assumed to be solute-free (i.e., $X_2 = 0$), and the "key component," butane, was identified as that component absorbed in appreciable amounts whose equilibrium line is most nearly parallel to the operating lines (i.e., the $K$ value for butane is approximately equal to $L_M^s/G_M^0$).

In Fig. 14-11, the composition of the gas with respect to components more volatile than butane will approach equilibrium with the liquid phase at the bottom of the tower. The gas compositions of the components less volatile (heavier) than butane will approach equilibrium with the oil entering the tower, and since $X_2 = 0$, the components heavier than butane will be completely absorbed.

Four theoretical trays have been stepped off for the key component (butane) on Fig. 14-11, and are seen to give a recovery of 75 percent of the butane. The operating lines for the other components have been drawn with the same slope and placed so as to give approximately the same number of theoretical trays. Figure 14-11 shows that equilibrium is easily achieved in fewer than four theoretical trays and that for the heavier components nearly complete recovery is obtained in four theoretical trays. The diagram also shows that absorption of the light components takes place in the upper part of the tower, and the final recovery of the heavier components takes place in the lower section of the tower.

**Algebraic Design Method for Dilute Systems** The design method just described can be performed algebraically by using the following modified version of the Kremser formula:

$$\frac{Y_1 - Y_2}{Y_1 - mX_2} = \frac{(A^0)^{N+1} - A^0}{(A^0)^{N+1} - 1} \tag{14-55}$$

where for dilute gas absorption $A^0 = L_M^s/mG_M^0$ and $m \approx K = y^0/x$.

The left side of Eq. (14-55) represents the efficiency of absorption of any one component of the feed gas mixture. If the solvent is solute-free so that $X_2 = 0$, the left side is equal to the fractional absorption of the component from the rich feed gas. When the number of theoretical trays $N$ and the liquid and gas feed rates $L_M^s$ and $G_M^0$ have been fixed, the fractional absorption of each component may be computed directly, and the operating lines need not be placed by trial and error as in the graphical method described previously.

According to Eq. (14-55), when $A^0$ is less than unity and $N$ is large,

$$(Y_1 - Y_2)/(Y_1 - mX_2) = A^0 \tag{14-56}$$

Equation (14-56) may be used to estimate the fractional absorption of more volatile components when $A^0$ of the component is greater than $A^0$ of the key component by a factor of 3 or more.

When $A^0$ is much larger than unity and $N$ is large, the right side of Eq. (14-55) becomes equal to unity. This signifies that the gas will leave the top of the tower in equilibrium with the incoming oil, and when $X_2 = 0$, it corresponds to complete absorption of the component in question. Thus, the least volatile components may be assumed to be at equilibrium with the lean oil at the top of the tower.

When $A^0 = 1$, the right side of Eq. (14-56) simplifies as follows:

$$(Y_1 - Y_2)/(Y_1 - mX_2) = N/(N+1) \tag{14-57}$$

For systems in which the absorption factor $A^0$ for each component is not constant throughout the tower, an effective absorption factor for use in the equations just presented can be estimated by the Edmister formula

$$A_e^0 = \sqrt{A_1^0(A_2^0 + 1) + 0.25} - 0.5 \tag{14-58}$$

This procedure is a reasonable approximation only when no pinch points exist within the tower and when the absorption factors vary in a regular manner between the bottom and the top of the tower.

***Example 14-8 Multicomponent Absorption, Concentrated Case*** A hydrocarbon feed gas is to be treated in an existing four-theoretical-tray absorber to remove butane and heavier components. The recovery specification for the key component, butane, is 75 percent. The composition of the exit gas from the absorber and the required liquid-to-gas ratio are to be estimated. The feed-gas composition and the equilibrium $K$ values for each component at the temperature of the (solute-free) lean oil are presented in the following table:

| Component | Mole % | $K$ value |
|---|---|---|
| Methane | 68.0 | 74.14 |
| Ethane | 10.0 | 12.00 |
| Propane | 8.0 | 3.43 |
| Butane | 8.0 | 0.83 |
| Pentane | 4.0 | 0.23 |
| $C_6$ plus | 2.0 | 0.065 |

For $N = 4$ and $Y_2/Y_1 = 0.25$, the value of $A^0$ for butane is found to be equal to 0.89 from Eq. (14-55) by using a trial-and-error method. The values of $A^0$ for the other components are then proportional to the ratios of their $K$ values to that of butane. For example, $A^0 = 0.89(0.833/12.0) = 0.062$ for ethane. The values of $A^0$ for each of the other components and the exit-gas composition as computed from Eq. (14-55) are shown in the following table:

| | | $Y_2$, mol/100 mols feed | Exit gas mol% | |
|---|---|---|---|---|
| Component | $A^0$ | | Example 14-8 | Rigorous |
| Methane | 0.010 | 67.3 | 79.1 | 79.5 |
| Ethane | 0.062 | 9.4 | 11.1 | 11.0 |
| Propane | 0.216 | 6.3 | 7.4 | 7.1 |
| Butane | 0.890 | 2.0 | 2.4 | 2.4 |
| Pentane | 3.182 | 0.027 | 0.03 | 0.05 |
| $C_6$ Plus | 11.406 | 0.0012 | 0.0014 | 0.0004 |

The molar liquid-to-gas ratio required for this separation is computed as $L^s_M/G^0_M = A^0 \times K = 0.89 \times 0.833 = 0.74$.

We note that this example is the analytical solution to the graphical design problem shown in Fig. 14-11, which therefore is the design diagram for this system.

The results in the last column in the preceding table have been obtained from a rigorous model in which the solvent rate has been calculated to obtain 75 percent recovery of butane. The excellent agreement with the simple model in Example 14-8 demonstrates that the simple procedure captures the essential characteristics of the absorption process.

The simplified design calculations presented in this subsection are intended to reveal the key features of gas absorption in multicomponent systems. It is expected that rigorous computations, based on the methods presented in Sec. 13, will be used in design practice. Nevertheless, it is valuable to study these simplified design methods and examples because they provide insight into the key aspects of multicomponent absorption.

## ABSORPTION WITH CHEMICAL REACTION

**Introduction** Many present-day commercial gas absorption processes involve systems in which chemical reactions take place in the liquid phase; an example of the absorption of $CO_2$ by MEA was presented earlier in this section. These reactions greatly increase the capacity of the solvent and enhance the rate of absorption when compared to physical absorption systems. In addition, the selectivity of reacting solutes is greatly increased over that of nonreacting solutes. For example, MEA has a strong selectivity for $CO_2$ compared to chemically inert solutes such as $CH_4$, CO, $O_2$, or $N_2$. Note that the design procedures presented here are theoretically and practically related to biofiltration, which is discussed in Sec. 22, Waste Management.

A necessary prerequisite to understanding the subject of absorption with chemical reaction is the development of a thorough understanding of the principles involved in physical absorption, as discussed earlier in this section and in Sec. 5. Excellent references on the subject of absorption with chemical reactions are the books by Dankwerts (*Gas-Liquid Reactions*, McGraw-Hill, New York, 1970), Astarita et al. (*Gas Treating with Chemical Solvents*, Wiley, New York, 1983), and Kohl and Nielsen (*Gas Purification*, Gulf Publishing Company, Houston, 1997).

**Recommended Overall Design Strategy** When one is considering the design of a gas absorption system involving chemical reactions, the following procedure is recommended:

1. Consider the possibility that the physical design methods described earlier in this section may be applicable.
2. Determine whether commercial design overall $K_Ga$ values are available for use in conjunction with the traditional design method, being careful to note whether the conditions under which the $K_Ga$ data were obtained are essentially the same as for the new design. Contact the various tower-packing vendors for information about whether $K_Ga$ data are available for your system and conditions.
3. Consider the possibility of scaling up the design of a new system from experimental data obtained in a laboratory bench-scale or small pilot-plant unit.

4. Consider the possibility of developing for the new system a rigorous, theoretically based design procedure that will be valid over a wide range of design conditions. Note that commercial software is readily available today to develop a rigorous model in a relatively small amount of time. These topics are further discussed in the subsections that follow.

**Dominant Effects in Absorption with Chemical Reaction** When the solute is absorbing into a solution containing a reagent that chemically reacts with it, diffusion and reaction effects become closely coupled. It is thus important for the design engineer to understand the key effects. Figure 14-12 shows the concentration profiles that occur when solute *A* undergoes an irreversible second-order reaction with component *B,* dissolved in the liquid, to give product *C.*

$$A + bB \rightarrow cC \tag{14-59}$$

The rate equation is

$$r_A = -k_2 C_A C_B \tag{14-60}$$

Figure 14-12 shows that the fast reaction takes place entirely in the liquid film. In such instances, the dominant mass-transfer mechanism is physical absorption, and physical design methods are applicable, but the resistance to mass transfer in the liquid phase is lower due to the reaction. On the other extreme, a slow reaction occurs in the bulk of the liquid, and its rate has little dependence on the resistance to diffusion in either the gas or the liquid films. Here the mass-transfer mechanism is that of chemical reaction, and holdup in the bulk liquid is the determining factor.

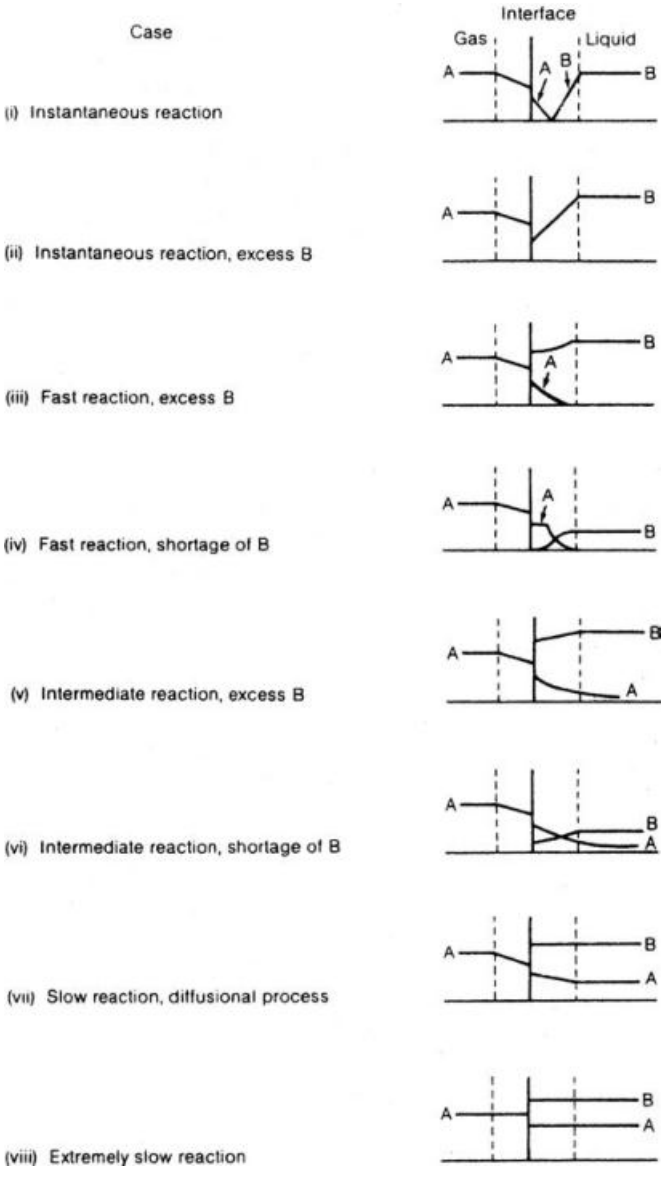

**FIG. 14-12** Vapor- and liquid-phase concentration profiles near an interface for absorption with chemical reaction.

The Hatta number is a dimensionless group used to characterize the importance of the speed of reaction relative to the diffusion rate.

$$N_{\text{Ha}} = \frac{\sqrt{D_A k_2 C_{B0}}}{k_L^0} \tag{14-61}$$

As the Hatta number increases, the effective liquid-phase mass-transfer coefficient increases. Figure 14-13, which was first developed by Van Krevelen and Hoftyzer [*Rec. Trav. Chim.* **67:** 563 (1948)] and later refined by Perry and Pigford and by Brian et al. [*AIChE J.* **7:** 226 (1961)], shows how the enhancement (defined as the ratio of the effective liquid-phase mass-transfer coefficient to its physical equivalent $\phi = k_L/k_L^0$) increases with $N_{\text{Ha}}$ for a second-order, irreversible reaction of the kind defined by Eqs. (14-60) and (14-61). The various curves in Fig. 14-13 were developed based on penetration theory, and they depend on the parameter $\phi_\infty - 1$, which is related to the diffusion coefficients and reaction coefficients, as shown below.

$$\phi_\infty = \sqrt{\frac{D_A}{D_B}} + \sqrt{\frac{D_A}{D_B}}\left(\frac{C_B}{C_A b}\right) \tag{14-62}$$

For design purposes, the entire set of curves in Fig. 14-13 may be represented by the following two equations:
For, $N_{\text{Ha}} \geq 2$:

$$k_L/k_L^0 = 1 + (\phi_\infty - 1)\{1 - \exp[-(N_{\text{Ha}} - 1)/(\phi_\infty - 1)]\} \tag{14-63}$$

For, $N_{\text{Ha}} \leq 2$:

$$k_L/k_L^0 = 1 + (\phi_\infty - 1)\{1 - \exp[-(\phi_\infty - 1)^{-1}]\} \exp[1 - 2/N_{\text{Ha}}] \tag{14–64}$$

Equation (14-64) was originally reported by Porter [*Trans. Inst. Chem. Eng.* **44:** T25 (1966)], and Eq. (14-64) was derived by William M. Edwards, the author of the sixth edition of this handbook.

The Van Krevelen-Hoftyzer (Fig. 14-13) relationship was tested by Nijsing et al. [*Chem. Eng. Sci.* **10:** 88 (1959)] for the second-order system in which $CO_2$ reacts with either NaOH or KOH solutions. Nijsing's results are shown in Fig. 14-14 and can be seen to be in excellent agreement with the second-order-reaction theory. Indeed, these experimental data are well described by Eqs. (14-62) and (14-63) when values of $b = 2$ and $D_A/D_B = 0.64$ are employed in the equations.

**Applicability of Physical Design Methods** Physical design models such as the classical isothermal design method or the classical adiabatic design method may be applicable for systems in which chemical reactions are either extremely fast or extremely slow, or when chemical equilibrium is achieved between the gas and liquid phases.

If the chemical reaction is extremely fast and irreversible, the rate of absorption may in some cases be completely governed by gas-phase resistance. For practical design purposes, one may assume, for example, that this gas-phase mass-transfer-limited condition will exist when the ratio $y_i/y$ is less than 0.05 everywhere in the apparatus.

From the basic mass-transfer flux relationship for species *A* (Sec. 5),

$$N_A = k_G(y - y_i) = k_L(x_i - x) \tag{14-65}$$

one can readily show that this condition on $y_i/y$ requires that the ratio $x/x_i$ be negligibly small (i.e., a fast reaction) and that the ratio $mk_G/k_L = mk_G/k_L^0\phi$ be less than 0.05 everywhere in the apparatus. The ratio $mk_G/k_L^0\phi$ will be small if the equilibrium backpressure of the solute over the liquid is small (i.e., small $m$ or high reactant solubility), or the reaction enhancement factor $\phi = k_L/k_L^0$ is very large, or both. The reaction enhancement factor $\phi$ will be large for all extremely fast pseudo-first-order reactions and will be large for extremely fast second-order irreversible reaction systems in which there is sufficiently large excess of liquid reagent.

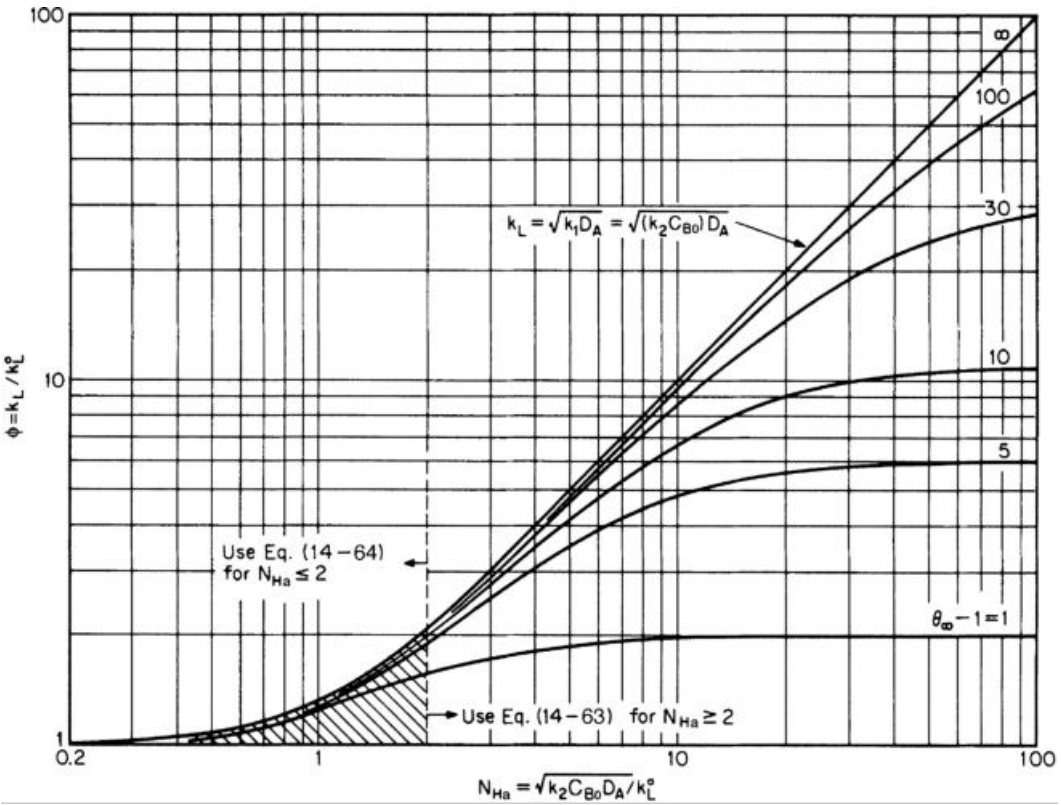

**FIG. 14-13** Influence of irreversible chemical reactions on the liquid-phase mass-transfer coefficient $k_L$. [*Adapted from Van Krevelen and Hoftyzer*, Rec. Trav. Chim. ***67:*** *563 (1948).*]

Figure 14-12, case (ii), illustrates the gas-film and liquid-film concentration profiles one might find in an extremely fast (gas-phase mass-transfer-limited), second-order irreversible reaction system. The solid curve for reagent $B$ represents the case in which there is a large excess of bulk liquid reagent $B^0$. Figure 14-12, case (iv), represents the case in which the bulk concentration $B^0$ is not large enough to prevent the depletion of $B$ near the liquid interface.

Whenever these conditions on the ratio $y_i/y$ apply, the design can be based on the physical rate coefficient $k_G$ or on the height of one gas-phase mass-transfer unit $H_G$. The gas-phase mass-transfer-limited condition is approximately valid for the following systems: absorption of $NH_3$ into water or acidic solutions, absorption of $H_2O$ into concentrated sulfuric acid, absorption of $SO_2$ into alkali solutions, absorption of $H_2S$ from a gas stream into a strong alkali solution, absorption of HCl into water or alkaline solutions, or absorption of $Cl_2$ into strong alkali solutions.

When the liquid-phase reactions are extremely slow, the gas-phase resistance can be neglected, and one can assume that the rate of reaction has a

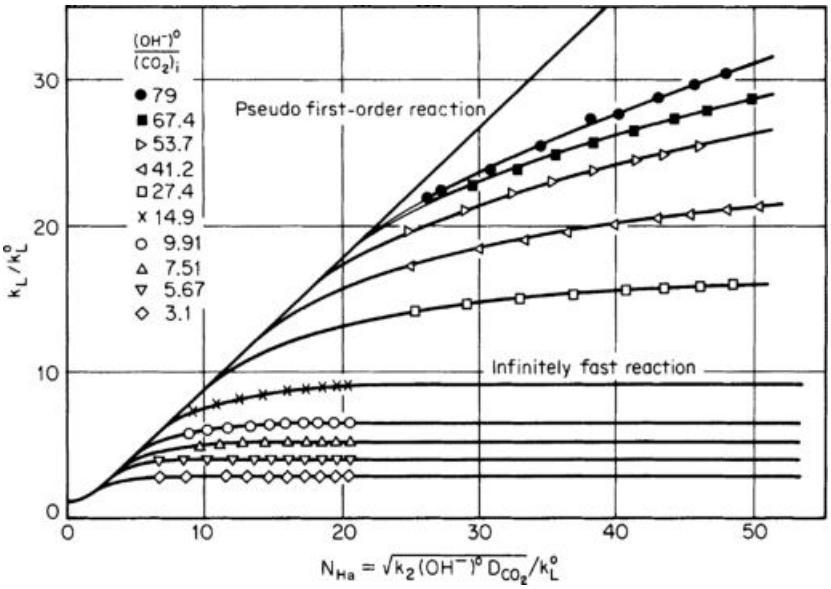

**FIG. 14-14** Experimental values of $k_L/k_L^0$ for absorption of $CO_2$ into NaOH solutions at 20°C. [*Data of Nijsing et al.*, Chem. Eng. *Sci.* ***10:*** *88 (1959).*]

predominant effect upon the rate of absorption. In this case the differential rate of transfer is given by the equation

$$dn_A = R_A f_H S\, dh = (k_L^0 a/\rho_L)(c_i - c) S\, dh \tag{14-66}$$

where $n_A$ = rate of solute transfer, $R_A$ = volumetric reaction rate ( function of $c$ and $T$), $f_H$ = fractional liquid volume holdup in tower or apparatus, $S$ = tower cross-sectional area, $h$ = vertical distance, $k_L^0$ = liquid-phase mass-transfer coefficient for pure physical absorption, $a$ = effective interfacial mass-transfer area per unit volume of tower or apparatus, $\rho_L$ = average molar density of liquid phase, $c_i$ = solute concentration in liquid at gas–liquid interface, and $c$ = solute concentration in bulk liquid.

Although the right side of Eq. (14-66) remains valid even when chemical reactions are extremely slow, the mass-transfer driving force may become increasingly small, until finally $c \approx c_i$. For extremely slow first-order irreversible reactions, the following rate expression can be derived from Eq. (14-66):

$$R_A = k_1 c = k_1 c_i/(1 + k_1 \rho_L f_H / k_L^0 a) \tag{14-67}$$

where $k_1$ = first-order reaction rate coefficient.

For dilute systems in countercurrent absorption towers in which the equilibrium curve is a straight line (i.e., $y_i = mx_i$), the differential relation of Eq. (14-66) is formulated as

$$dn_A = -G_M S\, dy = k_1 c f_H S\, dh \tag{14-68}$$

where $G_M$ = molar gas-phase mass velocity and $y$ = gas-phase solute mole fraction.

Substitution of Eq. (14-67) into Eq. (14-68) and integration lead to the following relation for an extremely slow first-order reaction in an absorption tower:

$$y_2 = y_1 \exp\left[-\frac{k_1 \rho_L f_H h_T/(mG_m)}{1 + k_1 \rho_L f_H/(k_L^0 a)}\right] \tag{14-69}$$

In Eq. (14-69), subscripts 1 and 2 refer to the bottom and top of the tower, respectively.

As discussed above, the Hatta number $N_{\text{Ha}}$ usually is used as the criterion for determining whether a reaction can be considered extremely slow. A reasonable criterion for slow reactions is

$$N_{\text{Ha}} = \sqrt{k_1 D_A}/k_L^0 \le 0.3 \tag{14-70}$$

where $D_A$ = liquid-phase diffusion coefficient of the solute in the solvent. Figure 14-12, cases (vii) and (viii), illustrates the concentration profiles in the gas and liquid films for the case of an extremely slow chemical reaction.

Note that when the second term in the denominator of the exponential in Eq. (14-69) is very small, the liquid holdup in the tower can have a significant influence upon the rate of absorption if an extremely slow chemical reaction is involved.

When chemical equilibrium is achieved quickly throughout the liquid phase, the problem becomes one of properly defining the physical and chemical equilibria for the system. It is sometimes possible to design a tray-type absorber by assuming chemical equilibrium relationships in conjunction with a stage efficiency factor, as is done in distillation calculations. Rivas and Prausnitz [*AIChE J.* **25:** 975 (1979)] have presented an excellent discussion and example of the correct procedures to be followed for systems involving chemical equilibria.

**Traditional Design Method** The traditional procedure for designing packed-tower gas absorption systems involving chemical reactions makes use of overall mass-transfer coefficients as defined by the equation

$$K_G a = n_A/(h_T S p_T \Delta y_{1m}^0) \tag{14-71}$$

where $K_G a$ = overall volumetric mass-transfer coefficient, $n_A$ = rate of solute transfer from the gas to the liquid phase, $h_T$ = total height of tower packing, $S$ = tower cross-sectional area, $p_T$ = total system pressure, and $\Delta y_{1m}^0$ is defined by the equation

$$\Delta y_{1m}^0 = \frac{(y - y^0)_1 - (y - y^0)_2}{\ln\left[\dfrac{(y - y^0)_1}{(y - y^0)_2}\right]} \tag{14-72}$$

in which subscripts 1 and 2 refer to the bottom and top of the absorption tower, respectively, $y$ = mole-fraction solute in the gas phase, and $y^0$ = gas-phase solute mole fraction in equilibrium with bulk-liquid-phase solute concentration $x$. When the equilibrium line is straight, $y^\circ = mx$.

The traditional design method normally makes use of overall $K_G a$ values even when resistance to transfer lies predominantly in the liquid phase. For example, the $CO_2$-NaOH system that is most commonly used for comparing $K_G a$ values of various tower packings is a liquid-phase-controlled system. When the liquid phase is controlling, extrapolation to different concentration ranges or operating conditions is not recommended since changes in the reaction mechanism can cause $k_L$ to vary unexpectedly, and the overall $K_G a$ do not capture such effects.

Overall $K_G a$ data may be obtained from tower-packing vendors for many of the established commercial gas absorption processes. Such data often are based either on tests in large-diameter test units or on actual commercial operating data. Since application to untried operating conditions is not recommended, the preferred procedure for applying the traditional design method is equivalent to duplicating a previously successful commercial installation. When this is not possible, a commercial demonstration at the new operating conditions may be required, or else one could consider using some of the more rigorous methods described later.

While the traditional design method is reported here because it has been used extensively in the past, it should be used with extreme caution. In addition to the lack of an explicit liquid-phase resistance term, the method has other limitations. Equation (14-71) assumes that the system is dilute ($y_{BM} \approx 1$) and that the operating and equilibrium lines are straight, which are weak assumptions for reacting systems. Also, Eq. (14-65) is strictly valid only for the temperature and solute partial pressure at which the original test was done, even though the total pressure $p_T$ appears in the denominator.

In using Eq. (14-71), therefore, it should be understood that the numerical values of $K_G a$ will be a complex function of pressure, temperature, the type and size of packing employed, the liquid and gas mass flow rates, and the system composition (e.g., the degree of conversion of the liquid-phase reactant).

Figure 14-15 illustrates the influence of system composition and degree of reactant conversion upon the numerical values of $K_G a$ for the absorption of $CO_2$ into sodium hydroxide at constant conditions of temperature, pressure, and type of packing. An excellent experimental study of the influence of operating variables upon overall $K_G a$ values is that of Field et al. (*Pilot-Plant Studies of the Hot Carbonate Process for Removing Carbon Dioxide and Hydrogen Sulfide*, U.S. Bureau of Mines Bulletin 597, 1962).

Table 14-2 illustrates the observed variations in $K_G a$ values for different packing types and sizes for the $CO_2$-NaOH system at a 25 percent reactant conversion for two different liquid flow rates. The lower rate of 2.7 kg/(s · m$^2$)

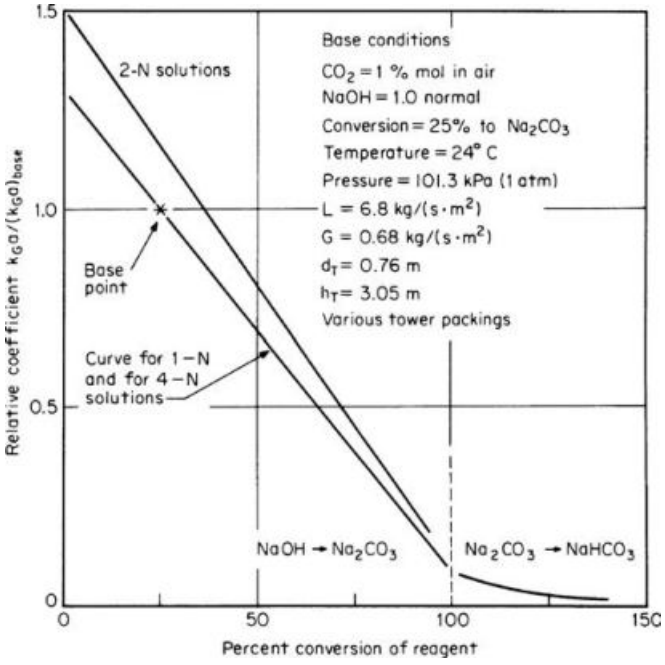

**FIG. 14-15** Effects of reagent-concentration and reagent-conversion levels upon the relative values of $K_G a$ in the $CO_2$-NaOH-$H_2O$ system. [*Adapted from Eckert et al.*, Ind. Eng. Chem. ***59****(2): 41 (1967).*]

Operating conditions: $CO_2$, 1 percent mole in air; NaOH, 4 percent weight (1 normal); 25 percent conversion to sodium carbonate; temperature, 24°C (75°F); pressure, 98.6 kPa (0.97 atm); gas rate = 0.68 kg/(s·m²) = 0.59 m/s = 500 lb/(h·ft²) = 1.92 ft/s except for values with asterisks, which were run at 1.22 kg/(s·m²) = 1.05 m/s = 900 lb/(h·ft²) = 3.46 ft/s superficial velocity; packed height, 3.05 m (10 ft); tower diameter, 0.76 m (2.5 ft). To convert table values to units of (lb·mol)/(h·ft³), multiply by 0.0624.

or 2000 lb/(h·ft²) is equivalent to 4 U.S. gal/(min·ft²) and is typical of the liquid rates employed in fume scrubbers. The higher rate of 13.6 kg/(s·m²) or 10,000 lb/(h·ft²) is equivalent to 20 U.S. gal/(min·ft²) and is more typical of absorption towers such as those used in $CO_2$ removal systems, for example. We also note that two gas velocities are represented in the table, corresponding to superficial velocities of 0.59 and 1.05 m/s (1.94 and 3.44 ft/s).

Table 14-3 presents a typical range of $K_Ga$ values for chemically reacting systems. The first two entries in the table represent systems that can be designed by the use of purely physical design methods because they are completely gas-phase mass transfer limited. To ensure a negligible liquid-phase resistance in these two tests, the HCl was absorbed into a solution maintained at less than 8 wt% HCl, and the $NH_3$ was absorbed into a water solution maintained below pH 7 by the addition of acid. The last two entries in Table 14-3 represent liquid-phase mass-transfer-limited systems.

**Scaling Up from Laboratory Data** Laboratory experimental techniques offer an efficient and cost-effective route to develop commercial absorption designs. For example, Ouwerkerk (*Hydrocarbon Process.*, April 1978, pp. 89–94) revealed that both laboratory and small-scale pilot plant data were employed as the basis for the design of an 8.5-m (28-ft) diameter commercial Shell Claus off-gas treating (SCOT) tray-type absorber. Ouwerkerk claimed that the cost of developing comprehensive design procedures can be minimized, especially in the development of a new process, by the use of these modern techniques.

In a 1966 paper that is considered a classic, Dankwerts and Gillham [*Trans. Inst. Chem. Eng.* **44:** T42 (1966)] showed that data taken in a small stirred-cell laboratory apparatus could be used in the design of a packed-tower absorber when chemical reactions are involved. They showed that if the packed-tower mass-transfer coefficient in the absence of reaction ($k_L^0$) can be reproduced in the laboratory unit, then the rate of absorption in the laboratory apparatus will respond to chemical reactions in the same way as in the packed column, even though the means of agitating the liquid in the two systems may be quite different.

According to this method, it is not necessary to investigate the kinetics of the chemical reactions in detail, nor is it necessary to determine the solubilities or diffusivities of the various reactants in their unreacted forms. To use the method for scaling up, one must independently obtain data on the values of the interfacial area per unit volume $a$ and the physical mass-transfer coefficient $k_L^0$ for the commercial packed tower. Once these data have been measured and tabulated, they can be used directly for scaling up the experimental laboratory data for any new chemically reacting system.

Dankwerts and Gillham did not investigate the influence of the gas-phase resistance in their study (for some processes, gas-phase resistance may be neglected). However, in 1975 Dankwerts and Alper [*Trans. Inst. Chem. Eng.* **53:** T42 (1975)] showed that by placing a stirrer in the gas space of the stirred-cell laboratory absorber, the gas-phase mass-transfer coefficient $k_G$ in the laboratory unit could be made identical to that in a packed-tower absorber. When this was done, laboratory data for chemically reacting systems having a significant gas-side resistance could successfully be scaled up to predict the performance of a commercial packed-tower absorber.

If it is assumed that the values for $k_G$, $k_L^0$, and $a$ have been measured for the commercial tower packing to be used, the procedure for using the laboratory stirred-cell reactor is as follows:

1. The gas-phase and liquid-phase stirring rates are adjusted to produce the same values of $k_G$ and $k_L^0$ as will exist in the commercial tower.
2. For the reaction system under consideration, experiments are made at a series of bulk-liquid and bulk-gas compositions representing the compositions to be expected at different levels in the commercial absorber (on the basis of material balance).
3. The ratios of $r_A(c_iB^0)$ are measured at each pair of gas and liquid compositions.

For the dilute-gas systems, one form of the equation to be solved in conjunction with these experiments is

$$h_T = \frac{G_M}{a}\int_{y2}^{y1}\frac{dy}{r_A} \tag{14-73}$$

where $h_T$ = height of commercial tower packing, $G_M$ = molar gas-phase mass velocity, $a$ = effective mass-transfer area per unit volume in the commercial

**TABLE 14-3 Typical $K_Ga$ Values for Various Chemically Reacting Systems, kmol/(h·m³)**

| Gas-phase reactant | Liquid-phase reactant | $K_Ga$ | Special conditions |
|---|---|---|---|
| HCl | $H_2O$ | 353 | Gas-phase limited |

Operating conditions (see text): 38-mm ceramic Intalox saddles; solute gases, 0.5–1.0 percent mole; reagent conversions = 33 percent; pressure, 101 kPa (1 atm); temperature, 16–24°C; gas rate = 1.3 kg/(s·m²) = 1.1 m/s; liquid rates = 3.4 to 6.8 kg/(s·m²); packed height, 3.05 m; tower diameter, 0.76 m. Multiply table values by 0.0624 to convert to (lb·mol)/(h·ft³).

tower, $y$ = mole fraction solute in the gas phase, and $r_A$ = experimentally determined rate of absorption per unit of exposed interfacial area.

By using the series of experimentally measured rates of absorption, Eq. (14-73) can be integrated numerically to determine the height of packing required in the commercial tower.

A number of different types of experimental laboratory units could be used to develop design data for chemically reacting systems. Charpentier [*ACS Symp. Ser.* **72:** 223–261 (1978)] has summarized the state of the art with respect to methods of scaling up laboratory data and has tabulated typical values of the mass-transfer coefficients, interfacial areas, and contact times to be found in various commercial gas absorbers, as well as in currently available laboratory units.

The laboratory units that have been used to date for these experiments were designed to operate at a total system pressure of about 101 kPa (1 atm) and at near-ambient temperatures. In practical situations, it may become necessary to design a laboratory absorption unit that can be operated either under vacuum or at elevated pressure and over a range of temperatures in order to apply the Dankwerts method.

It would be desirable to reinterpret existing data for commercial tower packings to extract the individual values of the interfacial area $a$ and the mass-transfer coefficients $k_G$ and $k_L^0$ to facilitate a more general usage of methods for scaling up from laboratory experiments. Some progress has already been made, as described later in this section. In the absence of such data, it is necessary to operate a pilot plant or a commercial absorber to obtain $k_G$, $k_L^0$, and $a$ as described by Ouwerkerk (*Hydrocarbon Process.*, April 1978, pp. 89–94).

Modern techniques use rigorous computer-based modeling methods to extract fundamental parameters from laboratory-scale measurements and then apply them to the design of commercial absorption towers. These techniques are covered next.

**Rigorous Computer-Based Absorber Design** While the techniques described earlier in this section are very useful for understanding the key effects in commercial absorbers, current design methods used in industrial practice for chemically reactive systems are increasingly based on rigorous computerized methods, and these are commercially available from software vendors. The advantages of the rigorous methods are as follows: (1) Approximations do not have to be made for special cases (e.g., fast chemical reactions or mass-transfer resistance dominated by the gas or liquid phase), and all effects can be simultaneously modeled. (2) Fundamental quantities such as kinetic parameters and mass-transfer coefficients can be extracted from laboratory and pilot-scale equipment, and applied to commercial absorber towers. (3) Integrated models can be developed for an entire absorption process flow sheet (e.g., the absorber-stripper system with heat integration presented in Fig. 14-3), and consequently the entire system may be optimized.

Computer programs for chemically reacting systems are available from several vendors. The specific approaches used to model the chemically reacting absorption system are slightly different among the different vendors. The general approach used and the benefits obtained are identified by considering a specific example of broad current interest: removal of $CO_2$ from flue gases discharged by a power plant using aqueous monoethanolamine (MEA), as presented by Zhang et al. [*Ind. Eng. Chem. Res.* **48:** 9233 (2009)].

The development and application of a rigorous model for a chemically reactive system typically involves five steps: (1) development of a thermodynamic model to describe the physical and chemical equilibrium; (2) adoption and use of a modeling framework to describe the mass transfer and chemical reactions; (3) parameterization of the mass-transfer and kinetic models based on laboratory, pilot-plant, or commercial-plant data; (4) parameterization of the hydraulic models to estimate operating features such as pressure drop and holdup; and (5) use of the integrated model to optimize the process and perform equipment design.

**Development of Thermodynamic Model for Physical and Chemical Equilibrium** The first and perhaps most important step in the development of the thermodynamic model is the *speciation,* or representation of the set of chemical reactions. For $CO_2$ absorption in aqueous MEA solutions, the set of reactions is

$$CO_2 + MEA + H_2O \leftrightarrow MEACOO^- + H_3O^+ \qquad (14\text{-}74a)$$

$$CO_2 + OH^- \leftrightarrow HCO_3^- \qquad (14\text{-}74b)$$

$$HCO_3^- + H_2O \leftrightarrow CO_3^{2-} + H_3O^+ \qquad (14\text{-}74c)$$

$$MEAH^+ + H_2O \leftrightarrow MEA + H_3O^+ \qquad (14\text{-}74d)$$

$$2H_2O \leftrightarrow H_3O^+ + OH^- \qquad (14\text{-}74e)$$

In addition, a model is needed that can describe the nonideality of a system containing molecular and ionic species. Zhang et al. (2009) adopted the model developed by Hilliard in his Ph.D. thesis [chemical engineering, University of Texas (2008)]. The combination of the speciation set of reactions [Eqs. (14-74*a*) to (14-74*e*)] and the nonideality model is capable of representing the solubility data, such as those presented in Figs. 14-1 and 14-2, to good accuracy. In addition, the model accurately and correctly represents the actual species present in the aqueous phase, which is important for faithful description of the chemical kinetics and species mass transfer across the interface. Finally, the thermodynamic model facilitates accurate modeling of the heat effects, such as those discussed in Example 14-6. The Gibbs-Helmholtz equation provides the rigorous relationship between vapor-liquid equilibrium and calorimetric data, Mathias and O'Connell [*I&EC Res.*, **51**: 5090 (2012)].

Wang et al. [*J. Geochem. Explor.* **101:** 112 (2009)], Chen and Song [*AIChE J.* **50:** 1928 (2004)], and Zhang, Que, and Chen [*Fluid Phase Equil.* **311:** 67 (2011)] have provided comprehensive discussions of speciation and electrolyte thermodynamic models.

**Adoption and Use of Modeling Framework** The rate of species generation and diffusion by chemical reaction can be described by film theory, penetration theory, or a combination of the two. The most popular description is in terms of a two-film theory, which is diagrammed in Fig. 14-16 for absorption. Accordingly, there exists a stable interface separating the gas and the liquid. A certain distance from the interface, large fluid motions exist, and these distribute the material rapidly and equally so that no concentration gradients develop; these regions are referred to as the "bulk" vapor and liquid in Fig. 14-16. Next to the interface, however, there are regions in which the fluid motion is slow; in these regions, termed *films* and denoted by lengths $\delta_V$ and $\delta_L$, material is transferred by diffusion alone. At the gas–liquid interface, material is transferred instantaneously, so the gas and liquid are in physical equilibrium at the interface. This means that $y_{AI}$ and $x_{AI}$ in Fig. 14-16 satisfy the equality of fugacity relationships. The rate of diffusion in absorption is therefore the rate of diffusion in the gas and liquid films adjacent to the interface. The model framework is completed by including terms for species generation (chemical equilibrium *and* chemical kinetics) in the gas and liquid film and bulk regions. Taylor, Krishna, and Kooijman (*Chem. Eng. Progress*, July 2003, p. 28) have provided an excellent discussion of rate-based models; these authors emphasize that the diffusion flux for multicomponent systems must be based on the Maxwell-Stefan approach. The book by Taylor and Krishna (*Multicomponent Mass Transfer*, Wiley, New York, 1993) provides a detailed discussion of the Maxwell-Stefan approach.

**Parameterization of Mass-Transfer, Hydraulic, and Kinetic Models** The mass-transfer and chemical kinetic rates required in the rigorous model are typically obtained from the literature, but they must be carefully evaluated, and fine-tuning through pilot-plant and commercial data is highly recommended.

Mass-transfer coefficient models for the vapor and liquid coefficients are of the general form

$$k_{i,j}^L = a\rho_L f(D_{i,j}^m, \mu_L, \rho_L, a, \text{internal characteristics}) \qquad (14\text{-}75a)$$

$$k_{i,j}^V = a\rho_V f(D_{i,j}^m, \mu_V, \rho_V, a, \text{internal characteristics}) \qquad (14\text{-}75b)$$

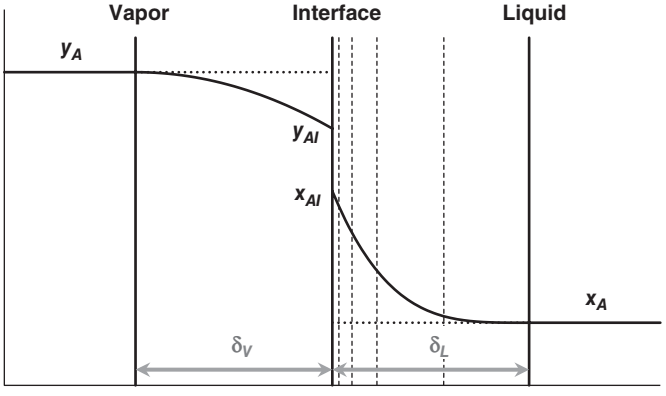

**FIG. 14-16** Concentration profiles in the vapor and liquid phases near the interface. The two regions in the extreme left and right represent the bulk vapor and liquid, with mole fractions $y_A$ and $x_A$, respectively. The two inside regions represent the vapor and liquid films, with thicknesses $\delta_V$ and $\delta_L$, respectively. The liquid film has been discretized into five segments (vertical dashed lines) with thinner ( finer) segments close to the interface.

where $a$ = effective interfacial area per unit volume, $D^m_{i,j}$ are the Stefan-Maxwell diffusion coefficients, $P$ = pressure, $\rho$ = molar density, and $\mu$ = viscosity. The functions in Eqs. (14-75*a*) and (14-75*b*) are correlations that depend on the column internals. Popular correlations in the literature are those by Onda at al. [ *J. Chem.. Eng. Jap.* **1:** 56 (1968)] for random packing, Bravo and Fair [*Ind. Eng. Chem. Proc. Des. Dev.* **21:** 162 (1982)] for structured packing, Chan and Fair [*Ind. Eng. Chem. Proc. Des. Dev.* **23:** 814 (1984)] for sieve trays, Scheffe and Weiland [*Ind. Eng. Chem. Res.* **26:** 228 (1987)] for valve trays, and Hughmark [*AIChE J.* **17:** 1295 (1971)] for bubble-cap trays. These references provide correlations of heat transfer, mass transfer, interfacial area, liquid holdup, and pressure drop, among other factors.

Kinetic models are usually developed by replacing a subset of the speciation reactions by kinetically-limited reversible reactions. For example, Zhang et al. (2009) replaced equilibrium reactions (14-74*a*) and (14-74*b*) with kinetically reversible reactions, and they retained the remaining three reactions as very fast and hence effectively at equilibrium. The kinetic constants were tuned using kinetic data, here from Aboudheir [Ph.D. thesis, chemical engineering, University of Regina (2002)]. It is very important that the kinetic models asymptote to the equilibrium limit for large residence times (e.g., very tall columns), as has been demonstrated by Mathias and Gilmartin [*Energy Procedia* **63:** 1171 (2014)].

There are many details that require attention in the rigorous models. The concentration variation in the liquid film is highly nonlinear, and hence the liquid film must be discretized, with more clustered segments in the vicinity of the interface, as is depicted by the vertical dashed lines in Fig. 14-16. The segment height should be chosen to be small enough so that the model is effectively simulating a continuous distribution. In both discretization and segment height, tests should be done to confirm that increased fine graining does not change the results—that is, that the asymptotic limit has been reached. Another choice that must be made is the *flow model*, which determines the bulk properties based on those of adjacent segments; for example, RateSep from AspenTech offers four flow models (*Mixed*, *CounterCurrent*, *Vplug,* and *Vplug-Pavg*), and these flow models have been described and analyzed by Zhang et al. (2009).

It is highly recommended that the mass-transfer correlations be tested and improved by using laboratory, pilot-plant, or commercial data for the specific application. Zhang et al. (2009) show that the model they developed accurately describes the University of Texas pilot plant data for measured results such as fraction of $CO_2$ removal and temperature profiles.

There are many examples in the technical literature where detailed process models have provided good results similar to those of Zhang et al. (2009). However, users of commercial software should perform due diligence to ensure that the models provide reliable and accurate results for the particular application of interest to them. Luo et al. [*Energy Procedia* **1:** 1249 (2009)] performed a systematic test of several commercial and in-house codes against 16 sets of data from four different pilot plants. Their key conclusions are as follows: "Basically all the simulators are capable of giving reasonable predictions on overall performance, i.e., $CO_2$ absorption rate. The reboiler duties are less well predicted, as well as concentration and temperature profiles. For the reboiler temperature there is very much scatter."

Commercial software generally provides for correction factors to adjust generalized correlations to the particular application. Users of commercial codes are again urged to perform due diligence and to apply reasonable correction factors (say, within ± 20%) when reliable pilot-plant or commercial data are available.

**Deployment of Rigorous Model for Process Optimization and Equipment Design** It is usually valuable to develop an integrated model for the absorption-stripping system, including the cross exchanger (see Fig. 14-3). Øi and Kvam (*Energy Procedia* **63:** 1186 (2014)] used various models to simulate entire flow sheets. They found that even though the models gave different absolute results, they predicted the same trends when flow sheet improvements (e.g., vapor compression or split flows) were adopted.

In this subsection, we have used the example of $CO_2$ removal from flue gases using aqueous alkanolamines to demonstrate the development and application of a rigorous model for a chemically reactive system. Modern software enables rigorous description of complex chemically reactive systems, but it is very important to carefully evaluate the models and to tune them using experimental data. A favorable result is that integrated models may be relied upon to predict trends accurately, and hence their best value may be to efficiently evaluate process improvements.

**Use of Literature for Specific Systems** A large body of experimental data obtained in bench-scale laboratory units and in small-diameter packed towers has been published since the early 1940s. One might wish to consider using such data for a particular chemically reacting system as the basis for scaling up to a commercial design. Extreme caution is recommended in interpreting such data for the purpose of developing commercial designs because extrapolating the data can lead to serious errors. Extrapolation to temperatures, pressures, or liquid-phase reagent conversions different from those that were used by the original investigators definitely should be regarded with caution. As noted earlier in this subsection, rigorous models are recommended to perform these extrapolations.

The General References at the beginning of this subsection can be an excellent source of information on specific chemically reacting systems. *Gas-Liquid Reactions* by Dankwerts (McGraw-Hill, New York, 1970) contains a tabulation of references to specific chemically reactive systems. *Gas Treating with Chemical Solvents* by Astarita et al. (Wiley, New York, 1983) deals with the absorption of acid gases and includes an extensive listing of patents. *Gas Purification* by Kohl and Nielsen (Gulf Publishing, Houston, 1997) provides a practical description of techniques and processes in widespread use and typically also sufficient design and operating data for specific applications.

In searching for data on a particular system, we recommend a computerized search of *Chemical Abstracts, Engineering Index,* and *National Technical Information Service* (NTIS) databases. Modern search engines such as *Google Scholar* will also rapidly produce much potentially valuable information.

The experimental data for the system $CO_2$-NaOH-$Na_2CO_3$ are unusually comprehensive and well known as the result of the work of many experimenters. A serious study of the data and theory for this system therefore is recommended as the basis for developing a good understanding of the kind and quality of experimental information needed for design purposes.

# EQUIPMENT FOR DISTILLATION AND GAS ABSORPTION: TRAY COLUMNS

Distillation and gas absorption are the prime and most common gas–liquid mass-transfer operations. Other operations that are often performed in similar equipment include stripping (often considered part of distillation), direct-contact heat transfer, flashing, washing, humidification, and dehumidification.

The most common types of contactors by far used for these are tray and packed towers. These are the focus of this subsection. Other contactors used from time to time and their applications are listed in Table 14-4.

In this subsection, the terms *gas* and *vapor* are used interchangeably. *Vapor* is more precise for distillation, where the gas phase is at equilibrium. Also, the terms *tower* and *column* are used interchangeably.

A cross-flow tray (Fig. 14-17) consists of the *bubbling area* and the *downcomer*. Liquid descending the downcomer from the tray above enters the bubbling area. Here, the liquid contacts gas ascending through the tray perforations, forming froth or spray. An *outlet weir* on the downstream side of the bubbling area helps maintain liquid level on the tray. Froth

**TABLE 14-4 Equipment for Liquid–Gas Systems**

| Equipment designation | Mode of flow | Gross mechanism | Continuous phase | Primary process applications |
|---|---|---|---|---|
| Tray column | Cross-flow, countercurrent | Integral | Liquid and/or gas | Distillation, absorption, stripping, DCHT, washing |
| Packed column | Countercurrent, cocurrent | Differential | Liquid and/or gas | Distillation, absorption, stripping, humidification, dehumidification, DCHT, washing |
| Wetted-wall ( falling-film) column | Countercurrent, cocurrent | Differential | Liquid and/or gas | Distillation, absorption, stripping, evaporation |
| Spray chamber | Cocurrent, cross-flow, countercurrent | Differential | Gas | Absorption, stripping, humidification, dehumidification |
| Agitated vessel | Complete mixing | Integral | Liquid | Absorption |
| Line mixer | Cocurrent | Differential | Liquid or gas | Absorption, stripping |

DCHT = direct contact heat transfer.

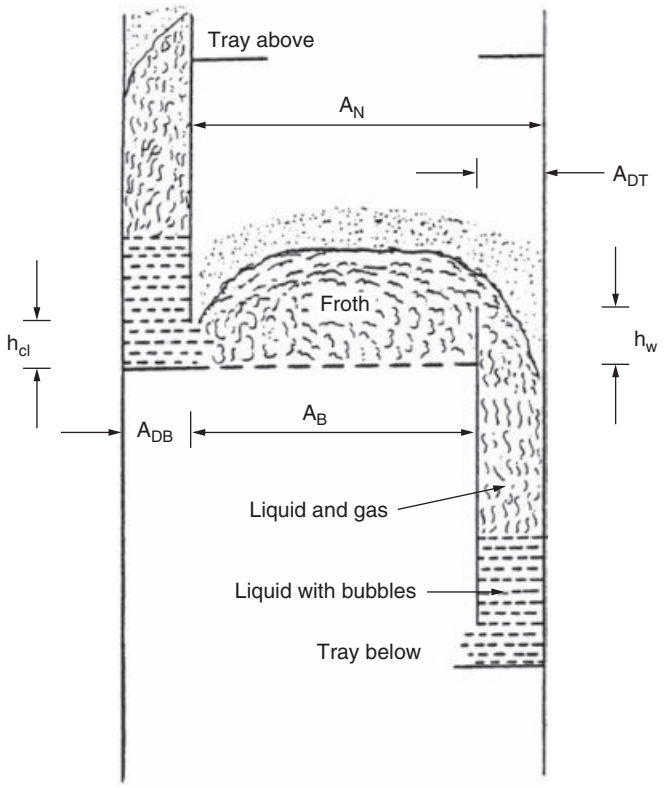

**FIG. 14-17** Schematic of a tray operating in the froth regime. (*Based on H. Z. Kister*, Distillation Design, *copyright © 1992 by McGraw-Hill; reprinted by permission.*)

overflowing the weir enters the outlet downcomer. Here, gas disengages from the liquid, and the liquid descends to the tray below. The bubbling area can be fitted with many types of tray hardware. The most common types by far are:

*Sieve trays* (Fig. 14-18*a*) are perforated plates. The velocity of upflowing gas keeps the liquid from descending through the perforations (weeping). At low gas velocities, liquid weeps through the perforations, bypassing part of the tray and reducing tray efficiency. Because of this, sieve trays have relatively poor turndown.

*Fixed valve trays* (Fig. 14-18*b*) have the perforations covered by a fixed cover, often a section of the tray floor pushed up. Their performance is similar to that of sieve trays, although it has been argued (Hebert and Sandford, *Chem. Eng. Progr.*, May 2016, p. 34) that the horizontal vapor deflection in valve trays reduces the potential for entrainment.

*Moving valve trays* (Fig. 14-18*c*) have the perforations covered by movable disks (valves). Each valve rises as the gas velocity increases. The upper limit of the rise is controlled by restricting legs on the bottom of the valve (Fig. 14-18*c*) or by a cage structure around the valve. As the gas velocity falls, some valves close completely, preventing weeping. This gives the moving valve tray good turndown.

Table 14-5 is a general comparison of the three main tray types, assuming proper design, installation, and operation. Sieve and valve trays are comparable in capacity, efficiency, entrainment, and pressure drop. The turndown of moving valve trays is much better than that of sieve and fixed valve trays. Sieve trays are least expensive; valve trays cost only slightly more. Maintenance, fouling tendency, and effects of corrosion are least troublesome in fixed valve and sieve trays (provided the perforations or fixed valves are large enough) and most troublesome with moving valve trays.

Fixed valve and sieve trays prevail when fouling or corrosion is expected, or if turndown is unimportant. Moving valve trays prevail when high turndown is required. The energy saved, even during short turndown periods, usually justifies their small additional costs.

An excellent updated detailed comparison of the common tray types that reflects the current industry trend to shift to fixed valve trays was presented by Hebert and Sandford (*Chem. Eng. Progr.*, May 2016, p. 34). Caution is required in comparing tray types on capacity and efficiency because hole sizes and open area often affect these more than the tray type.

## DEFINITIONS

**Tray Area Definitions** Some of these are illustrated in Fig. 14-17.

*Total tower cross-section area* $A_T$ The inside cross-section area of the empty tower (without trays or downcomers).

*Net area* $A_N$ (also called *free area)* The total tower cross-section area $A_T$ minus the area at the top of the downcomer $A_{DT}$. The net area represents the smallest area available for vapor flow in the intertray spacing.

*Bubbling area* $A_B$ (also called *active area)* The total tower cross-section area minus the sum of downcomer top area $A_{DT}$, downcomer seal area $A_{DB}$, and any other nonperforated areas on the tray. The bubbling area represents the area available for vapor flow just above the tray floor.

*Hole area* $A_h$ The total area of the perforations on the tray. The hole area is the smallest area available for vapor passage on a sieve tray.

*Slot area* $A_S$ The total (for all open valves) vertical curtain area through which vapor passes in a horizontal direction as it leaves the valves. It is a function of the narrowest opening of each valve and the number of valves that are open. The slot area is normally the smallest area available for vapor flow on a valve tray.

*Open slot area* $A_{SO}$ The slot area when all valves are open.

*Fractional hole area* $A_f$ The ratio of hole area to bubbling area (sieve trays) or slot area to bubbling area (valve trays).

**Vapor and Liquid Load Definitions** F-*factor* F This is the square root of the kinetic energy of the gas, defined by Eq. (14-76). The velocity in Eq. (14-76) is usually (not always) based on the tower cross-sectional area $A_T$, the net area $A_N$, or the bubbling area $A_B$. The user should beware of any data for which the area basis is not clearly specified.

$$F = u\sqrt{\rho_G} \tag{14-76}$$

C-*factor* C The *C*-factor, defined in Eq. (14-77), is the best gas load term for comparing capacities of systems of different physical properties. It has the same units as velocity (m/s or ft/s) and is directly related to droplet entrainment. As with the *F*-factor, the user should beware of any data for which the area basis is not clearly specified.

$$C = u\sqrt{\frac{\rho_G}{\rho_L - \rho_G}} \tag{14-77}$$

*Weir load* For trays (as distinct from downcomers), liquid load is normally defined as

$$Q_L = \frac{\text{volume of liquid}}{\text{length of outlet weir}} = \frac{Q}{L_w} \tag{14-78}$$

This definition describes the flux of liquid horizontally across the tray. Units often used are $m^3/(h \cdot m)$, $m^3/(s \cdot m)$, gpm/in, and gpm/ft.

*Downcomer liquid load* For downcomer design, the liquid load is usually defined as the liquid velocity at the downcomer entrance (m/s or ft/s):

$$Q_D = \frac{\text{volume of liquid}}{\text{downcomer entrance area}} = \frac{Q}{A_{DT}} \tag{14-79}$$

## FLOW REGIMES ON TRAYS

Three main flow regimes exist on industrial distillation trays. These regimes may all occur on the same tray under different liquid and gas flow rates (Fig. 14-19). An excellent discussion of the fundamentals and modeling of these flow regimes was presented by Lockett (*Distillation Tray Fundamentals,* Cambridge University Press, Cambridge, 1986). An excellent overview of these as well as less common flow regimes was given by Prince (*PACE,* June 1975, p. 31; July 1975, p. 18).

*Froth regime (or mixed regime; Fig. 14-20*a*).* This is the most common operating regime in distillation practice. Each perforation bubbles vigorously. The bubbles circulate rapidly through the liquid, are of nonuniform sizes and shapes, and travel at varying velocities. The froth surface is mobile and not level and is generally covered by droplets. Bubbles are formed at the tray perforations and are swept away by the froth.

As gas load increases in the froth regime, jetting begins to replace bubbling in some holes. The fraction of holes that is jetting increases with gas velocity. When jetting becomes the dominant mechanism, the dispersion

**FIG. 14-18** Common tray types. (*a*) Sieve. (*b*) Fixed valve. (*c*) Moving valve with legs. [*Part a, from Henry Z. Kister*, Chem. Eng., *September 8, 1980; reprinted courtesy of* Chemical Engineering. *Part b, Courtesy of Sulzer Chemtech and Fractionation Research Inc. (FRI). Part c, courtesy of Koch-Glitsch LP.*]

**TABLE 14-5 Comparison of the Common Tray Types**

| | Sieve trays | Fixed valve tray | Moving valve tray |
|---|---|---|---|
| Capacity | High | High | High to very high |
| Efficiency | High | High | High |
| Turndown | About 2:1. Not generally suitable for operation under variable loads | About 2.5:1. Not generally suitable for operation under variable loads | About 4:1 to 5:1. Some special designs achieve 8:1 or more |
| Entrainment | Moderate | Moderate | Moderate |
| Pressure drop | Moderate | Moderate | Slightly higher |
| Cost | Low | Low | About 20 percent higher |
| Maintenance | Low | Low | Moderate |
| Fouling tendency | Low to very low | Low to very low | Moderate |
| Effects of corrosion | Low | Very low | Moderate |
| Main applications | (1) Most columns when turndown is not critical (2) High fouling and corrosion potential | (1) Most columns when turndown is not critical (2) High fouling and corrosion potential | (1) Most columns (2) Services where turndown is important |

changes from froth to spray. Prado et al. [*Chemical Engineering Progr.* **83**(3): 32 (1987)] showed that the transition from froth to spray takes place gradually as jetting replaces bubbling in 45 to 70 percent of the tray holes.

*Emulsion regime (Fig. 14-20*b*).* At high liquid loads and relatively low gas loads, the high-velocity liquid bends the swarms of gas bubbles leaving the orifices and tears them off, so most of the gas becomes emulsified as small bubbles within the liquid. The mixture behaves as a uniform two-phase fluid, which obeys the Francis weir formula [see the subsection Pressure Drop and Eq. (14-109) (Hofhuis and Zuiderweg, *IChemE Symp. Ser.* **56:** 2.2/1 (1979); Zuiderweg, *Int. Chem. Eng.* **26**(1): 1 (1986)]. In industrial practice, the emulsion regime is the most common in high-pressure and high-liquid-rate operation.

*Spray regime (or drop regime, Fig. 14-20*c*).* At high gas velocities and low liquid loads, the liquid pool on the tray floor is shallow and easily atomized by the high-velocity gas. The dispersion becomes a turbulent cloud of liquid droplets of various sizes that reside at high elevations above the tray and follow free trajectories. Some droplets are entrained to the tray above, while others fall back into the liquid pools and become reatomized. In contrast to the liquid-continuous froth and emulsion regimes, the phases are reversed in the spray regime: here the gas is the continuous phase, while the liquid is the dispersed phase.

The spray regime often occurs where gas velocities are high and liquid loads are low (e.g., vacuum and rectifying sections at low liquid loads).

*Three-layered structure.* Van Sinderen, Wijn, and Zanting [*Trans. IChemE.* **81:** Part A, p. 94 (January 2003)] postulate a tray dispersion consisting of a bottom liquid-rich layer where jets/bubbles form; an intermediate liquid-continuous froth layer where bubbles erupt, generating drops; and a top gas-continuous layer of drops. The intermediate layer that dampens the bubbles and jets disappears at low liquid rates, and the drop layer approaches the tray floor, similar to the classic spray regime.

## PRIMARY TRAY CONSIDERATIONS

**Number of Passes** Tray liquid may be split into two or more flow passes to reduce tray liquid load $Q_L$ (Fig. 14-21). Each pass carries $1/N_p$ fraction of the total liquid load (e.g., ¼ in four-pass trays). Liquid in each pass reverses direction on alternate trays. Two-pass trays have perfect symmetry with full remixing in the center downcomers. Four-pass trays are symmetric along the centerline, but the side and central passes are nonsymmetric. Also, the center and off-center downcomers only partially remix the liquid, allowing any maldistribution to propagate. Maldistribution can cause major loss of efficiency and capacity in four-pass trays. Three-pass trays are even more prone to maldistribution due to their complete nonsymmetry. Most designers avoid three-pass trays altogether, jumping from two to four passes. Good practices for liquid and vapor balancing and for avoiding maldistribution in multipass trays were described by Pilling (*Chemical Engineering Progr.,* June 2005, p. 22), Bolles [*AIChE J.* **22**(1): 153 (1976)], and Kister (*Distillation Operation,* McGraw-Hill, New York, 1990).

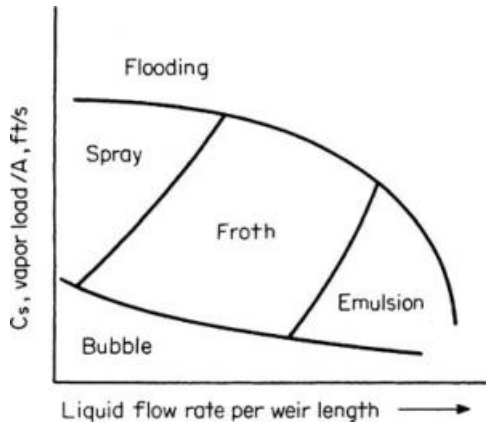

**FIG. 14-19** The flow regime likely to exist on a distillation tray as a function of vapor and liquid loads. (*From H. Z. Kister,* Distillation Design*, copyright ©1992 by McGraw-Hill; reprinted by permission.*)

Common design practice is to minimize the number of passes, resorting to a larger number only when the liquid load exceeds 100 to 140 $m^3/(h \cdot m)$ (11 to 15 gpm/in) of outlet weir length (Davies and Gordon, *Petro/Chem Eng.*, December 1961, p. 228). Trays smaller than 1.5 m (5 ft) in diameter seldom use more than a single pass; those with 1.5- to 3-m (5- to 10-ft) diameters seldom use more than two passes. In high liquid services with towers larger than 4 m (13 ft) in diameter four pass trays are common, and in some "mega towers" (larger than 7-m, or 23-ft in diameter) 6 or 8 pass trays are used.

**Tray Spacing** Taller spacing between successive trays raises capacity, leading to a smaller tower diameter, but it also raises tower height. There is an economic tradeoff between tower height and diameter. As long as the tradeoff exists, tray spacing has little effect on tower economics and is set to provide adequate access. In towers larger than 1.5 m (5 ft) in diameter, tray spacing is typically 600 mm (24 in), large enough to permit a worker to crawl between trays. In very large towers (>6-m or 20-ft diameter), tray spacings of 750 mm (30 in) are often used. In chemical towers (as distinct from petrochemical, refinery, and gas plants), 450 mm (18 in) has been a popular tray spacing. With towers smaller than 1.5 m (5 ft), tower walls are reachable from the manways, there is no need to crawl, and it becomes difficult to support thin and tall columns, so smaller tray spacing (typically 380 to 450 mm or 15 to 18 in) is favored. Towers taller than 50 m (160 ft) also favor smaller tray spacings (400 to 450 mm or 16 to 18 in). Finally, cryogenic towers enclosed in cold boxes favor very small spacings, as small as 150 to 200 mm (6 to 8 in), to minimize the size of the cold box.

More detailed considerations for setting tray spacing were discussed by Kister (*Distillation Operation,* McGraw-Hill, New York, 1990) and Mukherjee (*Chem. Eng.,* September 2005, p. 53).

**Outlet Weir** The outlet weir should maintain a liquid level on the tray high enough to provide sufficient gas–liquid contact without causing excessive pressure drop, downcomer backup, or a capacity limitation. Weir heights are usually set at 40 to 80 mm (1.5 to 3 in). In this range, weir heights have little effect on distillation efficiency [Van Winkle, *Distillation,* McGraw-Hill, New York, 1967; Kreis and Raab, *IChemE Symp. Ser.* **56:** 3.2/63 (1979); Kister, *Chem. Eng. Prog.*, June 2008, p. 39]. In operations where long residence times are necessary (e.g., chemical reaction, absorption, stripping, dust and mist scrubbing), taller weirs do improve efficiency, weirs 80 to 100 mm (3 to 4 in) are more common (Lockett, *Distillation Tray Fundamentals,* Cambridge University Press, Cambridge, UK, 1986), and success has been reported with up to 300 mm (12 in) weirs (Flowers, Evans, and Payne, Distillation Topical Conference, AIChE Spring Meeting, April 2018, Orlando, Florida).

Adjustable weirs (Fig. 14-22*a*) are used to provide additional flexibility. They are uncommon with conventional trays, but they are used with some proprietary trays. Swept-back weirs (Fig. 14-22*b*) are used to extend the effective length of side weirs, either to help balance liquid flows to nonsymmetric tray passes or to reduce the tray liquid loads. Picket fence weirs (Fig. 14-22*c*) are used to shorten the effective length of a weir, either to help balance multipass trays' liquid flows (they are used in center and

off-center weirs) or to raise tray liquid load and prevent drying in low-liquid-load services. To be effective, the pickets (or "weir blocks") need to be tall, typically around 300 to 400 mm (12 to 16 in) above the top of the weir. Excessive picketing (>70%) of the outlet weir length may induce excessive entrainment and premature flooding and should generally be avoided. An excellent discussion of weir picketing practices was provided by Summers and Sloley (*Hydroc. Proc.,* January 2007, p. 67).

**Downcomers** A downcomer is the drainpipe of the tray. It conducts liquid from one tray to the tray below. The fluid entering the downcomer is far from pure liquid; it is essentially the froth on the tray, typically 20 to 30 percent liquid by volume, with the balance being gas. Due to the density difference, most of this gas disengages in the downcomer and vents back to the tray from the downcomer entrance. Some gas bubbles usually remain in the liquid even at the bottom of the downcomer, ending on the tray below [Lockett and Gharani, *IChemE Symp. Ser.* **56:** 2.3/43 (1979)].

The straight, segmental vertical downcomer (Fig. 14-23*a*) is the most common downcomer geometry. It is simple and inexpensive and gives good use of the tower area for downflow. Circular downcomers (downpipes) (Fig. 14-23*b*) are cheaper, but they use tower area poorly and are only suitable for very low liquid loads. Sloped downcomers (Fig. 14-23*c, d*) improve

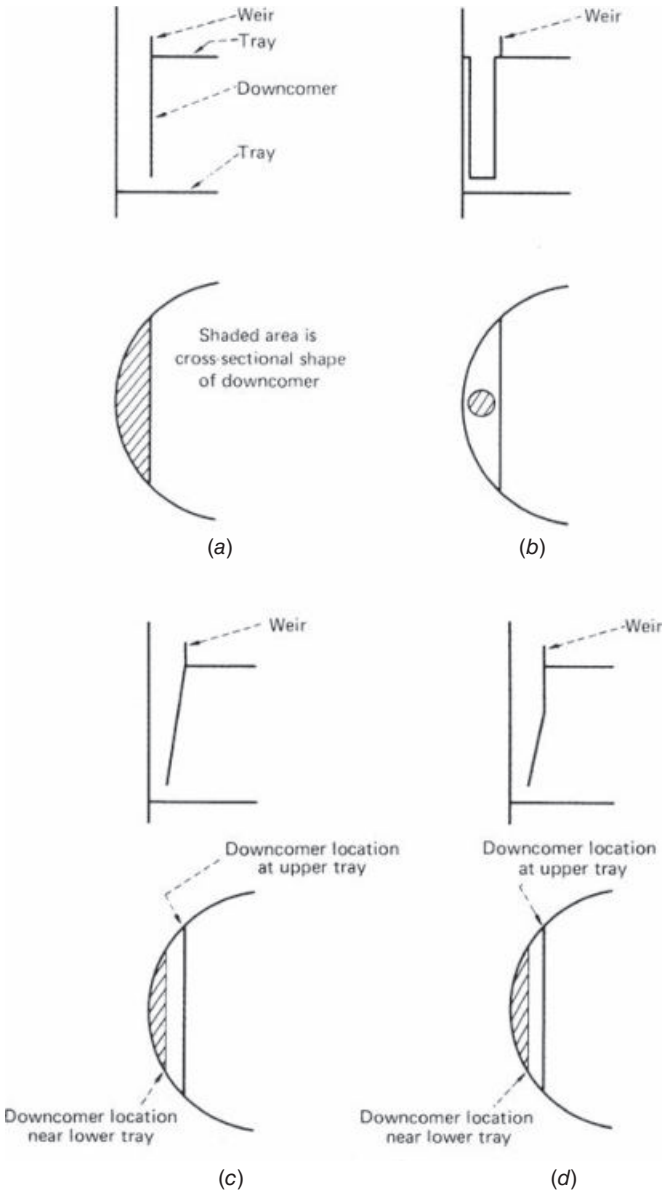

**FIG. 14-23** Common downcomer types. (*a*) Segmental. (*b*) Circular. (*c, d*) Sloped. (*From Henry Z. Kister, Chem. Eng., December 29, 1980; reprinted courtesy of* Chemical Engineering.)

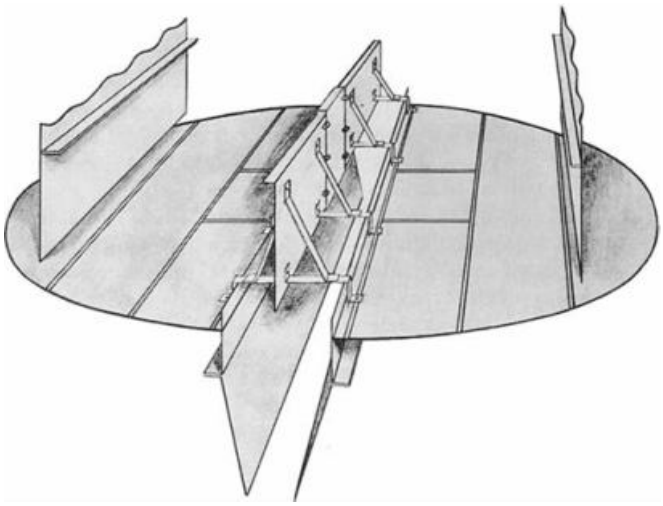

**FIG. 14-24** Antijump baffle. (*Reprinted courtesy of Koch-Glitsch LP.*)

tower area use for downflow. They provide sufficient area and volume for gas–liquid disengagement at the top of the downcomer, gradually narrowing as the gas disengages, minimizing the loss of bubbling area at the foot of the downcomer. Sloped downcomers are invaluable when large downcomers are required such as at high liquid loads, high pressures, and foaming systems. In conventional trays, typical ratios of downcomer top to bottom areas are 1.5 to 2, and higher ratios are used in some high-capacity trays (see later discussion).

*Antijump baffles* (Fig. 14-24) are sometimes installed just above center and off-center downcomers of multipass trays to prevent liquid from one pass skipping across the downcomer onto the next pass. Such liquid jump adds to the liquid load on each pass, leading to premature flooding. These baffles are essential with proprietary trays that induce forward push (see later discussion).

**Clearance Under the Downcomer** Restricting the downcomer bottom opening prevents gas from the tray from rising up the downcomer and interfering with its liquid descent (*downcomer unsealing*). A common design practice makes the downcomer clearance 13 mm (0.5 in) lower than the outlet weir height (Fig. 14-25) to ensure submergence at all times (Davies and Gordon, *Petro/Chem Eng.,* November 1961, p. 250). This practice is sound in the froth and emulsion regimes, where tray dispersions are liquid continuous, but it is ineffective in the spray regime, where tray dispersions are gas

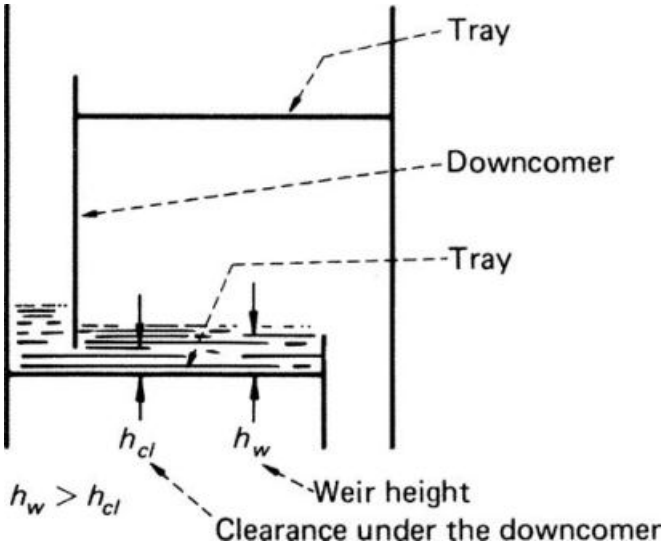

**FIG. 14-25** A common design practice of ensuring a positive downcomer seal. (*From Henry Z. Kister, Chem. Eng., December 29, 1980; reprinted courtesy of* Chemical Engineering.)

continuous and there is no submergence. Also, this practice can be unnecessarily restrictive at high liquid loads where high crests over the weirs sufficiently protect the downcomers from gas rise. Generally, downcomer clearances in the spray regime need to be smaller, while those in the emulsion regime can be larger, than those set by the above practice. Seal pans and inlet weirs are devices sometimes used to help with downcomer sealing while keeping downcomer clearances large. Details are in Kister's book (*Distillation Operation,* McGraw-Hill, New York, 1990).

**Hole Sizes** Small holes slightly enhance tray capacity when limited by entrainment flood. Reducing sieve hole diameters from 13 to 5 mm (½ to $^3/_{16}$ in) at a fixed hole area typically enhances capacity by 3 to 8 percent, more at low liquid loads. Small holes are effective for reducing entrainment and enhancing capacity in the spray regime [$Q_L < 20$ m$^3$/(h·m) of weir]. Hole diameter has only a small effect on pressure drop, tray efficiency, and turndown.

On the debit side, the plugging tendency increases exponentially as hole diameters diminish. Smaller holes are also more prone to corrosion. While 5-mm ($^3/_{16}$-in) holes easily plug even with scale and rust, 13-mm (½-in) holes are quite robust and are therefore very common. The small holes are only used in clean, noncorrosive services. Holes smaller than 5 mm are usually avoided because they require drilling (larger holes are punched), which is much more expensive. For highly fouling services, 19- to 25-mm (¾- to 1-in) holes are preferred.

Similar considerations apply to fixed valves. Small fixed valves have a slight capacity advantage, but they are far more prone to plugging than larger fixed valves.

For round moving valves, a common orifice size is 39 mm (117/32 in). The float opening is usually of the order of 8 to 10 mm (0.3 to 0.4 in).

In recent years there has been a trend toward minivalves, both fixed and moving. These are smaller and therefore give a slight capacity advantage while being more prone to plugging.

**Fractional Hole Area** Typical sieve and fixed valve tray hole areas are 8 to 12 percent of the bubbling areas. Smaller fractional hole areas bring about a capacity reduction when limited by entrainment or downcomer backup flood or by excessive pressure drop. At above 12 percent of the bubbling areas, the capacity gains from higher hole areas become marginal, while weeping, and at high liquid loads also channeling, escalate.

Typical open-slot areas for moving valve trays are 14 to 15 percent of the bubbling area. Here the higher hole areas can be afforded due to the high turndown of the valves.

Moving valves can have a sharp or a smooth ("venturi") orifice. The venturi valves have one-half the dry pressure drop of the sharp-orifice valves, but they are far more prone to weeping and channeling than the sharp-orifice valves. Sharp orifices are almost always preferred.

**Multipass Balancing** There are two balancing philosophies: equal bubbling areas and equal flow path lengths. Equal bubbling areas means that all active area panels on Fig. 14-21*d* are of the same area, and each panel has the same hole (or open-slot) area. In a four-pass tray, one-quarter of the gas flows through each panel. To equalize the $L/G$ ratio on each panel, the liquid needs to be split equally to each panel. Since the center weirs are longer than the side weirs, more liquid tends to flow toward the center weir. To equalize, side weirs are often swept back (Fig. 14-22*b*), while center weirs often contain picket fences (Fig. 14-22*c*).

The alternative philosophy (equal flow path lengths) provides more bubbling and perforation areas in the central panels of Fig. 14-21*d* and less in the side panels. To equalize the $L/G$ ratio, less liquid needs to flow toward the sides, which is readily achieved because the center weirs are naturally longer than the side weirs. Usually there is no need for swept-back weirs, and only minimal picket fencing is required at the center weir.

Equal flow path panels are easier to fabricate and are cheaper, while equal bubbling areas have a robustness and reliability advantage due to the ease of equally splitting the fluids. The author had good experience with both when they were well designed. Pass balancing is discussed in detail by Pilling (*Chem. Eng. Prog.,* June 2005, p. 22) and by Jaguste and Kelkar (*Hydroc. Proc.,* March 2006, p. 85).

**Channel Baffles** Excessive weeping is a major issue in services that handle large liquid loads with small vapor loads. To prevent weeping, the hole area can be reduced, but when it is reduced below about 5 percent of the bubbling area vapor–liquid contact suffers. For these cases, channel baffles (or downsizing baffles) can be used (Fig. 14-26) to block out a large fraction of the active area. The only vapor–liquid contact area is between the baffles, with the regions to the sides of the baffles blanked off. Their common design strategy is to largely reduce the bubbling area with only a small reduction in weir length (to accommodate the high weir load). The full flow path length is preserved (Fig. 14-26) to permit good contacting and efficiency. Summers and Chambers (Kister Distillation Symposium Proceedings, AIChE Spring Meeting, Austin, Tex., 2015) provide an excellent description of the good practices for channel baffles.

**FIG. 14-26** A tray with channel baffles. The only active area is between the baffles. The area to the sides of the baffles is blanked. (*Courtesy of Sulzer Chemtech AG.*)

## TRAY CAPACITY ENHANCEMENT

High-capacity trays evolved from conventional trays by including one or more capacity enhancement features such as those discussed below. These features enhance not only the capacity but usually also the complexity and cost. These features have varying impact on the efficiency, turndown, plugging resistance, pressure drop, and reliability of the trays.

**Truncated Downcomers/Forward Push Trays** Truncated downcomers/forward push trays include the Nye™ Tray, Maxfrac™ (Fig. 14-27*a*), Triton™, and MVGT™. In all these, the downcomer from the tray above terminates about 100 to 150 mm (4 to 6 in) above the tray floor. Liquid from the downcomer issues via holes or slots, directed downward or in the direction of liquid flow. The tray floor under each downcomer is equipped with fixed valves or side perforations. Gas issuing in this region, typically 10 to 20 percent of the total tray gas, is deflected horizontally in the direction of liquid flow by the downcomer floor. This horizontal gas flow pushes liquid droplets toward the tower wall directly above the outlet downcomer. The tower wall catches this liquid and directs it downward into the downcomer. This deentrains the gas space. In multipass trays, antijump baffles (Fig. 14-24), typically 300 mm or taller, are installed above center and off-center downcomers to catch the liquid and prevent its jumping from pass to pass. The rest of the tray features are similar to those of conventional trays. The tray floor may contain fixed valves, moving valves, or sieve holes.

Trays from this family are proprietary, and they have been extensively used in the last three decades with great success. Compared to equivalent conventional trays, the truncated downcomer/forward push trays give about 8 to 12 percent more gas-handling capacity at much the same efficiency.

**High Top-to-Bottom Downcomer Area and Forward Push** Sloping downcomers from top to bottom raises the available tray bubbling area and, therefore, the gas-handling capacity (see the subsection Downcomers). As long as the ratio of top to bottom areas is not excessive, sloping does not lower downcomer capacity. Downcomer choke flood restricts the downcomer entrance, not exit, because there is much less gas at the downcomer bottom. However, a high top-to-bottom area ratio makes the downcomer bottom a very short chord, which makes distribution of liquid to the tray below difficult. To permit high top-to-bottom area ratios, some trays use a special structure (Fig. 14-27*b*) to change the downcomer shape from segmental to semiarc or multichordal. This high ratio of top to bottom areas, combined with forward push (above) imparted by bubblers and directional fixed or moving valves, and sometimes directional baffles, is used in trays such as Superfrac™ III (Fig. 14-27*b*) and IV and V-Grid Plus™. When the downcomer inlet areas are large, these trays typically gain 15 to 20 percent capacity compared to equivalent conventional trays at much the same efficiency. Trays from this family are proprietary, and they have been used successfully for about two decades.

**Large Number of Truncated Downcomers** These include the MD™ (Fig. 14-27*c*) and Hi-Fi™ trays. The large number of downcomers raises the total weir length, moving tray operation toward the peak capacity point of 20 to 30 $m^3/(h \cdot m)$ (2 to 3 gpm/in) of outlet weir (see Fig. 14-30). The truncated downcomers extend about halfway to the tray below, discharging their liquid via holes or slots at the downcomer floor. The area directly under the downcomers is perforated or valved, and there is enough open height between the tray floor and the bottom of the downcomer for this perforated or valved area to be effective in enhancing the tray bubbling area.

Trays from this family are proprietary and have been successfully used for about five decades. Their strength is in high-liquid-load services where reducing weir loads provides major capacity gains. Compared to conventional trays, they can gain as much as 20 to 30 percent capacity but at an efficiency loss. The efficiency loss is of the order of 10 to 20 percent due to the large reduction in flow path length (see the subsection Tray Efficiency). When using these trays, the separation is maintained by either using more trays (typically at shorter spacing) or raising reflux and boilup. This lowers the net capacity gains to 10 to 20 percent above conventional trays. In some variations, forward push slots and antijump baffles are incorporated to enhance the capacity by another 10 percent.

**Radial Trays** These include the Slit™ tray and feature radial flow of liquid. In the efficiency-maximizing A variation (Fig. 14-27*d*), a multipipe distributor conducts liquid from each center downcomer to the periphery of the tray below, so liquid flow is from periphery to center on each tray. The capacity-maximizing B variation has central and peripheral (ring) downcomers on alternate trays, with liquid flow alternating from center-to-periphery to periphery-to-center on successive trays. The trays are arranged at small spacings (typically, 200 to 250 mm, or 8 to 10 in) and contain small fixed valves. Slit trays are used in chemical and pharmaceutical low-liquid-rate applications [<40 $m^3/(h \cdot m)$ or 4 gpm/in of outlet weir], typically at pressures ranging from moderate vacuum to slight superatmospheric.

**Centrifugal Force Deentrainment** These trays use a contact step similar to that in conventional trays, followed by a separation step that disentrains the tray dispersion by using centrifugal force. Separation of entrained liquid before the next tray allows very high gas velocities, as high as 50 percent above the system limit (see the subsection System Limit: The Ultimate Capacity of Fractionators), to be achieved. The capacity of these trays can be over 50 percent above that of conventional trays. The efficiency of these trays can be 20 percent less than that of conventional trays due to their typical very short flow paths (see the subsection Tray Efficiency).

These trays include the Ultrfrac™, the ConSep™ (Fig. 14-27*e*), and the Swirl Tube™ trays. This technology has been sporadically used in Eastern Europe for quite some time. It is now making inroads into distillation in the rest of the world, and it looks very promising.

## OTHER TRAY TYPES

**Bubble-Cap Trays (Fig. 14-28*a*)** These are flat perforated plates with risers (chimneylike pipes) around the holes, and caps in the form of inverted cups over the risers. The caps are usually (but not always) equipped with slots through which some of the gas comes out, and may be round or rectangular. Liquid and froth are trapped on the tray to a depth at least equal to the riser or weir height, giving the bubble-cap tray a unique ability to operate at very low gas and liquid rates.

The bubble-cap tray was the workhorse of distillation before the 1960s. It was superseded by the much cheaper (as much as 10 times) sieve and valve trays. Compared to the bubble-cap trays, sieve and valve trays also offer slightly higher capacity and efficiency and lower entrainment and pressure drop, and they are less prone to corrosion and fouling. Today, bubble-cap trays are only used in special applications where liquid or gas rates are very low. A large amount of information on bubble-cap trays is documented in several texts (e.g., Bolles in B. D. Smith, *Design of Equilibrium Stage Processes,* McGraw-Hill, New York, 1963; Bolles, *Pet. Proc.,* February 1956, p. 65; March 1956, p. 82; April 1956, p. 72; May 1956, p. 109; Ludwig, *Applied Process Design for Chemical and Petrochemical Plants,* 2d ed., vol. 2, Gulf Publishing, Houston, 1979).

**Dual-Flow Trays** These are sieve trays with no downcomers (Fig. 14-28*b*). Liquid continuously weeps through the holes, hence their low efficiency. At peak loads they are typically 5 to 10 percent less efficient than sieve or valve trays, but as the gas rate is reduced, the efficiency gap rapidly widens, giving poor turndown. The absence of downcomers gives dual-flow trays more area, and therefore greater capacity, less entrainment, and less pressure drop, than conventional trays. Their pressure drop is further reduced by their large fractional hole area (typically 18 to 30 percent of the tower area). However, this low pressure drop also renders dual-flow trays prone to gas and liquid maldistribution.

In general, gas and liquid flows pulsate, with a particular perforation passing both gas and liquid intermittently, but seldom simultaneously. In

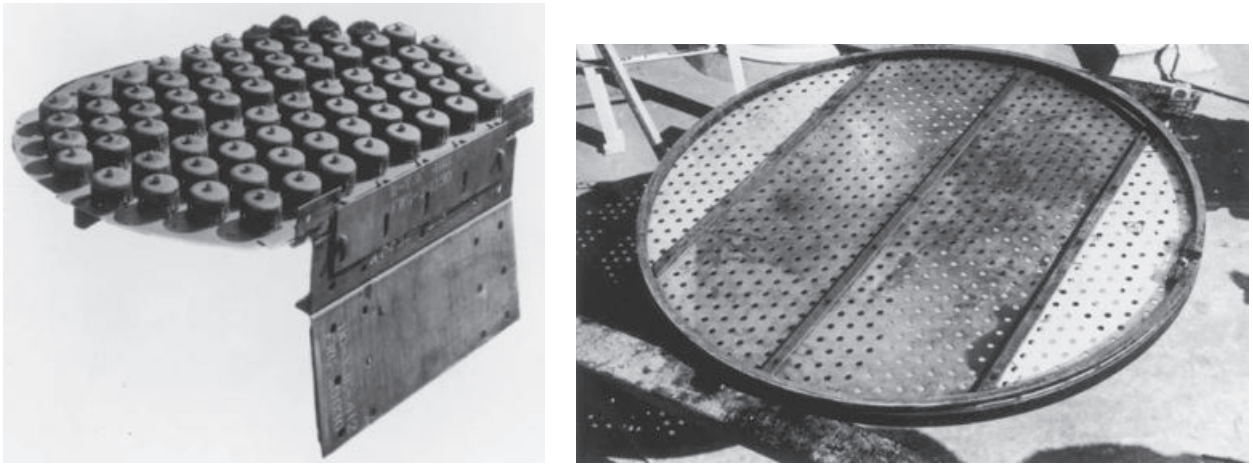
large-diameter (>2.5 m, or 8 ft) dual-flow trays, the pulsations sometimes develop into sloshing, instability, and vibrations. The Ripple Tray™ is a proprietary variation in which the tray floor is corrugated to minimize this instability.

With large holes (16 to 25 mm), dual-flow trays are some of the most fouling-resistant and corrosion-resistant devices in the industry. This defines their main application: highly fouling services, slurries, and corrosive services. Dual-flow trays are also the least expensive and easiest to install and maintain.

A wealth of information for the design and rating of dual-flow trays, much of it originating from FRI data, was published by Garcia and Fair [*Ind. Eng. Chem. Res.* **41:**1632 (2002)].

**Baffle Trays** Baffle trays ("shed decks," "shower decks") (Fig. 14-29*a*) are solid half-circle plates, sloped slightly in the direction of outlet flow,



(*a*) (*b*)

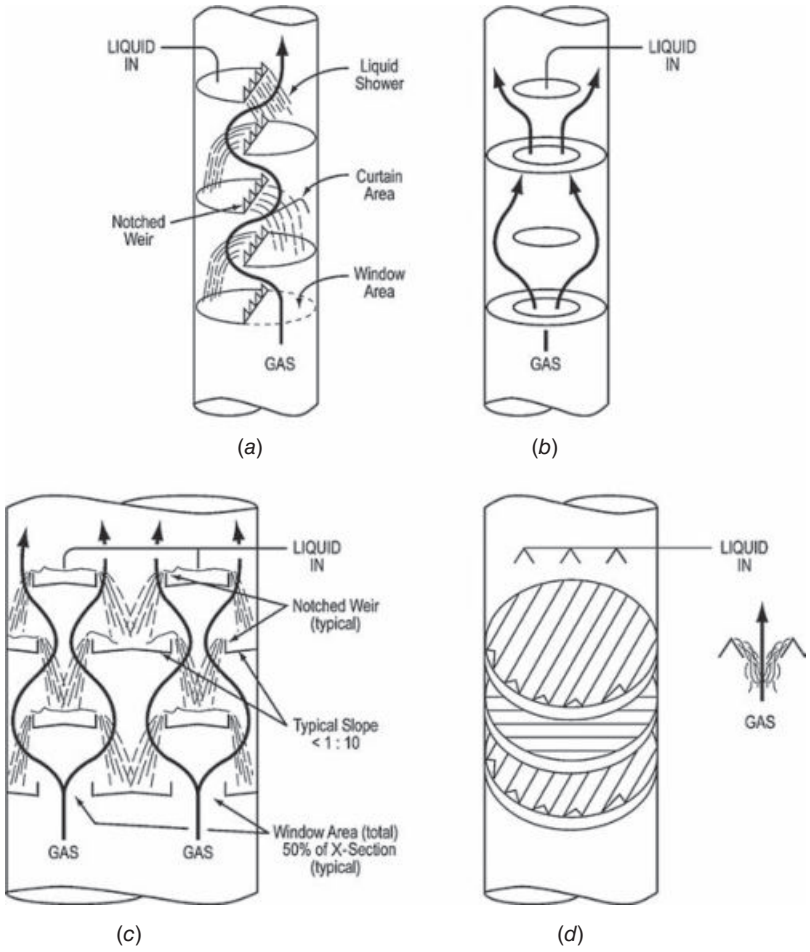
with or without weirs at the end. Gas contacts the liquid as it showers from the plate. This contact is inefficient, typically giving 30 to 40 percent of the efficiency of conventional trays. This limits their application mainly to heat-transfer and scrubbing services. The capacity is high and pressure drop is low due to the high open area (typically 50 percent of the tower cross-sectional area). Since there is not much that can plug up, the baffle trays are perhaps the most fouling-resistant devices in the industry, and their main application is in extremely fouling services. To be effective in these services, their liquid rate needs to exceed 20 $m^3/(h \cdot m)$ (2 gpm/in) of outlet weir and dead spots formed due to poor support design eliminated (Kister, *Distillation Troubleshooting*, Wiley, New York, 2006).



(*a*) (*b*) (*c*) (*d*)

**FIG. 14-29** Baffle tray variations. (*a*) Segmental. (*b*) Disk and doughnut. (*c*) Multipass. (*d*) Angle irons.

There are several geometric variations. The disk and doughnut trays (Fig. 14-29*b*) replace the half-circle segmental plates with alternate plates shaped as disks and doughnuts, each occupying about 50 percent of the tower cross-sectional area. In large towers, multipass baffle trays (Fig. 14-29*c*) are used. Another variation uses angle irons, with one layer oriented at 90° to the one below (Fig. 14-29*d*). Multipass baffle trays, as well as angle irons, require good liquid (and to a lesser extent, also good gas) distribution, as has been demonstrated from field heat-transfer measurements [Kister and Schwartz, *Oil & Gas J.,* p. 50 (May 20, 2002)]. Excellent overviews of the fundamentals and design of baffle trays were given by Fair and Lemieux (Fair, *Hydro. Proc.,* May 1993, p. 75; Lemieux, *Hydroc. Proc.,* September 1983, p. 106). Mass-transfer efficiency data with baffle trays by Fractionation Research Inc. (FRI) have been released and presented together with their correlation (Fair, paper presented at the AIChE Annual Meeting, San Francisco, November 2003). Kister and Olsson (*Chem. Eng. Prog.*, July 2011, p. 22) analyzed published test data from FRI and others, as well as plant data, to derive an improved baffle tray flood correlation based on the liquid velocity through the windows.

## FLOODING

Flooding is by far the most common upper capacity limit of a distillation tray. The column diameter is set to ensure that the column can achieve the required throughput without flooding. Towers are usually designed to operate at 80 to 90 percent of the flood limit.

Flooding is an excessive accumulation of liquid inside a column. Flood symptoms include a rapid rise in pressure drop (the accumulating liquid increases the liquid head on the trays), liquid carryover from the column top, reduction in bottom flow rate (the accumulating liquid does not reach the tower bottom), and instability (accumulation is non-steady-state). This liquid accumulation is generally induced by one of the following mechanisms.

**Entrainment (Jet) Flooding** Froth or spray height rises with gas velocity. As the froth or spray approaches the tray above, some of the liquid is aspirated into the tray above as entrainment. Upon a further increase in gas flow rate, massive entrainment of the froth or spray begins, causing liquid accumulation and flood on the tray above.

Entrainment flooding can be subclassified into *spray entrainment flooding* (common) and *froth entrainment flooding* (uncommon). Froth entrainment flooding occurs when the froth envelope approaches the tray above, and it is therefore only encountered with small tray spacings (<450 mm or 18 in) in the froth regime. At larger (and often even lower) tray spacing, the froth breaks into spray well before the froth envelope approaches the tray above.

The entrainment flooding prediction methods described here are based primarily on spray entrainment flooding. Considerations unique to froth entrainment flooding can be found elsewhere (Kister, *Distillation Design,* McGraw-Hill, New York, 1992).

**Spray Entrainment Flooding Prediction** Most entrainment flooding prediction methods derive from the original work of Souders and Brown [*Ind. Eng. Chem.* **26**(1): 98 (1934)]. Souders and Brown theoretically analyzed entrainment flooding in terms of droplet settling velocity. Flooding occurs when the upward vapor velocity is high enough to suspend a liquid droplet, giving

$$C_{SB} = u_{S,\text{flood}} \sqrt{\frac{\rho_G}{\rho_L - \rho_G}} \tag{14-80}$$

The Souders and Brown constant $C_{SB}$ is the *C*-factor [Eq. (14-77)] at the entrainment flood point. Most modern entrainment flooding correlations retain the Souders and Brown equation (14-80) as the basis, but they depart from the notion that $C_{SB}$ is a constant. Instead, they express $C_{SB}$ as a weak function of several variables, which differ from one correlation to another. Depending on the correlation, $C_{SB}$ and $u_{S,\text{flood}}$ are based either on the net area $A_N$ or on the bubbling area $A_B$.

The constant $C_{SB}$ is roughly proportional to the tray spacing to a power of 0.5 to 0.6 (Kister, *Distillation Design,* McGraw-Hill, New York, 1992). Figure 14-30 demonstrates the effect of liquid rate and fractional hole area on $C_{SB}$. As liquid load increases, $C_{SB}$ first increases, then peaks, and finally declines. Some interpret the peak as the transition from the froth to the spray regime [Porter and Jenkins, *I. Chem. E. Symp. Ser.* **56,** Summary Paper, London (1979)]. $C_{SB}$ increases slightly with fractional hole area at lower liquid rates, but there is little effect of fractional hole area on $C_{SB}$ at high liquid rates. $C_{SB}$ slightly increases as hole diameter is reduced.

For sieve trays, the entrainment flood point can be predicted by using the method by Kister and Haas [*Chem. Eng. Progr.* **86**(9): 63 (1990)]. The method is said to reproduce a large database of measured flood points to within ±15 percent. $C_{SB,\text{flood}}$ is based on the net area. The equation is

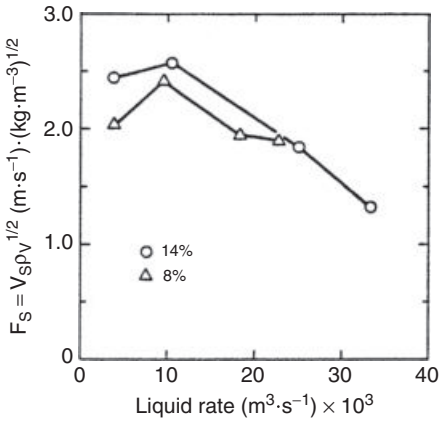


**FIG. 14-30** Effect of liquid rate and fractional hole area on flood capacity. FRI sieve tray test data, cyclohexane/*n*-heptane, 165 kPa (24 psia), $D_T$ = 1.2 m (4 ft), $S$ = 610 mm (24 in), $h_w$ = 51 mm (2 in), $d_H$ = 12.7 mm (0.5 in), straight downcomers, $A_D/A_T$ = 0.13. (*From T. Yanagi and M. Sakata,* Ind. Eng. Chem. Proc. Des. Dev. *21: 712; copyright © 1982, American Chemical Society, reprinted by permission.*)

$$C_{SB,\text{flood}} = 0.0277(d_h^2\,\sigma/\rho_L)^{0.125}(\rho_G/\rho_L)^{0.1}(\text{TS}/h_{ct})^{0.5} \tag{14-81}$$

where $d_h$ = hole diameter, mm
$\sigma$ = surface tension, mN/m (dyn/cm)
$\rho_G$, $\rho_L$ = vapor and liquid densities, kg/m$^3$
TS = tray spacing, mm
$h_{ct}$ = clear liquid height at the froth-to-spray transition, mm; obtained from:

$$h_{ct} = h_{ct,\text{H}_2\text{O}}\,(996/\rho_L)^{0.5(1-n)} \tag{14-82}$$

$$h_{ct,\text{H}_2\text{O}} = \frac{0.497\,A_f^{-0.791}d_h^{0.833}}{1 + 0.013\,Q_L^{-0.59}A_f^{-1.79}} \tag{14-83}$$

$$n = 0.00091 d_h/A_f \tag{14-84}$$

In Eq. (14-83), $Q_L$ = m$^3$ liquid downflow/(h · m weir length) and $A_f$ = fractional hole area based on active ("bubbling") area; for instance, $A_f = A_h/A_a$.

The Kister and Haas method can also be applied to valve trays, but the additional approximations reduce its data prediction accuracy for valve trays to within ±20 percent. For valve trays, adaptations of Eqs. (14-81) to (14-84) are required:

$$d_h = \frac{4 \times (\text{area of opening of one fully open valve})}{\text{wetted perimeter of opening of one fully open valve}} \tag{14-85}$$

$$A_f = \frac{\text{no. of valves} \times (\text{area of opening of one fully open valve})}{\text{active (bubbling) area}} \tag{14-86}$$

A correlation for valve tray entrainment flooding that has gained respect and popularity throughout the industry is the Glitsch "Equation 13" (Glitsch, Inc., *Ballast Tray Design Manual,* 6th ed., 1993; available from Koch-Glitsch, Wichita, Kans.). This equation has been applied successfully for valve trays from different manufacturers, as well as for sieve trays with large fractional hole areas (12 to 15 percent). With tray spacings of 600 mm and higher, its flood prediction accuracy for valve trays has generally been within ±10 percent in the author's experience. The Glitsch correlation is

$$\frac{\%\text{flood}}{100} = \frac{C_B}{\text{CAF}} + 1.359\frac{Q\,\text{FPL}}{A_B\,\text{CAF}} \tag{14-87}$$

where

$$\text{CAF} = 0.3048\,\text{CAF}_0\,\text{SF} \tag{14-88}$$

$C_B$ is the operating *C*-factor based on the bubbling area, m/s; $Q$ is the liquid flow rate, m$^3$/s; $A_B$ is the bubbling area, m$^2$; FPL is the flow path length, m, that is, the horizontal distance between the inlet downcomer and the

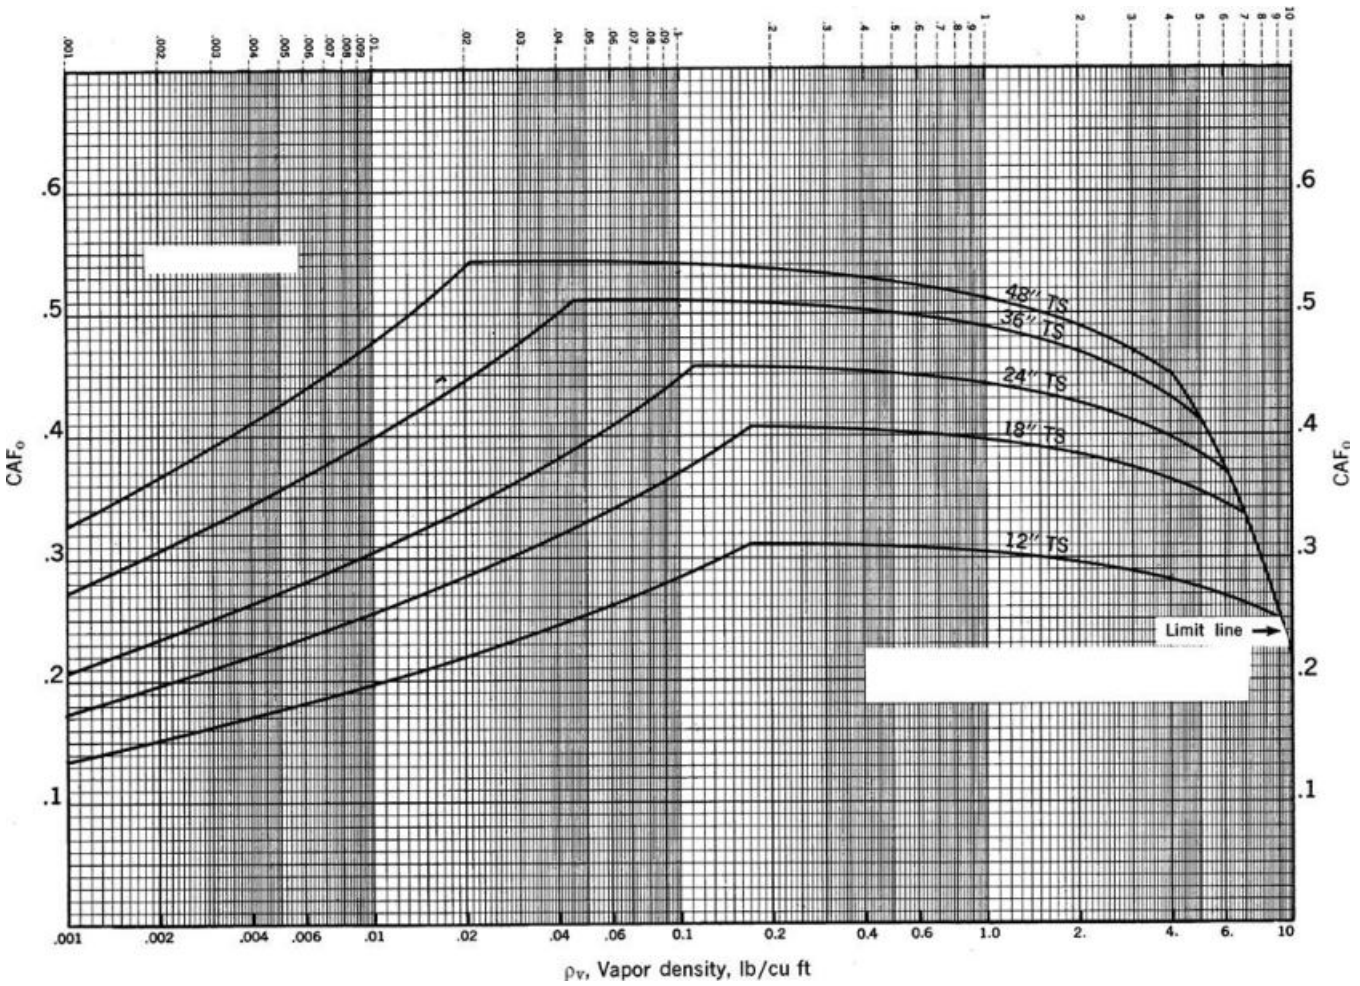

**FIG. 14-31** Flood capacity of moving valve trays. (*Courtesy of Koch-Glitch LP.*)

outlet weir. The flow path length becomes shorter as the number of passes increases. $CAF_0$ and CAF are the flood *C*-factors. $CAF_0$ is obtained from Fig. 14-31 in English units (ft/s). Equation (14-88) converts $CAF_0$ to the metric CAF (m/s) and corrects it by using a system factor SF. Values of SF are given in Table 14-9.

The Fair correlation [*Pet/Chem Eng.* **33**(10): 45 (September 1961)] for decades has been the standard of the industry for entrainment flood prediction. It uses a plot (Fig. 14-32) of surface-tension-corrected Souders and Brown flood factor $C_{SB}$ against the dimensionless flow parameter. The flow parameter represents a ratio of liquid to vapor kinetic energies:

$$F_{LG} = \frac{L}{G}\left(\frac{\rho_G}{\rho_L}\right)^{0.5} \tag{14-89}$$

Low values of $F_{LG}$ indicate vacuum operation; high values indicate operation at higher pressures or at high liquid/vapor loadings. The liquid-to-gas ratio $L/G$ is based on mass flow rates. For multipass trays, the ratio needs to be divided by the number of passes. The strength of the correlation is at the lower flow parameters. At higher flow parameters (high $L/G$ ratios, high pressures, emulsion flow), Fig. 14-32 gives excessively conservative predictions, with the low values of $C_{sbf}$ to the right likely to result from downcomer flow restrictions rather than excessive entrainment. The curves may be expressed in equation form as [Lygeros and Magoulas, *Hydrocarbon Proc.* **65**(12): 43 (1986)]:

$$C_{sbf} = 0.0105 + 8.127(10^{-4})(\mathrm{TS}^{0.755})\exp[-1.463\,F_{LG}^{0.842}] \tag{14-90}$$

where TS = plate spacing, mm.

Figure 14-32 or Eq. (14-90) may be used for sieve, valve, or bubble-cap trays. The value of the capacity parameter (ordinate term in Fig. 14-32) may be used to calculate the maximum allowable vapor velocity through the net area of the plate:

$$U_{nf} = C_{sbf}\left(\frac{\sigma}{20}\right)^{0.2}\left(\frac{\rho_L - \rho_g}{\rho_g}\right)^{0.5} \tag{14-91}$$

where $U_{nf}$ = gas velocity through net area at flood, m/s
$C_{sbf}$ = flood capacity parameter corrected for surface tension, m/s
$\sigma$ = liquid surface tension, mN/m (dyn/cm)
$\rho_L$ = liquid density, kg/m$^3$
$\rho_G$ = gas density, kg/m$^3$

The application of the correlation is subject to the following restrictions:

1. System is low or nonfoaming.
2. Weir height is less than 15 percent of tray spacing.
3. Sieve-tray perforations are 13 mm (½ in) or less in diameter.
4. Ratio of slot (bubble cap), perforation (sieve), or full valve opening (valve plate) area $A_h$ to active area $A_a$ is 0.1 or greater. Otherwise the value of $U_{nf}$ obtained from Fig. 14-32 should be corrected:

| $A_h/A_a$ | $U_{nf}/U_{nf,\text{Fig. 14-31}}$ |
|---|---|
| 0.10 | 1.00 |
| 0.08 | 0.90 |
| 0.06 | 0.80 |

where $A_h$ = total slot, perforated, or open-valve area on tray.

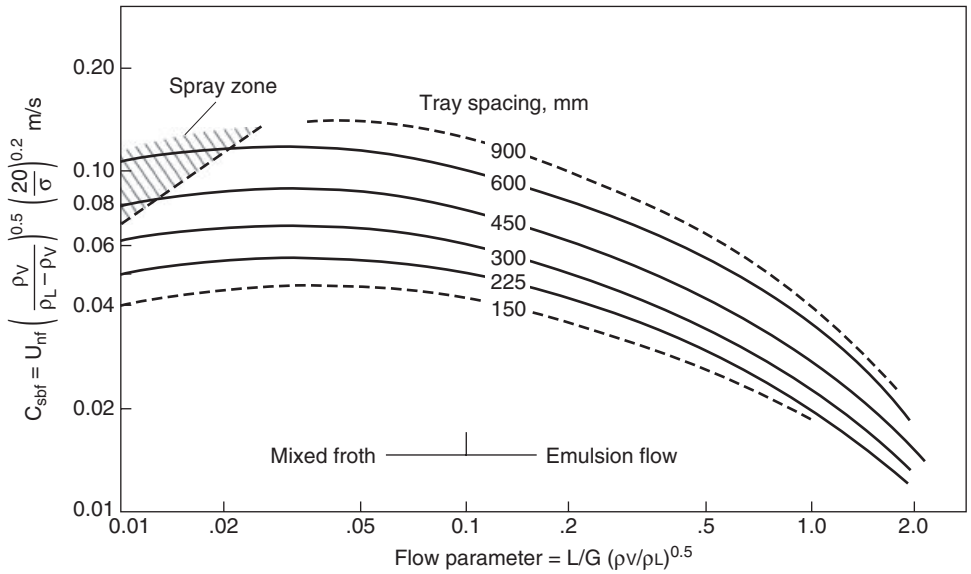

**FIG. 14-32** Fair's entrainment flooding correlation for columns with cross-flow trays (sieve, valve, bubble-cap). [*Fair, Pet/Chem Eng* ***33****(10): 45 (September 1961).*]

***Example 14-9 Flooding of a Distillation Tray*** An available sieve tray column of 2.5 m diameter is being considered for an ethylbenzene/styrene separation. An evaluation of loading at the top tray will be made. Key dimensions of the single-pass tray are:

| | |
|---|---|
| Column cross section, $m^2$ | 4.91 |
| Downcomer area, $m^2$ | 0.25 |
| Net area, $m^2$ | 4.66 |
| Active area, $m^2$ | 4.41 |
| Hole area, $m^2$ | 0.617 |
| Hole diameter, mm | 4.76 |
| Weir length, m | 1.50 |
| Weir height, mm | 38 |
| Tray spacing, mm | 500 |

Conditions and properties at the top tray are:

| | |
|---|---|
| Temperature, °C | 78 |
| Pressure, torr | 100 |
| Vapor flow, kg/h | 25,500 |
| Vapor density, $kg/m^3$ | 0.481 |
| Liquid flow, kg/h | 22,000 |
| Liquid density, $kg/m^3$ | 841 |
| Surface tension, mN/m | 25 |

*Solution.* The method of Kister and Haas gives:

$$Q_L = \frac{22{,}000}{841 \times 1.50} = 17.44 \text{ m}^3/\text{h}\cdot\text{m weir}$$

$$A_f = \frac{0.617}{4.41} = 0.14$$

By Eq. (14-83), $h_{ct,H2O} = 7.98$ mm

Eq. (14-84): $n = 0.0309$

Eq. (14-82): $h_{ct} = 8.66$ mm

Finally, by Eq. (14-81),

$$C_{SB,\text{flood}} = 0.0277[(4.76^2)(25/841)]^{0.125} \times (0.481/841)^{0.1}(500/8.66)^{0.5}$$

$$= 0.0947 \text{ m/s}$$

Alternatively, applying the Fair correlation:

The flow parameter $F_{LG} = 0.021$ [Eq. (14-89)]. From Fig. 14-31, $C_{sbf} = 0.095$ m/s. Then, correcting for surface tension, based on the net area,

$$C_{sbf} = 0.095(25/20)^{0.2} = 0.0993 \text{ m/s}$$

about 5 percent higher than the answer obtained from Kister and Haas.

For the design condition, the *C*-factor based on the net area is

$$C = \frac{25{,}500}{3600(0.481)(4.66)}\sqrt{\frac{0.481}{841-0.481}} = 0.0756 \text{ m/s}$$

or about 80 percent of flood. The proposed column is entirely adequate for the service required.

**System Limit (Ultimate Capacity)** This limit is discussed later under the subsection System Limit: The Ultimate Capacity of Fractionators.

**Downcomer Backup Flooding** Aerated liquid backs up in the downcomer because of tray pressure drop, liquid height on the tray, and frictional losses in the downcomer apron (Fig. 14-33). All these increase with increasing liquid rate. Tray pressure drop also increases as the gas rate rises. When the backup of aerated liquid exceeds the tray spacing, liquid accumulates on the tray above, causing downcomer backup flooding.

Downcomer backup is calculated from the pressure balance

$$h_{dc} = h_t + h_w + h_{ow} + h_{da} + h_{hg} \tag{14-92}$$

where $h_{dc}$ = clear liquid height in downcomer, mm liquid
$h_t$ = total pressure drop across the tray, mm liquid
$h_w$ = height of weir at tray outlet, mm liquid
$h_{ow}$ = height of crest over weir, mm liquid
$h_{da}$ = head loss due to liquid flow under downcomer apron, mm liquid
$h_{hg}$ = liquid gradient across tray, mm liquid

The heights of head losses in Eq. (14-92) should be in consistent units, e.g., millimeters or inches of liquid under operating conditions on the tray.

As noted, $h_{dc}$ is calculated in terms of equivalent clear liquid. Actually, the liquid in the downcomer is aerated and actual backup is

$$h'_{dc} = \frac{h_{dc}}{\phi_{dc}} \tag{14-93}$$

where $\phi_{dc}$ is an average *relative* froth density (ratio of froth density to liquid density) in the downcomer. Design must not permit $h'_{dc}$ to exceed the value of tray spacing plus weir height; otherwise, flooding can be precipitated.

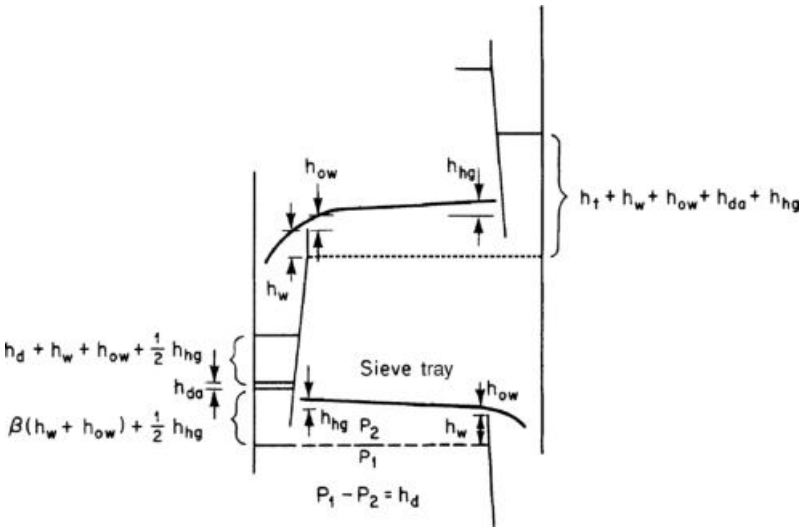

**FIG. 14-33** Pressure-drop contributions for trays. $h_d$ = pressure drop through cap or sieve, equivalent height of tray liquid; $h_w$ = height of weir; $h_{ow}$ = weir crest; $h_{hg}$ = hydraulic gradient; $h_{da}$ = loss under downcomer.

The value of $\phi_{dc}$ depends on the tendency for gas and liquid to disengage (froth to collapse) in the downcomer. For cases favoring rapid bubble rise (low gas density, low liquid viscosity, low system foamability), collapse is rapid, and fairly clear liquid fills the bottom of the downcomer (Fig. 14-17). For such cases, it is usual practice to employ a higher value of $\phi_{dc}$. For cases favoring slow bubble rise (high gas density, high liquid viscosity, high system foamability), lower values of $\phi_{dc}$ should be used. As the critical point is approached in high-pressure distillations and absorptions, special precautions with downcomer sizing are mandatory. Table 14-6 lists values of $\phi_{dc}$ commonly used by the industry.

**Downcomer Choke Flooding** This is also called downcomer entrance flood or downcomer velocity flood. A downcomer must be sufficiently large to transport all the liquid downflow. Excessive friction losses in the downcomer entrance, and/or excessive flow rate of gas venting from the downcomer in counterflow, will impede liquid downflow, initiating liquid accumulation (termed downcomer choke flooding) on the tray above. The prime design parameter is the downcomer top area. Farther down the downcomer, gas disengages from the liquid, and the volumes of aerated liquid downflow and vented gas upflow are greatly reduced. With sloped downcomers, the downcomer bottom area is normally set at 50 to 60 percent of the top downcomer area. This taper is small enough to keep the downcomer top area the prime choke variable.

There is no satisfactory published correlation for downcomer choke. The best that can be done in the absence of data or correlation is to apply the criteria for maximum velocity of clear liquid at the downcomer entrance. Kister (*Distillation Operation,* McGraw-Hill, New York, 1990) surveyed the multitude of published criteria for maximum downcomer velocity and incorporated them into a single set of guidelines (Table 14-7). Some values, marked with an asterisk (*), were revised to reflect the author's recent experiences. The values given in Table 14-7 are not conservative. For a conservative design, multiply the values from Table 14-7 by a safety factor of 0.75. For very highly foaming systems, where antifoam application is undesirable, there are benefits to reducing downcomer design velocities down to 0.1 to 0.15 ft/s.

Another criterion sometimes used is to provide sufficient residence time in the downcomer to allow adequate disengagement of gas from the descending liquid, so that the liquid is relatively gas-free by the time it enters the tray below. Inadequate removal of gas from the liquid may choke the downcomer. Kister (*Distillation Operation,* McGraw-Hill, New York, 1990) reviewed various published criteria for downcomer residence times and recommended those by Bolles (private communication, 1977) and Erbar and Maddox (Maddox, *Process Engineer's Absorption Pocket Handbook,* Gulf Publishing, Houston, 1985). Both sets of guidelines are similar and are summarized in Table 14-8. The residence times in Table 14-8 are *apparent residence times*, defined as the ratio of the total downcomer volume to the clear liquid flow in the downcomer.

As a segmental downcomer becomes smaller, its width decreases faster than its length, turning the downcomer into a long, narrow slot. This geometry increases the resistance to liquid downflow and to the upflow of disengaging gas. Small downcomers are also extremely sensitive to foaming, fouling, construction tolerances, and the introduction of debris. Generally, segmental downcomers smaller than 5 percent of the column

**TABLE 14-6 Criteria for Downcomer Aeration Factors**

| Foaming tendency | Bolles' criterion* | | Glitsch's criterion† | | Fair et al.'s criterion‡ | |
|---|---|---|---|---|---|---|
| | Examples | $\phi_{dc}$ | Examples | $\phi_{dc}$ | Examples | $\phi_{dc}$ |
| Low | Low-molecular-weight hydrocarbons§ and alcohols | 0.6 | $\rho_G < 1.0$ lb/ft$^3$ | 0.6 | Rapid bubble rise systems, such as low gas density, low liquid viscosity | 0.5 |
| Moderate | Distillation of medium-molecular-weight hydrocarbons | 0.5 | $1.0 < \rho_G < 3.0$ lb/ft$^3$ | 0.5 | | |
| High | Mineral oil absorbers | 0.4 | $\rho_G > 3.0$ lb/ft$^3$ | 0.4 | | |
| Very high | Amines, glycols | 0.3 | | | Slow bubble rise systems, such as high gas density, high liquid viscosity, foaming systems | 0.2–0.3 |

cross-sectional area should be avoided. Additional discussion of small downcomers is available (Kister, *Distillation Operation,* McGraw-Hill, New York, 1990).

**Derating ("System") Factors** With certain systems, traditional flooding equations consistently give optimistic predictions. To allow for this discrepancy, an empirical derating or system factor (SF < 1.0) is applied. To obtain the actual or derated flood load, the flood gas load (entrainment flooding) or flood liquid load (downcomer choke) obtained from the traditional equations is multiplied by the derating factor. In the case of downcomer backup flood, the froth height from the traditional flood equation is divided by the derating factor.

Derating factors are vaguely related to the foaming tendency, but they are also applied to nonfoaming systems where standard flooding equations consistently predict too high. Sometimes, derating factors are used solely as overdesign factors. Brierley (*Chem. Eng. Prog.,* July 1994, p. 68) states that some derating factors actually evolved from plant misoperation or from misinterpretation of plant data. Kister (*Distillation Operation,* McGraw-Hill, New York, 1990) compiled the derating factors found in the literature into Table 14-9.

The application of derating factors is fraught with inconsistent practices and confusion. Caution is required. The following need to be carefully specified:

1. The flooding mechanism to which the derating factor applies (entrainment, downcomer backup, downcomer choke, or all these) must be specified.
2. Avoiding double derating. For instance, the values in Table 14-9 may apply with Eq. (14-81) because Eq. (14-81) does not take foaminess into account. However, they will double-derate a flood calculation that is made with a correlation or criteria that already take foaminess into account, such as the criteria for downcomer choke in Tables 14-7 and 14-8. Similarly, two different factors from Table 14-9 may apply to a single system; only one should be used.
3. Derating factors vary from source to source, and they may depend on the correlation used as well as the system. For instance, some caustic wash applications have a track record of foaming more severely than other caustic wash applications (see note in Table 14-9). The derating factors in Table 14-9 are a useful guide, but they are far from absolute.

## ENTRAINMENT

Entrainment (Fig. 14-34) is liquid transported by the gas to the tray above. As the lower tray liquid is richer with the less-volatile components, entrainment counteracts the mass-transfer process, reducing tray efficiency. At times entrainment may transport nonvolatile impurities upward to contaminate the tower overhead product, or it may damage rotating machinery located in the path of the overhead gas.

**TABLE 14-8 Recommended Minimum Residence Time in the Downcomer**

| Foaming tendency | Example | Residence time, s |
|---|---|---|
| Low | Low-molecular-weight hydrocarbons,* alcohols | 3 |
| Medium | Medium-molecular-weight hydrocarbons | 4 |
| High | Mineral oil absorbers | 5 |
| Very high | Amines and glycols | 7 |

*The author believes that low-molecular-weight hydrocarbons refer to light hydrocarbons at atmospheric conditions or under vacuum. The foaming tendency of light-hydrocarbon distillation at medium pressure [>7 bar (100 psia)] is medium; at high pressure [>21 bar (300 psia)], it is high.
SOURCE: W. L. Bolles (Monsanto Company), private communication, 1977.

**Effect of Gas Velocity** Entrainment increases with gas velocity to a high power. Generally, smaller powers, indicative of a relatively gradual change, are typical of low-pressure systems. Higher powers, which indicate a steep change, are typical of high-pressure systems.

Due to the steep change of entrainment with gas velocity at high pressure, the gas velocity at which entrainment becomes significant tends to coincide with the flood point. At low pressure, the rate of change of entrainment with gas velocity is much slower, and entrainment can be significant even if the tray is operating well below the flood point. For this reason, excessive entrainment is a common problem in low-pressure and vacuum systems, but it is seldom troublesome with high-pressure systems. If encountered at high pressure, entrainment usually indicates flooding or abnormality.

**Effect of Liquid Rate** As the liquid rate is raised at constant gas rate, entrainment first diminishes, then passes through a minimum, and finally increases [Sakata and Yanagi, *I. Chem. E. Symp. Ser.* **56:** 3.2/21 (1979); Porter and Jenkins, *I. Chem. E. Symp. Ser.* **56:** Summary Paper (1979); Friend, Lemieux, and Schreiner, *Chem. Eng.,* October 31, 1960, p. 101]. The entrainment minima coincide with the maxima in plots of entrainment flood *F*-factor against liquid load (Fig. 14-30). At the low liquid loads (spray regime), an increase in liquid load suppresses atomization, drop formation, and consequently entrainment. At higher liquid loads, an increase in liquid load reduces the effective tray spacing, thereby increasing entrainment. The entrainment minima have been interpreted by many workers as the tray dispersion change from predominantly spray to the froth regime [Porter and Jenkins, *I. Chem. E. Symp. Ser.* **56:** Summary Paper (1979); Kister and Haas, *I. Chem. E. Symp. Ser.* **104:** A483 (1987)].

**Effect of Other Variables** Entrainment diminishes with higher tray spacing and increases with hole diameter [Kister and Haas, *I. Chem. E. Symp. Ser.* **104:** A483 (1987); *Ind. Eng. Chem. Res.* **27:** 2331 (1988); Lemieux and Scotti, *Chem. Eng. Prog.* **65**(3): 52 (1969)]. The hole diameter effect is large in the spray regime but small in the froth regime. In the spray regime, entrainment also increases as the fractional hole area is lowered, but this variable has little effect in the froth regime [Yanagi and Sakata, *Ind. Eng. Chem. Proc. Des. Dev.* **21:** 712 (1982); and Kister and Haas, *I. Chem. E. Symp. Ser.* **104:** A483 (1987)].

**Entrainment Prediction** For spray regime entrainment, the Kister and Haas correlation was shown to give good predictions to a wide commercial and pilot-scale data bank [*I. Chem. E. Symp. Ser.* **104:** A483 (1987)]. The correlation is

$$E_S = 4.742^{(10/\sqrt{\sigma})^{1.64}} \chi^{(10/\sqrt{\sigma})} \tag{14-94}$$

where

$$\chi = 872\left(\frac{u_B h_{Lt}}{\sqrt{d_H S}}\right)^4 \left(\frac{\rho_G}{Q_L \rho_L}\right)\left(\frac{\rho_L - \rho_G}{\sigma}\right)^{0.25} \tag{14-95}$$

and

$$h_{Lt} = \frac{h_{ct}}{1 + 0.00262 h_w} \tag{14-96}$$

The terms in Eqs. (14-94) through (14-96) are in the metric units described in the Nomenclature table at the beginning of this section.

The recommended range of application of the correlation is given in Table 14-10. The clear liquid height at the froth-to-spray transition $h_{ct}$ is calculated using the corrected Jeronimo and Sawistowski [*Trans. Inst. Chem. Engnrs.* **51:** 265 (1973)] correlation as per Eqs. (14-82) to (14-84).

For decades, the Fair correlation [*Pet/Chem. Eng.* **33**(10): 45 (September 1961)] has been used for entrainment prediction. In the spray regime, the Kister and Haas correlation was shown to be more accurate [Koziol and Mackowiak, *Chem. Eng. Process.* **27:** 145 (1990)]. In the froth regime, the Kister and Haas correlation does not apply, and Fair's correlation remains the standard of the industry. Fair's correlation (Fig. 14-35) predicts entrainment in

**TABLE 14-9 Derating ("System") Factors**

| System | Factor | Reference | Notes |
|---|---|---|---|
| Nonfoaming regular systems | 1.0 | 1–4 | |
| High pressure ($\rho_G$ >1.8 lb/ft$^3$) | $2.94/\rho_G^{0.32}$ | 2 | Do not double-derate. |

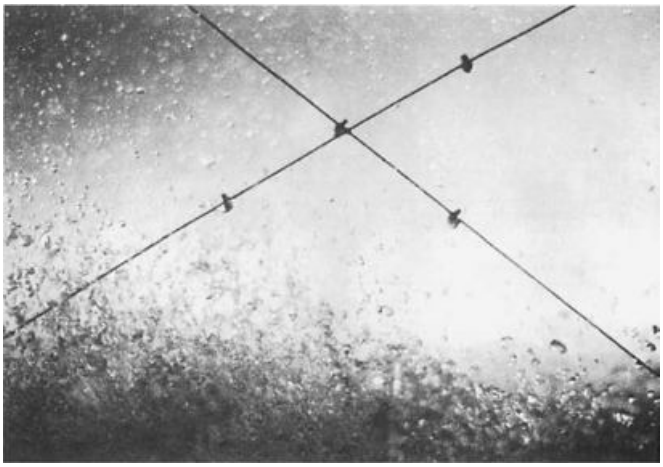

**FIG. 14-34** Entrainment. [*Reprinted courtesy of Fractionation Research Inc. (FRI).*]

terms of the flow parameter [Eq. (14-89)] and the ratio of gas velocity to entrainment flooding gas velocity. The ordinate values $\Psi$ are fractions of gross liquid downflow, defined as follows:

$$\Psi = \frac{e}{L_m + e} \tag{14-97}$$

where $e$ = absolute entrainment of liquid, mol/time
$L_m$ = liquid downflow rate without entrainment, mol/time

Figure 14-35 also accepts the validity of the Colburn equation [*Ind. Eng. Chem.* **28:** 526 (1936)] for the effect of entrainment on efficiency:

$$\frac{E_a}{E_{mv}} = \frac{1}{1 + E_{mv}[\psi/(1-\psi)]} \tag{14-98}$$

where $E_{mv}$ = Murphree vapor efficiency [see Eq. (14-134)]
$E_a$ = Murphree vapor efficiency, corrected for recycle of liquid entrainment

The Colburn equation is based on complete mixing on the tray. For incomplete mixing, such as liquid approaching plug flow on the tray, Rahman and Lockett [*I. Chem. E. Symp. Ser.* **61:** 111 (1981)] and Lockett et al. [*Chem. Eng. Sci.* **38:** 661 (1983)] have provided corrections.

Fair (paper presented at the AIChE Annual Meeting, Chicago, Ill., November 1996) correlated data for efficiency reduction due to the rise of entrainment near entrainment flood, getting

$$\ln \psi = A + B\Phi + C\Phi^2 \tag{14-99}$$

where $\Phi$ is the fractional approach to entrainment flood and $A$, $B$, and $C$ are constants given by

| | $A$ | $B$ | $C$ |
|---|---|---|---|
| Highest likely efficiency loss | –3.1898 | –4.7413 | 7.5312 |
| Median (most likely) efficiency loss | –3.2108 | –8.9049 | 11.6291 |
| Lowest likely efficiency loss | 4.0992 | –29.9141 | 25.3343 |

|---|---|
| Flow regime | Spray only |
| Pressure | 20–1200 kPa (3–180 psia) |
| Gas velocity | 0.4–5 m/s (1.3–15 ft/s) |
| Liquid flow rate | 3–40 m$^3$/(m · h) (0.5–4.5 gpm/in) |
| Gas density | 0.5–30 kg/m$^3$ (0.03–2 lb/ft$^3$) |
| Liquid density | 450–1500 kg/m$^3$ (30–90 lb/ft$^3$) |
| Surface tension | 5–80 mN/m |
| Liquid viscosity | 0.05–2 cP |
| Tray spacing | 400–900 mm (15–36 in) |
| Hole diameter | 3–15 mm (0.125–0.75 in) |
| Fractional hole area | 0.07–0.16 |
| Weir height | 10–80 mm (0.5–3 in |

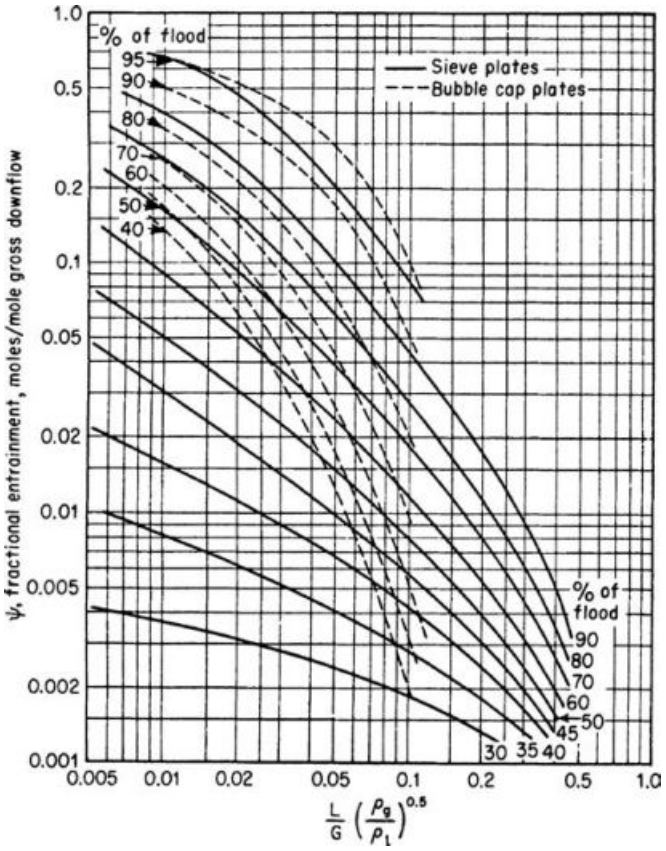

**FIG. 14-35** Entrainment correlation. $L/G$ = liquid/gas mass ratio; $\rho_l$ and $\rho_g$ = liquid and gas densities. [*Fair*, Pet./Chem. Eng. ***33****(10): 45 (September 1961).*]

Either the Kister and Haas or the Fair method can be used to evaluate Φ. The correlation has been tested with sieve trays in the flow parameter range of 0.024 to 0.087.

***Example 14-10 Entrainment Effect on Tray Efficiency*** For the column in Example 14-9, estimate the efficiency loss should the operation be pushed from the design 80 percent of flood to 90 percent of flood. The midrange dry Murphree tray efficiency is 70 percent.

*Solution* The vapor and liquid densities and $L/V$ ratio remain unchanged from Example 14-9, and so is the flow parameter (calculated 0.021 in Example 14-9). At 80 and 90 percent of flood, respectively, Fig. 14-35 gives ψ = 0.15 and 0.24. The respective efficiency reductions are calculated from Eq. (14-98),

$$\frac{E_a}{E_{mv}} = \frac{1}{1+0.70[0.15/(1-0.15)]} = 0.89$$

$$\frac{E_a}{E_{mv}} = \frac{1}{1+0.70[0.24/(1-0.24)]} = 0.82$$

signifying an efficiency loss from 62 to 57 percent.

Alternatively, at 80 and 90 percent of entrainment flood, the median value of ψ from Eq. (14-99) is

$$\ln \psi = -3.2108 - 8.9049(0.80) + 11.6291(0.80^2)$$

giving $\psi = 0.056$, and from Eq. (14-98), $E_o/E_{mv} = 0.96$

$$\ln \psi = -3.2108 - 8.9049(0.90) + 11.6291(0.90^2)$$

giving $\psi = 0.164$, and from Eq. (14-98), $E_o/E_{mv} = 0.88$

signifying an efficiency reduction from 67 to 62 percent.

## PRESSURE DROP

In vacuum distillation, excessive pressure drop causes excessive bottom temperatures which, in turn, increase degradation, polymerization, coking, and fouling, and also load up the column, vacuum system, and reboiler. In the suction of a compressor, excessive pressure drop increases the compressor size and energy usage. Such services try to minimize tray pressure drop. Methods for estimating pressure drops are similar for most conventional trays. The total pressure drop across a tray is given by

$$h_t = h_d + h'_L \tag{14-100}$$

where $h_t$ = total pressure drop, mm liquid
$h_d$ = pressure drop across the dispersion unit (dry hole for sieve trays; dry valve for valve trays), mm liquid
$h'_L$ = pressure drop through aerated mass over and around the disperser, mm liquid

It is convenient and consistent to relate all of these pressure-drop terms to the height of equivalent clear liquid (deaerated basis) on the tray, in either millimeters or inches of liquid.

Pressure drop across the disperser is calculated by variations of the standard orifice equation:

$$h_d = K\left(\frac{\rho_G}{\rho_L}\right)U_h^2 \tag{14-101}$$

where $U_h$ = linear gas velocity through slots (valve trays) or perforations (sieve tray), m/s.

For sieve trays, $K = 50.8/C_v^2$. Values of $C_v$ are taken from Fig. 14-36. Values from Fig. 14-36 may be calculated from

$$C_v = 0.74(A_h/A_a) + \exp[0.29(t_t/d_h) - 0.56] \tag{14-102a}$$

Recent work by Summers (*Chem. Eng.*, June 2009, p. 36) and Summers and Cai (Chem. Eng., August 2017, p. 38) shows that the dry pressure drop data fit can be improved by using the alternative equation

$$C_v = (d_h/p)^{0.1}\,[0.997 - 0.34/\{1.0 + (4.925\,t_t/d_h)^{3.582}\}] \tag{14-102b}$$

where $t_t$ is the tray thickness, mm, and $p$ is the center-to-center hole pitch, mm.

For Sulzer's fixed valve trays, Summers and van Sinderen (*Distillation 2001: Topical Conference Proceedings,* AIChE Spring National Meeting, Houston, April 22–26, 2001, p. 444) provided the following equation for $K$:

$$K = 58 + 386A_f \quad \text{for MVG fixed valves} \tag{14-103a}$$

$$K = 58 + 461A_f \quad \text{for SVG and LVG fixed valves} \tag{14-103b}$$

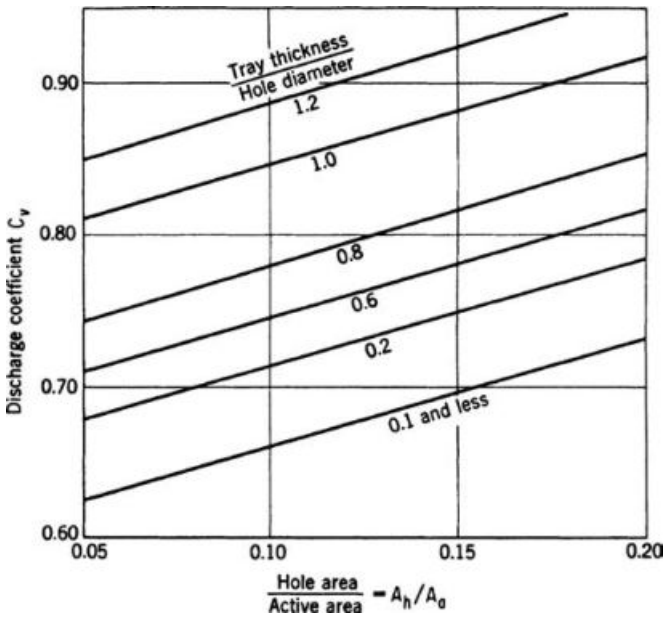

**FIG. 14-36** Discharge coefficients for gas flow, sieve trays. [*Liebson, Kelley, and Bullington, Pet. Refiner* ***36****(3): 288 (1957).*]

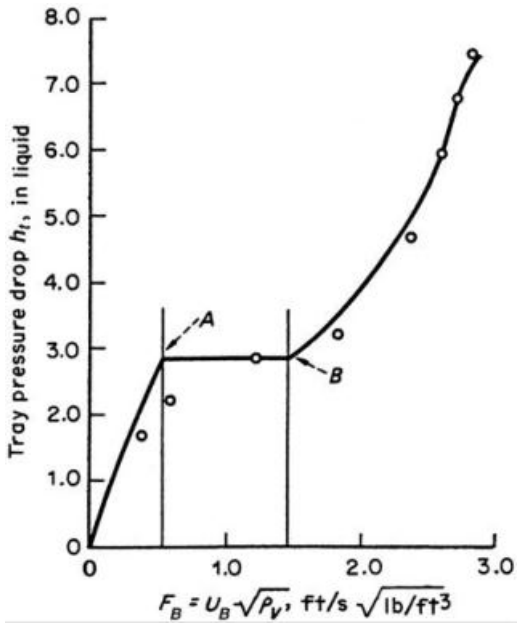

**FIG. 14-37** Typical moving valve tray pressure-drop profile. (*From G. F. Klein, Chem. Eng., May 3, 1982, p. 81; reprinted courtesy of* Chemical Engineering.)

Figure 14-37 illustrates the pressure drop of a typical moving valve tray as a function of gas velocity. At low velocities, all valves are closed. Gas rises through the crevices between the valves and the tray deck, with increasing pressure drop as the gas velocity rises. Once point *A,* the closed balance point (CBP), is reached, some valves begin to open. Upon further increase in gas velocity, more valves open until point *B,* the open balance point (OBP), is reached. Between points *A* and *B,* gas flow area increases with gas velocity, keeping pressure drop constant. Further increases in gas velocity increase pressure drop similar to that in a sieve tray.

The term $K$ in Eq. (14-101) depends on valve slot area, orifice geometry, deck thickness, and the type, shape, and weight of the valves. These are best obtained from the manufacturer's literature, but they can also be calculated from Bolles' [*Chem. Eng. Prog.* **72**(9): 43 (1976)], Lockett's (*Distillation Tray Fundamentals,* Cambridge University Press, Cambridge, UK, 1986), and Klein's (*Chem. Eng.,* May 3, 1982, p. 81) methods.

For valve trays, Klein gives the following values for $K$ (in $s^2 \cdot mm/m^2$) in Eq. (14-101), when based on the total hole area (not slot area):

| | Sharp orifice | Venturi valve |
|---|---|---|
| All valves open ($K_O$) | $254.5\,(2.64/t_t)^{0.5}$ | 122 |
| All valves closed ($K_C$) | 1683 | 841 |

The velocity at which the valves start to open (point *A*) is given by

$$U_{h,\text{closed}} = 1.14[t_v(R_{vw}/K_C)(\rho_M/\rho_G)]^{0.5} \tag{14-104}$$

where $U_{h,\text{closed}}$ = hole area at point *A*, m/s; $t_v$ = valve thickness, mm; $R_{vw}$ = ratio of valve weight with legs to valve weight without legs, given in Table 14-11; $K_C$ = orifice coefficient with all valves closed (see above), $s^2 \cdot mm/m^2$; $\rho_M$ = valve metal density, $kg/m^3$ (about 8000 $kg/m^3$ for steel); $\rho_G$ = gas density, $kg/m^3$.

The velocity at which all the valves are open $U_{h,\text{open}}$ can be calculated from

$$U_{h,\text{open}} = U_{h,\text{closed}}(K_C/K_O)^{0.5} \tag{14-105}$$

**TABLE 14-11 $R_{VW}$ Values for Eq. (14-104)**

| Valve type | Sharp | Venturi |
|---|---|---|
| Three-leg | 1.23 | 1.29 |
| Four-leg | 1.34 | 1.45 |
| Cages (no legs) | 1.00 | 1.00 |

Pressure drop through the aerated liquid [$h'_L$, in Eq. (14-100)] is calculated by

$$h'_L = \beta h_{ds} \tag{14-106}$$

where $\beta$ = aeration factor, dimensionless
$h_{ds}$ = calculated height of clear liquid, mm (dynamic seal)

The aeration factor $\beta$ has been determined from Fig. 14-38 for valve and sieve trays. For sieve trays, values of $\beta$ in the figure may be calculated from

$$\beta = 0.0825 \ln \frac{Q}{L_w} - 0.269 \ln F_h + 1.679 \tag{14-107}$$

where $L_w$ = weir length, m
$F_h$ = $F$-factor for flow through holes, $F_h = U_h\rho_G^{0.5}$, m/s $(kg/m^3)^{0.5}$

For sieve and valve trays,

$$h_{ds} = h_w + h_{ow} + 0.5h_{hg} \tag{14-108}$$

where $h_w$ = weir height, mm
$h_{ow}$ = height of crest over weir, mm clear liquid
$h_{hg}$ = hydraulic gradient across tray, mm clear liquid

The value of weir crest $h_{ow}$ may be calculated from the Francis weir equation and its modifications for various weir types. For a segmental weir and for height in millimeters of clear liquid,

$$h_{ow} = 664\left(\frac{Q}{L_w}\right)^{2/3} \tag{14-109}$$

where $Q$ = liquid flow, $m^3/s$
$L_w$ = weir length, m

For serrated weirs,

$$h_{ow} = 851\left(\frac{Q'}{\tan\theta/2}\right)^{0.4} \tag{14-110}$$

where $Q'$ = liquid flow, $m^3/s$ per serration
$\theta$ = angle of serration, deg

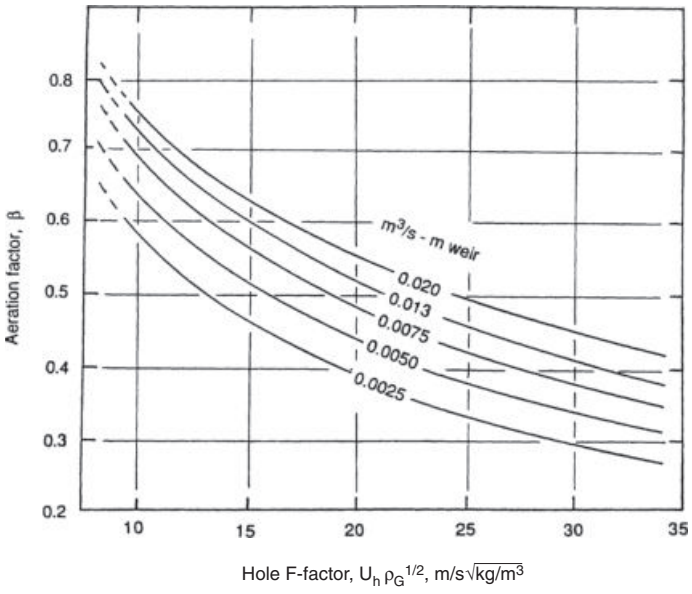
For circular weirs,

$$h_{ow} = 44{,}300\left(\frac{Q}{d_w}\right)^{0.704} \tag{14-111}$$

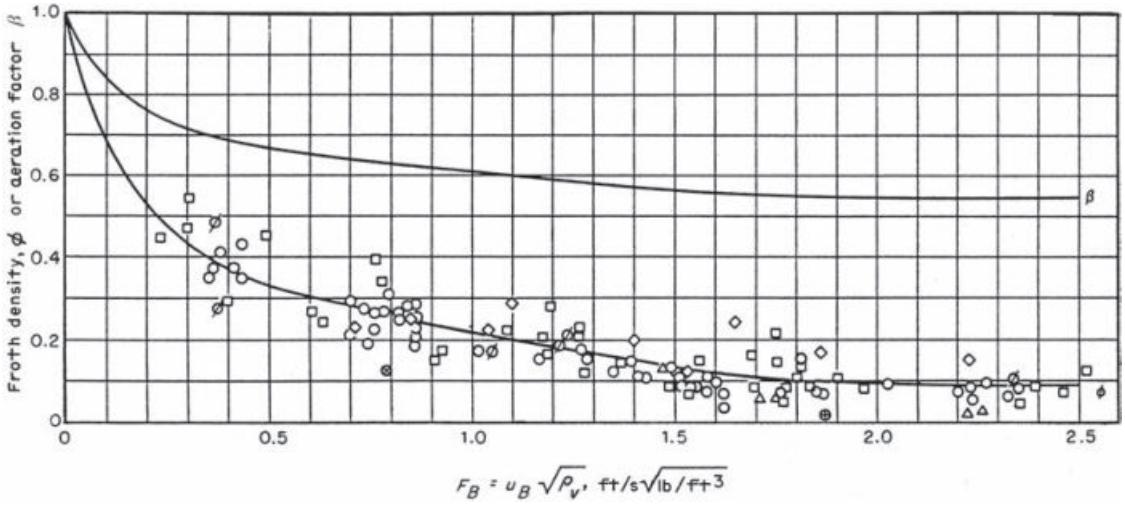
where $q$ = liquid flow, $m^3/s$
$d_w$ = weir diameter, mm

For most sieve and valve trays, the hydraulic gradient is small and can be dropped from Eq. (14-108). Some calculation methods are available and are detailed in previous editions of this handbook. A rule of thumb for hydraulic gradients on sieve and valve trays which gives reasonable fit (albeit with large scatter) to FRI and industrial gamma scan data (Kister, *The Distillation Topical Conference,* AIChE Spring Meeting, Houston, Tex., April 2012) is 17 mm/m (0.2 in/ft) of flow path length in the froth and emulsion regimes ($Q_L$ >54 $m^3/h \cdot m$ or >6 gpm/in of outlet weir length), and zero in the spray regime ($Q_L$ <18 $m^3/h \cdot m$ or <2 gpm/in of outlet weir). For weir loads between 18 and 54 $m^3/h \cdot m$ the rule recommends linear interpolation in weir loads.

As noted, the weir crest $h_{ow}$ is calculated on an equivalent clear-liquid basis. A more realistic approach is to recognize that in general a froth or spray flows over the outlet weir (settling can occur upstream of the weir if a large "calming zone" with no dispersers is used). Bennett et al. [*AIChE J.* **29:** 434 (1983)] allowed for froth overflow in a comprehensive study of pressure drop across sieve trays; their correlation for residual pressure drop $h'_L$ in Eq. (14-100) is presented in detail in the seventh edition of this handbook, including a worked example. Although more difficult to use, the method of Bennett et al. was recommended when determination of pressure drop is of critical importance.



(*a*)



(*b*)

**FIG. 14-38** Aeration factor for pressure drop calculation. (*a*) Sieve trays. [*Bolles and Fair*, Encyclopedia of Chemical Processing and Design, *vols. 16, 86. J. M. McKetta (ed.), Marcel Dekker, New York, 1982.*] (*b*) Valve trays. (*From G. F. Klein,* Chem. Eng.*, May 3, 1982, p. 81; reprinted courtesy of* Chemical Engineering.)

***Example 14-11 Pressure Drop, Sieve Tray*** For the conditions of Example 14-9, estimate the pressure drop for flow across one tray. The thickness of the tray metal is 2 mm and the pitch is 12.4 mm. The superficial *F*-factor is 2.08 m/s$(kg/m^3)^{1/2}$.

*Solution* Equations (14-100), (14-106), and (14-107), where $h_t = h_d + \beta(h_w + h_{ow})$, are used. For $F_S = 2.08$, $F_B = 2.32$ and $F_H = 16.55$. From Example 14-9, $L_w = 1.50$ m and $h_w = 38$ mm. For a liquid rate of 22,000 kg/hr, $Q = 7.27(10^{-3})$ $m^3/s$, and $Q/L_w = 4.8(10^{-3})$. By Eq. (14-107) or Fig. 14-38, $\beta = 0.48$. From Eq. (14-102a) or Fig. 14-36, $C_v = 0.75$. Then, by Eq. (14-101), $h_d = 29.0$ mm liquid. Alternatively, from Eq. (14-102b), $C_v = 0.88$, giving $h_d = 21.0$ mm liquid. For conservative estimate, select $h_d = 29.0$ mm liquid. Using Eq. (14-109), $h_{ow} = 18.9$ mm. Finally, $h_t = h_d + \beta(h_w + h_{ow}) = 29.0 + 0.48(38 + 18.9) = 56.4$ mm liquid.

When straight or serrated segmental weirs are used in a column of circular cross section, a correction may be needed for the distorted pattern of flow at the ends of the weirs, depending on liquid flow rate. The correction factor $F_w$ from Fig. 14-39 is used directly in Eq. (14-109). Even when circular downcomers are used, they are often fed by the overflow from a segmental weir.

**Loss Under Downcomer** The head loss under the downcomer apron, as millimeters of liquid, may be estimated from

$$h_{da} = 165.2\left(\frac{Q}{A_{da}}\right)^2 \tag{14-112}$$

where $Q$ = volumetric flow of liquid, $m^3/s$ and $A_{da}$ = most restrictive (minimum) area of flow under the downcomer apron, $m^2$. Equation (14-112) was derived from the orifice equation with an orifice coefficient of 0.6. Although the loss under the downcomer is small, the clearance is significant from the aspect of tray stability and liquid distribution.

The term $A_{da}$ should be taken as the most restrictive area for liquid flow in the downcomer outlet. Usually, this is the area under the downcomer apron (i.e., the downcomer clearance times the length of the segmental downcomer), but not always. For instance, if an inlet weir is used and the area between the segmental downcomer and the inlet weir is smaller than the area under the downcomer apron, the smaller area should be used.

## OTHER HYDRAULIC LIMITS

**Weeping** Weeping is liquid descending through the tray perforations, short-circuiting the contact zone, which lowers tray efficiency. At the tray floor, liquid static head that acts to push liquid down the perforations is counteracted by the gas pressure drop that acts to hold the liquid on the tray. When the static head overcomes the gas pressure drop, weeping occurs.

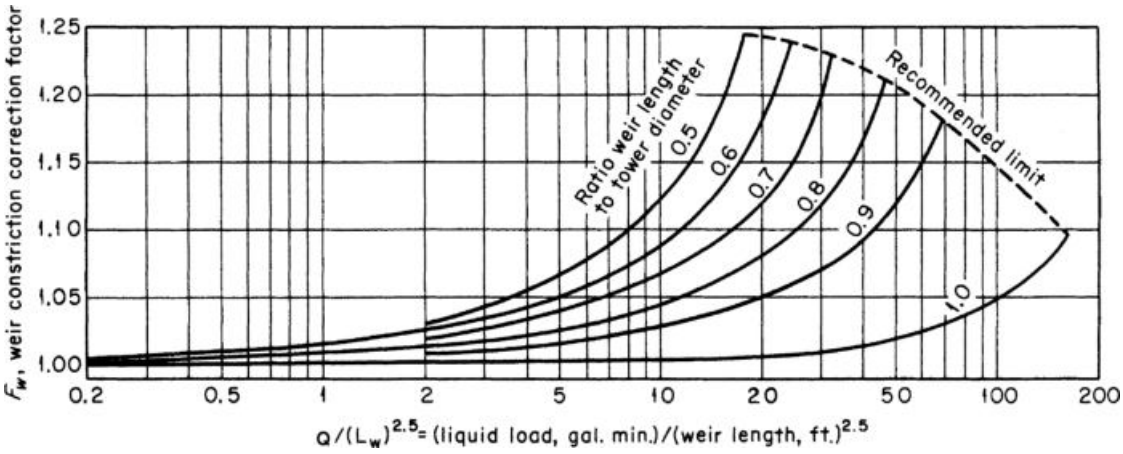


**FIG. 14-39** Correction for effective weir length. To convert gallons per minute to cubic meters per second, multiply by $6.309 \times 10^{-5}$; to convert feet to meters, multiply by 0.3048. [*Bolles, Pet. Refiner* ***25:*** *613 (1946).*]

Some weeping usually takes place under all conditions due to sloshing and oscillation of the tray liquid. Generally, this weeping is too small to appreciably affect tray efficiency. The *weep point* is the gas velocity at which weeping first becomes noticeable. At this point, little efficiency is lost. As gas velocity is reduced below the weep point, the weep rate increases. When the weep rate becomes large enough to significantly reduce tray efficiency, the lower tray operating limit is reached.

The main factor that affects weeping is the fractional hole area. The larger it is, the smaller the gas pressure drop and the greater the weeping tendency. Larger liquid rates and taller outlet weirs increase liquid heads and therefore weeping. Hole diameter has a complex effect on weeping, detailed by Lockett and Banik [*Ind. Eng. Chem. Proc. Des. Dev.* **25:** 561 (1986)].

Tests by Lockett and Banik show that weeping is often nonuniform, with some hydraulic conditions favoring weeping from the tray inlet and others from the tray outlet. Weeping from the tray inlet is particularly detrimental to tray efficiency because the weeping liquid bypasses two trays.

***Weep Rate Prediction*** Lockett and Banik [*Ind. Eng. Chem. Proc. Des. Dev.* **25:** 561 (1986)] and Hsieh and McNulty (*Chem. Eng. Progr.,* July 1993, p. 71) proposed correlations for predicting weep rates from sieve trays. Colwell and O'Bara (Paper presented at the AIChE Meeting, Houston, April 1989) recommended the Lockett and Banik correlation for low pressures (<1100 kPa or 165 psia), and the Hsieh and McNulty correlation for high pressures (>1100 kPa or 165 psia). They also corrected the Lockett and Banik correlation to improve its accuracy near the weep point.

The *Lockett and Banik correlation* (as corrected by Colwell and O'Bara) is

$$\frac{W}{A_h} = \frac{29.45}{\sqrt{\mathrm{Fr}_h}} - 44.18 \qquad \mathrm{Fr}_h < 0.2 \tag{14-113a}$$

$$\frac{W}{A_h} = \frac{1.841}{\mathrm{Fr}_h^{1.533}} \qquad \mathrm{Fr}_h > 0.2 \tag{14-113b}$$

where

$$\mathrm{Fr}_h = 0.373 \frac{u_h^2}{h_c} \frac{\rho_v}{\rho_L - \rho_v} \tag{14-114}$$

Equations (14-113) and (14-114) use English units: $W$ is the weep rate, gpm; $A_h$ is the hole area, ft$^2$; $u_h$ is the hole velocity, ft/s; and $h_c$ is the clear liquid height, in. Colwell's [*Ind. Eng. Chem. Proc. Des. Dev.* **20**(2): 298 (1981)] method below has been recommended for obtaining the clear liquid height $h_c$ in Eq. (14-114).

$$h_c = \phi_f \left\{ 0.527 \left( \frac{Q_L(1 - f_w}{C_d \phi_f} \right)^{2/3} + h_w \right\} \tag{14-115}$$

where $\phi_f$ is given by Eq. (14-119) and $C_d$ is given by Eq. (14-116),

$$\left.\begin{aligned} C_d &= 0.61 + 0.08 \frac{h_{fow}}{h_w} \qquad \frac{h_{fow}}{h_w} < 8.135 \\ C_d &= 1.06 \left( 1 + \frac{h_w}{h_{fow}} \right)^{1.5} \qquad \frac{h_{fow}}{h_w} > 8.135 \end{aligned}\right\} \tag{14-116}$$

$$h_{fow} = h_f - h_w \tag{14-117}$$

where $h_f$ is given by Eq. (14-122). The froth density $\phi_f$ is calculated from

$$\eta = 12.6 \mathrm{Fr}^{0.4} \left( \frac{A_B}{A_h} \right)^{0.25} \tag{14-118}$$

$$\phi_f = \frac{1}{\eta + 1} \tag{14-119}$$

$$\mathrm{Fr} = 0.37 \frac{\rho_v u_B^2}{h_c(\rho_L - \rho_v)} \tag{14-120}$$

The term $f_w$ in Eq. (14-115) is the ratio of weep rate from the tray to the total liquid flow entering the tray, calculated as follows:

$$f_w = W/\mathrm{GPM} \tag{14-121}$$

Some trial and error is required in this calculation because the clear liquid height $h_c$ and the froth density $\phi_f$ depend on each other, and the weep fraction $f_w$ depends on the clear liquid height $h_c$. Clear liquid height is related to froth height and froth density by

$$h_c = \phi_f h_f \tag{14-122}$$

The terms in Eqs. (14-115) to (14-122) are in English units and are explained in the Nomenclature table.

With large-diameter trays and low liquid loads, a small ratio of $W/A_h$ corresponds to a large fractional weep. Under these conditions, the Lockett and Banik correlation is inaccurate. The correlation is unsuitable for trays with very small (<3-mm or $\frac{1}{8}$-in) holes. The correlation appears to fit most data points to an accuracy of ±15 to ±30 percent.

The *Hsieh and McNulty correlation* (*Chem. Eng. Progr.,* July 1993, p. 71) is

$$\sqrt{J_G^*} + m\sqrt{J_L^*} = C_w \tag{14-123}$$

where

$$J_G^* = u_h \left[ \frac{\rho_G}{gZ(\rho_L - \rho_G)} \right]^{0.5} \tag{14-124}$$

and

$$J_L^* = \frac{W}{448.83 A_h}\left[\frac{\rho_L}{gZ(\rho_L - \rho_G)}\right]^{0.5} \quad (14\text{-}125)$$

$$Z = h_C^{1.5}/(12 d_H^{0.5}) \quad (14\text{-}126)$$

The terms in Eqs. (14-123) to (14-126) are in English units and are explained in the Nomenclature. For sieve trays, $m = 1.94$ and $C_w = 0.79$. Note that the constants are a slight revision of those presented in the original paper (C. L. Hsieh, private communication, 1991). Clear liquid height is calculated from Colwell's correlation [Eqs. (14-115) to (14-122)]. The Hsieh and McNulty correlation applies to trays with 9 percent and larger fractional hole area. For trays with smaller hole area, Hsieh and McNulty expect the weeping rate to be smaller than predicted.

***Weeping from Valve Trays*** An analysis of weeping from valve trays [Bolles, *Chem. Eng. Progs.* **72**(9): 43 (1976)] showed that in a well-designed valve tray, the weep point is below the gas load at which the valves open; and throughout the valve opening process, the operating point remains above the weep point. In contrast, if the tray contains too many valves, or the valves are too light, excessive valve opening occurs before the gas pressure drop is high enough to counter weeping. In this case, weeping could be troublesome.

Weep point correlations for valve trays were presented by Bolles [*Chem. Eng. Progs.* **72**(9): 43 (1976)] and by Klein (*Chem. Eng.,* Sept. 17, 1984, p. 128). Hsieh and McNulty (*Chem. Eng. Progr.,* July 1993, p. 71) gave a complex extension of their weep rate correlation to valve trays.

**Dumping** As gas velocity is lowered below the weep point, the fraction of liquid weeping increases until all the liquid fed to the tray weeps through the holes and none reaches the downcomer. This is the *dump point*, or the *seal point*. The dump point is well below the range of acceptable operation of distillation trays. Below the dump point, tray efficiency is slashed, and mass transfer is extremely poor. Operation below the dump point can be accompanied by severe hydraulic instability due to unsealing of downcomers.

Extensive studies on dumping were reported by Prince and Chan [*Trans. Inst. Chem. Engr.* **43:** T49 (1965)]. The Chan and Prince dump-point correlation was recommended and is presented in detail elsewhere (Kister, *Distillation Design,* McGraw-Hill, 1992). Alternatively, the dump point can be predicted by setting the weep rate equal to 100 percent of the liquid entering the tray in the appropriate weep correlation.

**Stability at Low Vapor Rates** Summers (*Distillation and Absorption 2010*, Einhoven University of Technology, The Netherlands, p. 611) analyzed weep data to show that the following criterion for stable tray operation at turndown keeps the weep rate well below 30 percent:

$$\eta = (h_d/h'_L)^{0.5} > 0.6 \quad (14\text{-}126a)$$

where $\eta$ is the stability factor, dimensionless; $h_d$ is the dry pressure drop, mm of liquid; and $h'_L$ is the clear liquid height, mm liquid. Although the clear liquid heights used in Summers' derivation were calculated from pressure drop data using Eq. (14-100), he later recommended to the author (private communication, 2017) that the Colwell correlation [Eq. (14-115)] be used for the clear liquid height $h'_L$ calculation. The stability factor is proportional to the hole Froude number, which represents the ratio of the upward vapor inertial forces keeping the liquid on the tray to the downward gravity forces pulling the liquid down the holes.

For two-pass and multipass trays, an additional instability may result from vapor channeling through one panel and not another. Summers proposes an additional preliminary criterion for such trays, but this criterion needs data verification. Olsson and Kister (*Kister Distillation Symposium,* AIChE Spring Meeting, March 26–30, San Antonio, Tex., 2017) identified a multiplicity of stable hydraulic steady states for two-pass and multipass moving valve trays operating in the flat region of Fig. 14-37, some with severely channeled vapor through one of the panels, with a likely efficiency and turndown loss. Their findings need data verification.

**Turndown** The turndown ratio is the ratio of the normal operating (or design) gas throughput to the minimum allowable gas throughout. The minimum allowable throughput is usually set by excessive weeping, while normal operating throughput is a safe margin away from the relevant flooding limit.

*Sieve and fixed valve trays* have a poor turndown ratio (about 2:1). Their turndown can be improved by blanking some rows of tray holes, which reduces the tendency to weep, but this will also reduce the tray's maximum capacity. Turndown of *moving valve trays* is normally between about 4:1 and 5:1. Special valve designs can achieve even better turndown ratios, between 6:1 and 10:1, and even more. Turndown can also be enhanced by blanking strips (which require valve removal) or valve leg crimping. Sloley and Fleming (*Chem. Eng. Progr.,* March 1994, p. 39) stress that correct implementation of turndown enhancement is central to achieving a desired turndown. When poorly implemented, turndown may be restricted by poor vapor–liquid contact rather than by weeping.

**Vapor Channeling** All the correlations in this section assume an evenly distributed tray vapor. When the vapor preferentially channels through a tray region, premature entrainment flood and excessive entrainment take place due to a high vapor velocity in that region. At the same time, other regions become vapor-deficient and tend to weep, which lowers tray efficiency.

Work by Davies [*Pet. Ref.* **29**(8): 93 and **29**(9): 121 (1950)] based on bubble-cap tray studies suggests that the vapor pressure drop of the tray (the *dry pressure drop*) counteracts channeling. The higher the dry tray pressure drop, the greater the tendency for vapor to spread uniformly over the bubbling area. If the dry tray pressure drop is too small compared with the channeling potential, channeling prevails.

Perhaps the most common vapor channeling mechanism is *vapor cross-flow channeling* (VCFC, Fig. 14-40). The hydraulic gradient on the tray induces preferential vapor rise at the outlet and middle of the tray and a vapor-deficient region near the tray inlet. The resulting high vapor velocities near the tray outlet step up entrainment, while the low vapor velocities near the tray inlet induce weeping. Interaction between adjacent trays (Fig. 14-40) accelerates both the outlet entrainment and the inlet weeping. The net result is excessive entrainment and premature flooding at the tray middle and outlet, simultaneous with weeping from the tray inlet, accompanied by a loss of efficiency and turndown.

VCFC takes place when the following four conditions exist simultaneously [Kister, Larson, and Madsen, *Chem. Eng. Progr.,* November 1992, p. 86; Kister, *The Chemical Engineer* **544:** 18 (1993); Kister, Clancy-Jundt, and Miller., *PTQ* **Q1:** 39 (2015)]:

1. Absolute pressure <800 kPa (120 psia).
2. High liquid rates [>50 $m^3/(m \cdot h)$ or 6 gpm/in of outlet weir].
3. High ratio (>2:1) of flow path length to tray spacing.
4. Low dry tray pressure drop. On sieve and fixed valve trays, this means high (>11 and 12 percent, respectively) fractional hole area. On moving valve trays, this means venturi valves (smooth orifices) or long-legged valves (>15 percent slot area). On all trays, the channeling tendency and severity escalate rapidly as the dry pressure drop diminishes (e.g., as fractional hole area increases).

Hartman (*Distillation 2001: Topical Conference Proceedings,* AIChE Spring National Meeting, Houston, Tex., April 22–26, 2001, p. 108) reports VCFC even with conventional valve trays (14 percent slot area) at a very high ratio (3.6:1) of flow path length to tray spacing and tray truss obstruction.

VCFC is usually avoided by limiting fractional hole areas, avoiding venturi valves, and using forward-push devices. Resitarits and Pappademos (Paper presented at the AIChE Annual Meeting, Reno, Nevada, November 2001) cited tray inlet inactivity as a contributor to VCFC, and they advocate inlet forward-push devices to counter it.

**Downcomer Unsealing** When a downcomer loses its liquid seal, gas rises through it and interferes with liquid descent, leading to capacity bottlenecks, poor separation, instability, and inability to start up.

On conventional trays, at weir loads exceeding 20 to 30 $m^3/h \cdot m$ of outlet weir length, the outlet weir generates a frothy pool (Fig. 14-20*a*, *b*). This liquid pool will seal the downcomer as long as the downcomer clearance is lower than the liquid head. In contrast, at low weir loads (<20 to 30 $m^3/h \cdot m$ of outlet weir length), and especially at high gas velocities, the gas atomizes

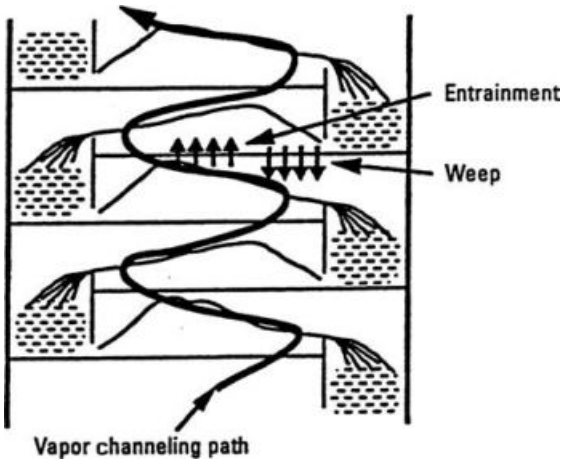

**FIG. 14-40** Vapor cross-flow channeling. Note entrainment near the tray middle and outlet, and weep near the tray inlet. (*Kister, H. Z., K. F. Larson, and P. Madsen,* Chem. Eng. Prog., *Nov. 1992, p. 86; reproduced with permission.*)

the tray liquid, forming a dispersion known as the spray regime or drop regime. In this regime, there is no frothy pool, and the liquid resides as atomized drops in the inter-tray space (Fig. 14-20*c*). The continuous gas phase reaches the downcomer outlet. The absence of static seal preventing gas rise up the downcomer renders the downcomers prone to seal loss.

Downcomer unsealing is common at start-ups and/or with low weir loads. With little liquid on the trays, the gas ascends through both the trays and downcomers, following the path of least resistance. A large downcomer clearance gives little resistance, allowing a large amount of gas into the downcomer. The high gas velocity through the downcomer impedes liquid descent. Unable to descend, the liquid accumulates on the tray above, flooding it. The flood may either propagate up the tower or intermittently flood a few trays and then dump, generating instability. Detailed modeling and troubleshooting guidelines were presented by Kister and Mohamed (*Gas Processing*, January/February 2015, p. 39, and March/April 2015, p. 49). Keeping downcomer clearances at 25 mm or less in clean services (up to 40 mm in fouling services), judicious use of inlet weirs, and switching to well-designed bubble-cap trays have been effectively applied to prevent downcomer unsealing. It is important to emphasize that these measures should only be considered at low weir loads (<20 to 30 $m^3/h \cdot m$ of outlet weir length). At weir loads exceeding 30 $m^3/h \cdot m$ of outlet weir length, a liquid pool forms on the tray, rendering these measures unnecessary, even detrimental.

Downcomer seal loss is also encountered in many high-capacity trays, in which maximizing capacity leads to downcomers that terminate in the inter-tray vapor space, well above the floor of the tray below. Terminating in the vapor space, the liquid pool on the tray does not reach their outlets, so vapor can easily break into these downcomers. Bernard (*Distillation Topical Conference Proceedings,* AIChE Spring Meeting, Chicago, Ill., March 2011) demonstrated that a model derived for low weir loads can be extended to evaluate unsealing in high-capacity trays, and to devise a successful start-up strategy.

Downcomer seal loss can also be caused by tray damage or by tray plugging. With a plugged tray, the pressure drop through the active area rises, incurring high resistance to gas flow, making going up a downcomer the path of lesser resistance. When the tray plugging is extensive, gas can break into downcomers, especially when there are multiple downcomers.

## TRANSITION BETWEEN FLOW REGIMES

**Froth–Spray** Froth–spray transition has been investigated for sieve trays using a variety of techniques. The gradual nature of this transition bred a multitude of criteria for defining it and made its correlation difficult. Excellent overviews were given by Lockett (*Distillation Tray Fundamentals,* Cambridge University Press, Cambridge, UK, 1986) and Prado, Johnson, and Fair [*Chem. Eng. Progr.* **83**(3): 32 (1987)]. Porter and Jenkins [*I. Chem. E. Symp. Ser.* **56:** Summary Paper (1979)] presented a simple correlation for the froth-to-spray transition.

$$F_{LG}\frac{N_p A_B}{L_w} = 0.0191 \tag{14-127}$$

The terms of this equation are in English units and are explained in the Nomenclature. This correlation is based on the premise that froth-to-spray transition occurs when the entrainment versus liquid load relationship passes through a minimum (see the subsection Entrainment). Alternatively, it was argued that the minimum represents a transition from the froth regime to a partially developed spray region (Kister, Pinczewski, and Fell, paper presented in the 90th National AIChE Meeting, Houston, April 1981). If this alternative argument is valid, then when the correlation predicts froth, it is highly unlikely that the column operates in the spray regime; but when it predicts spray, the column may still be operating in the froth regime. Entrainment studies by Ohe (*Distillation 2005: Topical Conference Proceedings,* AIChE Spring National Meeting, Atlanta, April 10–13, 2005, p. 283) argue that the entrainment minima represent minimum liquid residence times on the tray and are unrelated to the froth–spray transition.

A second correlation is by Pinczeweski and Fell [*Ind. Eng. Chem. Proc. Des. Dev.* **21:** 774 (1982)]

$$u_B\sqrt{\rho_G} = 2.25\left(\frac{Q_L\sqrt{\rho_L}}{100}\right)^n \tag{14-128}$$

The terms of Eq. (14-128) are in English units and are explained in the Nomenclature. The exponent $n$ is calculated from Eq. (14-84). Equation (14-128) is based on transition data obtained from orifice jetting measurements for the air–water system and on entrainment minimum data for some hydrocarbon systems.

Summers and Sloley (*Hydroc. Proc.*, January 2007, p. 67) extended a correlation by Lockett (*Distillation Tray Fundamentals*, Cambridge University Press, Cambridge, UK, 1986) to define a spray factor given by

$$\text{Spray factor} = Kh_c\rho_L^{0.5}/(d_h u_h \rho_V^{0.5}) \tag{14-129}$$

where $K = 1$ for sieve trays, 2.5 for movable or fixed valves, $h_c$ is the clear liquid height, mm, calculated using the Colwell correlation Eq. (14-115), $u_h$ is the hole velocity, m/s, and other symbols are as described above.

According to Summers and Sloley, spray factors exceeding 2.78 in Eq. (14-129) signify operation definitely outside of the spray regime. Below 2.78, the lower the spray factor, the higher the potential for the operation to be in the spray regime, with vapor lifting liquid off the tray deck (or blowing the liquid off the tray). The equation indicates that devices where the vapor enters the tray horizontally are much less prone to liquid lifting off the tray. Compared to the two earlier correlations, Eq. (14-129) shows a much stronger dependence on the fractional hole area.

**Froth–Emulsion** Froth–emulsion transition occurs [Hofhuis and Zuiderweg, *I. Chem. E. Symp. Ser.* **56:** 2, 2/1 (1979)] when the aerated mass begins to obey the Francis weir formula. Using this criterion, the latest version of this transition correlation is

$$F_{LG}\frac{N_p A_B}{L_w h_c} = 0.0208 \tag{14-130}$$

The terms of this equation are in English units and are explained in the Nomenclature; $h_c$ is calculated from the Hofhuis and Zuiderweg equation.

$$h_c = 2.08\left(F_{LG}\frac{N_p A_B}{L_w}p\right)^{0.25} h_w^{0.5} \tag{14-131}$$

An inspection of the experimental data correlated shows that this, too, is a gradual transition, which occurs over a range of values rather than at a sharp point.

## TRAY EFFICIENCY

**Definitions**

***Overall Column Efficiency*** This is the ratio of the number of theoretical stages to the number of actual stages

$$E_{OC} = N_t/N_a \tag{14-132}$$

Since tray efficiencies vary from one section to another, it is best to apply Eq. (14-132) separately for the rectifying and stripping sections. In practice, efficiency data and prediction methods are often too crude to give a good breakdown between the efficiencies of different sections, and so Eq. (14-132) is applied over the entire column.

***Point Efficiency*** This is defined by Eq. (14-133) (Fig. 14-41*a*):

$$E_{OG} = \left(\frac{y_n - y_{n-1}}{y_n^* - y_{n-1}}\right)_{\text{point}} \tag{14-133}$$

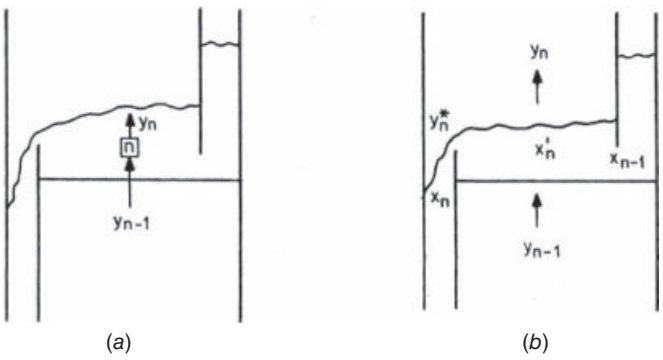

**FIG. 14-41** Point and Murphree efficiencies. (*a*) Point. (*b*) Murphree. (*From H. Z. Kister,* Distillation Design, *copyright © 1992 by McGraw-Hill; reprinted by permission.*)

where $y_n^*$ is the composition of vapor in equilibrium with the liquid at point $n$. The term $y_n$ is actual vapor composition at that point. The point efficiency is the ratio of the change of composition at a point to the change that would occur on a theoretical stage. As the vapor composition at a given point cannot exceed the equilibrium composition, fractional point efficiencies are always lower than 1. If there is a composition gradient on the tray, point efficiency will vary between points on the tray.

***Murphree Tray Efficiency*** [*Ind. Eng. Chem.* **17:** 747 (1925)] This is the same as point efficiency, except that it applies to the entire tray instead of to a single point (Fig. 14-41*b*):

$$E_{MV} = \left( \frac{y_n - y_{n-1}}{y_n^* - y_{n-1}} \right)_{\text{tray}} \tag{14-134}$$

If both liquid and vapor are perfectly mixed, liquid and vapor compositions on the tray are uniform, and the Murphree tray efficiency will coincide with the point efficiency at any point on the tray. In practice, a concentration gradient exists in the liquid, and $x_n$ at the tray outlet is lower than $x'_n$ on the tray (see Fig. 14-41*b*). This frequently lowers $y_n^*$ relative to $y_n$, thus enhancing tray efficiency [Eq. (14-134)] compared with point efficiency. The value of $y_n^*$ may even drop below $y_n$. In this case, $E_{MV}$ exceeds 100 percent [Eq. (14-134)].

Overall column efficiency can be calculated from the Murphree tray efficiency by using the relationship developed by Lewis [*Ind. Eng. Chem.* **28:** 399 (1936)].

$$E_{OC} = \frac{\ln[1 + E_{MV}(\lambda - 1)]}{\ln \lambda} \tag{14-135}$$

where

$$\lambda = m \frac{G_M}{L_M} \tag{14-136}$$

Equation (14-135) is based on the assumption of constant molar overflow and a constant value of $E_{MV}$ from tray to tray. It needs to be applied separately to each section of the column (rectifying and stripping) because $G_M/L_M$, and therefore $\lambda$, varies from section to section. Where molar overflow or Murphree efficiencies vary throughout a section of column, the section needs to be divided into subsections small enough to render the variations negligible.

The point and Murphree efficiency definitions just given are expressed in terms of vapor concentrations. Analogous definitions can be made in terms of liquid concentrations. Further discussion is elsewhere (Lockett, *Distillation Tray Fundamentals,* Cambridge University Press, Cambridge, UK, 1986).

**Fundamentals** Figure 14-42 shows the sequence of steps for converting phase resistances to a tray efficiency. Gas and liquid film resistances are added to give the point efficiency. Had both vapor and liquid on the tray been perfectly mixed, the Murphree tray efficiency would have equaled the point efficiency. Since the phases are not perfectly mixed, a model of the vapor and liquid mixing patterns is needed for converting point efficiency to tray efficiency. Liquid mixing patterns are plug flow, backmixing, and stagnant zones, while vapor mixing patterns are perfect mixing and plug flow.

Lewis [*Ind. Eng. Chem.* **28:** 399 (1936)] was the first to derive quantitative relationships between the Murphree and the point efficiencies. He derived three mixing cases, assuming plug flow of liquid in all. The Lewis cases give the maximum achievable tray efficiency. In practice, efficiency is lower due to liquid and vapor nonuniformities and liquid mixing.

Most tray efficiency models are based on Lewis case 1 with vapor perfectly mixed between trays. For case 1, Lewis derived the following relationship:

$$E_{MV,\text{dry}} = \frac{\exp(\lambda E_{OG}) - 1}{\lambda} \tag{14-137}$$

The "dry" Murphree efficiency calculated thus far takes into account the vapor and liquid resistances and the vapor–liquid contact patterns, but it is uncorrected for the effects of entrainment and weeping. This correction converts the dry efficiency to a "wet" or actual Murphree tray efficiency. Colburn [Eq. (14-98), under Entrainment] incorporated the effect of entrainment on efficiency, assuming perfect mixing of liquid on the tray.

**Factors Affecting Tray Efficiency** Following is a summary based on the industry's experience. A detailed discussion of the fundamentals is found in Lockett's book (*Distillation Tray Fundamentals,* Cambridge University Press, Cambridge, UK, 1986). A detailed discussion of the reported

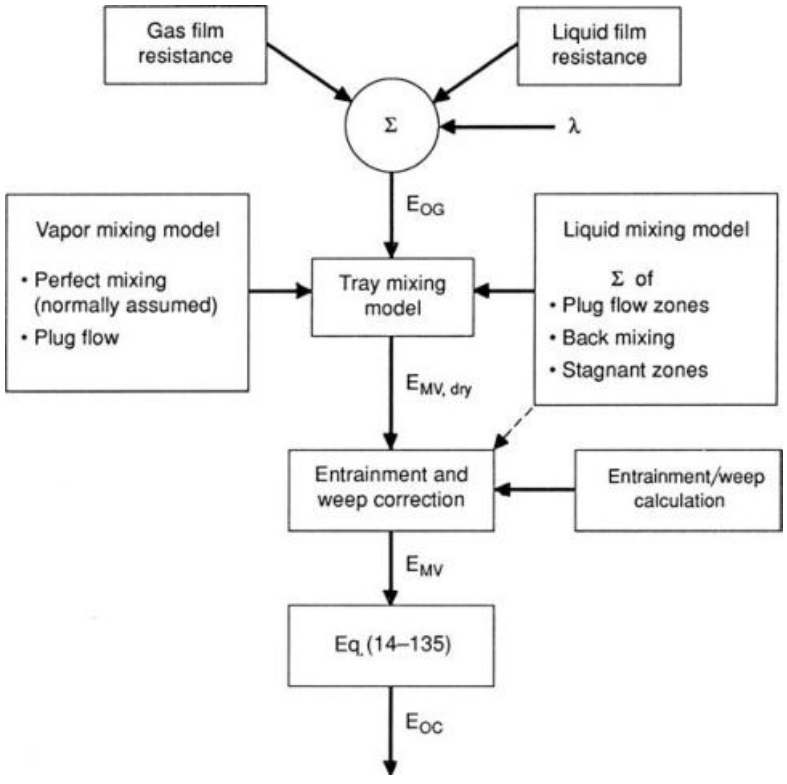

**FIG. 14-42** Sequence of steps for theoretical prediction of tray efficiency. (*From H. Z. Kister,* Distillation Design, *copyright © 1992 by McGraw-Hill; reprinted by permission.*)

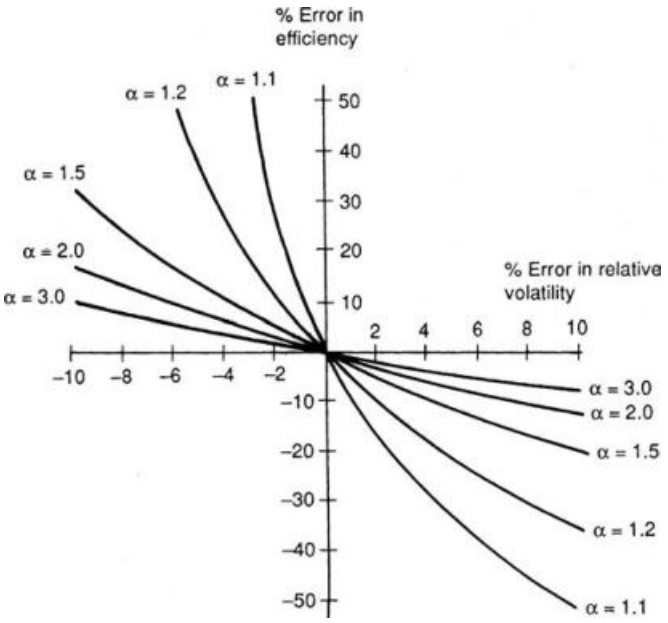

**FIG. 14-43** Direct effect of errors in relative volatility on error in tray efficiency. (*From H. Z. Kister,* Distillation Design, *copyright © 1992 by McGraw-Hill; reprinted by permission.*)

experience, and the basis of statements made in this section, are in Kister's book (*Distillation Design,* McGraw-Hill, New York, 1992) and later paper (*Chem. Eng. Progr.*, June 2008, p. 39). One useful finding both by Kister and by Hennigan (*Distillation 2011: Topical Conference Proceedings,* AIChE Spring National Meeting, Chicago, Ill., March 2011, p. 151) is that for hydraulically sound tray designs, tray geometry has only a small influence on tray efficiency.

***Errors in Vapor–Liquid Equilibrium (VLE)*** Errors in relative volatility are the most underrated factor affecting tray efficiency. Figure 14-43 shows the direct effect of the errors [Deibele and Brandt, *Chem. Ing. Tech.* **57**(5): 439 (1985); Roy P. and G. K. Hobson, *I. Chem. E. Symp. Ser.* **104:** A273 (1987)]. At very low relative volatilities ($\alpha < 1.2$), small errors in VLE have a huge impact on tray efficiency. For instance, at $\alpha = 1.1$, a −3 percent error gives a tray efficiency 40 to 50 percent higher than its true value (Fig. 14-43). Since VLE errors are seldom lower than ±2 to 3 percent, tray efficiencies of low-volatility systems become meaningless unless accompanied by VLE data. Likewise, comparing efficiencies derived for a low-volatility system by different sources is misleading unless one is using identical VLE.

Figure 14-43 shows that errors in relative volatility are a problem only at low relative volatilities; for $\alpha > 1.5$ to 2.0, VLE errors have negligible direct impact on tray efficiency.

Most efficiency data reported in the literature are obtained at total reflux, and there are no indirect VLE effects. For measurements at finite reflux ratios, the indirect effects below compound the direct effect of Fig. 14-43. Consider a case where $\alpha_{apparent} < \alpha_{true}$ and test data at a finite reflux are analyzed to calculate tray efficiency. Due to the volatility difference, $R_{min,apparent} > R_{min,true}$. Since the test was conducted at a fixed reflux flow rate, $(R/R_{min})_{apparent} < (R/R_{min})_{true}$. A calculation based on the apparent $R/R_{min}$ will give more theoretical stages than a calculation based on the true $R/R_{min}$. This means a higher apparent efficiency than the true value.

The indirect effects add to those of Fig. 14-43, widening the gap between true and apparent efficiency. The indirect effects exponentially escalate as minimum reflux is approached. Small errors in VLE or reflux ratio measurement (this includes column material balance as well as reflux rate) alter $R/R_{min}$. Near minimum reflux, even small $R/R_{min}$ errors induce huge errors in the number of stages, and therefore in tray efficiency. Efficiency data obtained near minimum reflux are therefore meaningless and potentially misleading.

***Accuracy of Mass Balance and Reflux/Reboil Measurements*** Errors in these variables affect efficiencies derived from test data. This includes errors in physical properties (e.g., densities, latent heats) that are used for evaluating the molar reflux ratio. When the measured apparent molar reflux ratio is lower than the true reflux ratio, a calculation based on the measured reflux ratio will give a false high tray efficiency. These errors escalate exponentially as minimum reflux is approached.

***Liquid Flow Patterns on Large Trays*** The most popular theoretical models (below) postulate that liquid crosses the tray in plug flow with superimposed backmixing, and that the vapor is perfectly mixed. Increasing tray diameter promotes liquid plug flow and suppresses backmixing.

The presence of stagnant zones on large-diameter distillation trays is well established, but the associated efficiency loss is poorly understood; in some cases, significant efficiency losses, presumably due to stagnant zones, were reported [Weiler, Kirkpatrick, and Lockett, *Chem. Eng. Progr.* **77**(1): 63 (1981)], while in other cases, no efficiency difference was observed [Yanagi and Scott, *Chem. Eng. Progr.* **69**(10): 75 (1973)]. Several techniques are available for eliminating stagnant regions (see Kister, *Distillation Design,* McGraw-Hill, New York, 1992, for some), but their effectiveness for improving tray efficiency is uncertain.

***Weir Height*** Taller weirs raise the liquid level on the tray in the froth and emulsion regimes. This increases interfacial area and vapor contact time, which should theoretically enhance efficiency. In the spray regime, weir height affects neither liquid level nor efficiency. In distillation systems, the improvement of tray efficiency due to taller weirs is small, often marginal.

***Length of Liquid Flow Path*** Longer liquid flow paths enhance the liquid–vapor contact time and the significance of liquid plug flow, and therefore raise efficiency. Typically, doubling the flow path length (such as going from two-pass to one-pass trays at a constant tower diameter) raises tray efficiency by 5 to 15 percent.

***Fractional Hole Area*** Efficiency increases with a reduction in fractional hole area. Tests by Yanagi and Sakata [*Ind. Eng. Chem. Proc. Des. Dev.* **21:** 712 (1982)] in commercial-scale towers showed a 5 to 10 percent increase in tray efficiency when fractional hole area was lowered from 14 to 8 percent (Fig. 14-44).

***Hole Diameter*** The jury is out on the effect of hole diameter on tray efficiency. There is, however, a consensus that the effect of hole diameter on efficiency is small, often negligible.

***Tray Spacing*** Commercial-scale test data (Kister, *Chem. Eng. Progr.*, June 2008, p. 39) showed little effect of tray spacing on tray efficiency.

***Vapor–Liquid Loads and Reflux Ratio*** Vapor and liquid loads, as well as the reflux ratio, have a small effect on tray efficiency (Fig. 14-44) as long as no capacity or hydraulic limits (flood, weep, channeling, etc.) are violated.

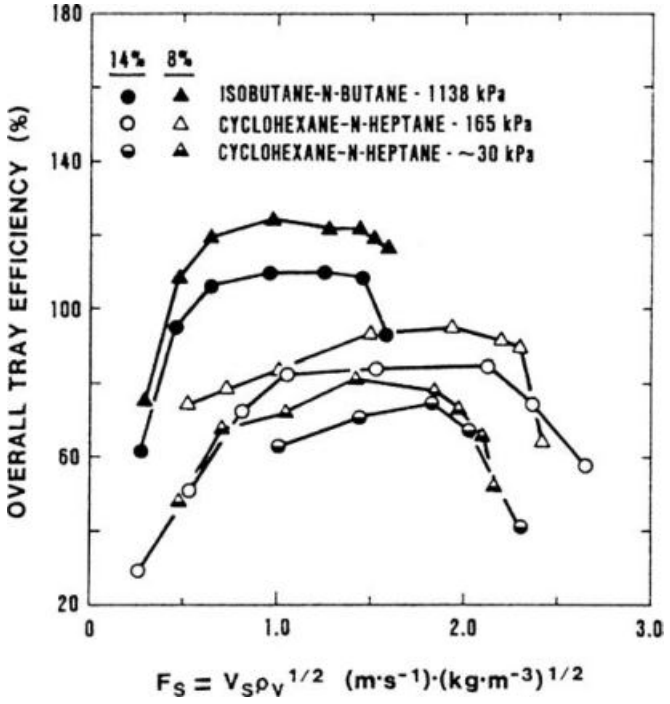

**FIG. 14-44** Efficiency reduction when fractional hole area is increased, also showing little effect of vapor and liquid loads on efficiency in the normal operating range (between excessive weeping and excessive entrainment). Also shown is the small increase in efficiency with pressure. FRI data, total reflux, $D_T = 1.2$ m, $S = 610$ mm, $h_w = 50.8$ mm, $d_H = 12.7$ mm. (*Reprinted with permission from T. Yanagi and M. Sakata,* Ind. Eng. Chem. Proc. Des. Dev. ***21:*** *712; copyright © 1982, American Chemical Society.*)

***Viscosity, Relative Volatility*** Efficiency increases as liquid viscosity and relative volatility diminish. These effects are reflected in the O'Connell correlation, to be described later.

***Two Liquid Phases*** Herron, Kruelskie, and Fair's [*AIChE J.* **34**(8): 1267 (1988)] oil–water tests in a pilot-scale tower showed that gas agitation on the trays caused the two liquid phases to behave as a homogenous liquid that followed general correlations for pressure drop, liquid holdup, froth height, downcomer backup, and entrainment with no foaming or unusual efficiency trends. They concluded that when immiscible liquids are both present in significant proportions, designers need not fear unusual hydraulic or mass-transfer behavior. The Davies, Ali, and Porter [*AIChE J.* **33**(1): 161 (1987)] *n*-hexane/1-propanol/water tests in an Oldershaw column showed foaming only on those plates with liquid composition near that of the one-phase/two-phase transition. Mortaheb, Kosuge, and Asano [*Chem. Eng. J.* **88:** 59 (2002)] concurred with Herron et al. on tray efficiency but noted that the second liquid phase raised the mass-transfer resistance in the liquid.

***Surface Tension*** There is uncertainty about the effect of surface tension on tray efficiency. Often, it is difficult to divorce the surface tension effects from those of other physical properties.

***Pressure*** Tray efficiency slightly increases with pressure (Fig. 14-44), reflecting the rise of efficiency with a reduction in liquid viscosity and in relative volatility, which generally accompany a distillation pressure increase.

At pressures exceeding 10 to 20 bar (150 to 300 psia), and especially at high liquid rates, vapor entrainment into the downcomer liquid becomes important, and tray efficiency decreases with further increases in pressure [Zuiderweg, *Int. Chem. Eng.* **26**(1): 1 (1986)].

***Maldistribution*** Maldistribution can cause major efficiency reduction in multipass trays (>two passes). Further discussion appears in the subsection Number of Passes.

## OBTAINING TRAY EFFICIENCY

Efficiency prediction methods are listed below in decreasing order of reliability. An excellent paper by Hennigan (*Distillation 2011: Topical Conference Proceedings,* AIChE Spring National Meeting, Chicago, Ill., March, 2011, p. 151) offers methods to critically review efficiency numbers and to manage the uncertainties involved.

**Rigorous Testing** Rigorous testing of a plant column is generally the most reliable method of obtaining tray efficiency. Test procedures can be found elsewhere (AIChE Equipment Testing Procedures Committee, *AIChE Equipment Testing Procedure—Trayed and Packed Columns,* 3d ed., Wiley, New York, 2014; Cai, "Column Performance Testing Procedures," chap. 3 in Gorak and Schoenmakers, *Distillation Operation and Application*, Academic Press, New York, 2014).

**Scale-Up from an Existing Commercial Column** As long as data are for the same system under similar process conditions, loadings, and operating regimes, data obtained in one column directly extend to another. Fractional hole area and the number of tray passes have a small but significant effect on efficiency, and any changes in these parameters need to be allowed for during scale-up. The empirical information in the subsection Factors Affecting Tray Efficiency can be used to estimate the magnitude of the changes on efficiency.

**Scale-Up from Existing Commercial Column to Different Process Conditions** During scale-up, test data are analyzed by computer simulation. The number of theoretical stages is varied until the simulated product compositions and temperature profile match the test data. Tray efficiency is determined by the ratio of theoretical stages to actual trays. In this procedure, errors in VLE are offset by compensating errors in tray efficiency. For instance, if the relative volatility calculated by the simulation is too high, fewer stages will be needed to match the measured data, that is, "apparent" tray efficiency will be lower. Scale-up will be good as long as the VLE and efficiency errors continue to offset each other equally. This requires that process conditions (feed composition, feed temperature, reflux ratio, etc.) remain unchanged during scale-up.

When process conditions change, the VLE and efficiency errors no longer offset each other equally. If the true relative volatility is higher than simulated, then the scale-up will be conservative. If the true relative volatility is lower than simulated, the scale-up will be optimistic. A detailed discussion is found in Kister, *Distillation Design,* McGraw-Hill, New York, 1992.

**Experience Factors** These are tabulations of efficiencies previously measured for various systems. Tray efficiency is insensitive to tray geometry (above), so in the absence of hydraulic anomalies and issues with VLE data, efficiencies measured in one tower are extensible to others distilling the same system. A small allowance to variations in tray geometry as discussed above is in order. Caution is required with mixed aqueous-organic systems, where concentration may have a marked effect on physical properties, relative volatility, and efficiency. Table 14-12 shows typical tray efficiencies reported in the literature.

Vital, Grossel, and Olsen [*Hydroc. Proc.* **63**(11): 147 (1984)] and Garcia and Fair [*Ind. Eng. Chem. Res.* **39:** 1809 (2000)] present an extensive tabulation of tray efficiency data collected from the published literature.

The *GPSA Engineering Data Book* (10th ed., Gas Processors Association, 1987) and Kaes (*Refinery Process Modeling—A Practical Guide to Steady State Modeling of Petroleum Processes Using Commercial Simulators,* Athens Printing Co., Athens, Ga., 2000) tabulate typical efficiencies in gas plant and refinery columns, respectively. Pilling (Paper presented at the 4th Topical Conference on Separations Science and Technology, November 1999, available from Sulzer Chemtech, Tulsa, Okla.) tabulated more typical efficiencies. Similar information is often available from simulation guide manuals. The quality and reliability of efficiencies from these sources vary and are generally lower than the reliability of actual measured data.

**Scale-Up from a Pilot- or Bench-Scale Column** This is a very common scale-up. No reduction in efficiency on scale-up is expected as long as several precautions are observed. These precautions, generally relevant to pilot- or bench-scale columns, are spelled out with specific reference to the Oldershaw column.

***Scale-Up from Oldershaw Columns*** One laboratory-scale device that found wide application in efficiency scale-up is the Oldershaw column [Fig. 14-45, Oldershaw, *Ind. Eng. Chem. Anal. Ed.* **13:** 265 (1941)]. This glass column is available from a number of laboratory supply houses. Typical column diameters are 25 to 100 mm (1 to 4 in), with tray spacing the same as the column diameter. Metal Oldershaw columns were available in the past but nowadays are scarce.

Fair, Null, and Bolles [*Ind. Eng. Chem. Process Des. Dev.* **22:** 53 (1983)] found that efficiency measurements in Oldershaw columns closely approach the point efficiencies [Eq. (14-133)] measured in commercial sieve-tray columns (Fig. 14-46) providing (1) the systems being distilled are the same, (2) comparison is made at the same relative approach to the flood point, (3) operation is at total reflux, and (4) a standard Oldershaw device is used in the laboratory experimentation.

A mixing model can be used to convert the Oldershaw point efficiencies to overall column efficiencies. This enhances the commercial column efficiency estimates. A conservative approach suggested by Fair et al. is to apply the Oldershaw column efficiency as the estimate for the overall column efficiency of the commercial column, taking no credit for the greater plug-flow character upon scale-up. The author prefers this conservative approach, considering the poor reliability of mixing models.

Previous work with Oldershaw columns [Ellis, Barker, and Contractor, *Trans. Instn. Chem. Engnrs.* **38:** 21 (1960)] presents an additional note of caution. Cellular (i.e., wall-supported) foam may form in pilot or Oldershaw columns, but is rare in commercial columns. For a given system, higher Oldershaw column efficiencies were measured under cellular foam conditions than under froth conditions. For this reason, Gerster [*Chem. Eng. Progr.* **59**(3): 35 (1963)] warned that when cellular foam can form, scale-up from an Oldershaw column may be dangerous. The conclusions presented by Fair et al. do not extend to Oldershaw columns operating in the cellular foam regime. Cellular foam can be identified by lower pilot column capacity compared to a standard mixture that is visualized not to form cellular foam.

Heat losses are a major issue in pilot and Oldershaw columns and can lead to optimistic scale-up. Special precautions are needed to keep these at a minimum. Vacuum jackets with viewing ports are commonly used.

Uses of Oldershaw columns for less conventional systems and applications were described by Fair, Reeves, and Seibert (Topical Conference on Distillation, AIChE Spring Meeting, New Orleans, March 10–14, 2002, p. 27). The applications described include scale-up in the absence of good VLE, steam stripping efficiencies, individual component efficiencies in multicomponent distillation, determining component behavior in azeotropic separation, and foam testing.

**Empirical Efficiency Prediction** An empirical correlation that has been the standard of the industry for distillation tray efficiency prediction for seven decades is the O'Connell plot [*Trans. Am. Inst. Chem. Eng.* **42:** 741 (1946)], Fig. 14-47. O'Connell extended an earlier correlation by Drickamer and Bradford [*Trans. Am. Inst. Chem. Eng.* **39:** 319 (1943)] of tray efficiency as a function of liquid viscosity for petroleum cuts. O'Connell's extension added relative volatility to the *x*-axis, making it suitable to a wide range of chemical and refinery systems.

Lockett (*Distillation Tray Fundamentals,* Cambridge University Press, Cambridge, UK, 1986) noted some theoretical sense in O'Connell's correlation. Higher viscosity usually implies lower liquid diffusivity and therefore greater liquid-phase resistance and lower efficiency. Higher relative volatility increases the significance of the liquid-phase resistance, thus reducing efficiency. Chen and Chuang [*Ind. Eng. Chem. Res.* **34**(9): 3078 (1995)]

**TABLE 14-12 Representative Tray Efficiencies**

| Tray | System | Column diameter, ft | Tray spacing, in | Pressure, psia | Efficiency, % | % hole (slot) area | Ref. |
|---|---|---|---|---|---|---|---|
| Sieve | Methanol-water | 3.2 | 15.7 | 14.7 | 70–90 | 10.8 | 2 |

showed that the O'Connell correlation can be derived from theory if one assumes that distillation mass transfer is liquid-film controlled. Recently, Duss and Taylor (*Kister Distillation Symposium*, AIChE Spring Meeting, San Antonio, Tex., March 26–30, 2017, p. 285) successfully showed that the O'Connell Correlation can be derived from first principles by assuming that the number of transfer units in the vapor equals the number of transfer units in the liquid. For each phase, the transfer unit equals the mass transfer coefficient times the interfacial area per unit volume in the froth, times the residence time in the froth. They also proposed a slightly modified O'Connell equation that shows promise.

Lockett expresses the O'Connell plot in equation form:

$$E_{OC} = 0.492(\mu_L \alpha)^{-0.245} \tag{14-138}$$

The viscosity is in cP, and $E_{OC}$ is fractional. The volatility and viscosity are evaluated at the average arithmetic temperature between the column top and bottom temperatures. The relative volatility is between the key components.

The O'Connell correlation was based on data for bubble-cap trays. For sieve and valve trays, its predictions are likely to be slightly conservative.

Schon (*Distillation 2011: Topical Conference Proceedings,* AIChE Spring National Meeting, Chicago, Ill., March 2011) reports success with a modified O'Connell analysis (MOCA) in which empirical correction factors are added to the slope and intercept in Eq. (14-138) and are individually fitted for each stage to match the simulation of test data.

**Theoretical Efficiency Prediction** Theoretical tray efficiency prediction is based on the two-film theory and the sequence of steps in Fig. 14-42. Almost all methods evolved from the AIChE model (AIChE Research Committee, *Bubble Tray Design Manual,* American Institute of Chemical Engineers, New York, 1958). This model was developed over five years in the late 1950s in three universities. Since then, several aspects of the AIChE model have been criticized, corrected, and modified. Reviews are given by Lockett (*Distillation Tray Fundamentals,* Cambridge University Press, Cambridge, UK, 1986) and Chan and Fair [*Ind. Eng. Chem. Proc. Des. Dev.* **23:** 814 (1984)]. An improved version of the AIChE model, which alleviated several of its shortcomings, updated its hydraulic and mass-transfer relationships, and generally gave good predictions when tested against a wide data bank, was produced by Chan and Fair.

The Chan and Fair correlation is considered the most reliable fundamental correlation for tray efficiency, but even this correlation has been unable to rectify several theoretical and practical limitations inherited

from the AIChE correlation (see Kister, *Distillation Design,* McGraw-Hill, New York, 1992). Garcia and Fair [*Ind. Eng. Chem. Res.* **39:** 1818, (2000)] proposed a more fundamental and accurate model that is also more complicated to apply.

The prime issue that appears to plague fundamental tray efficiency methods is their tendency to predict efficiencies of 80 to 100 percent for distillation columns larger than 1.2 m (4 ft) in diameter. In the real world, most columns run closer to 60 percent efficiency. Cai and Chen (*Distillation 2003: Topical Conference Proceedings*, AIChE Spring National Meeting, New Orleans, La., March 30–April 3, 2003) show that published eddy diffusivity models, which are based on small-column work, severely underestimate liquid backmixing and overestimate plug flow in commercial-scale columns, leading to optimistic efficiency predictions. Which other limitations (if any) in the theoretical methods contribute to the mismatch, and to what degree, is unknown. For this reason, the author would not recommend any currently published theoretical tray efficiency correlation for obtaining design efficiencies.

***Example 14-12 Estimating Tray Efficiency*** For the column in Example 14-9, estimate the tray efficiency, given that the relative volatility near the feed point is 1.3 and the viscosity is 0.25 cP.

*Solution* Table 14-12 presents measurements by Billet (*Packed Column Analysis and Design,* Ruhr University, Bochum, Germany, 1989) for ethylbenzene-styrene under similar pressure with sieve and valve trays. The column diameter and tray spacing in Billet's tests were close to those in Example 14-9. Since both have single-pass trays, the flow path lengths are similar. The fractional hole area (14 percent in Example 14-9) is close to that in Table 14-12 (12.3 percent for the tested sieve trays, 14 to 15 percent for standard valve trays). So the values in Table 14-12 should be directly applicable, that is, 70 to 85 percent. A conservative estimate would be 70 percent. The actual efficiency should be about 5 to 10 percent higher.

Alternatively, using Eq. (14-138) or Fig. 14-47, $E_{OC} = 0.492(0.25 \times 1.3)^{-0.245} = 0.65$ or 65 percent. As stated, the O'Connell correlation tends to be slightly conservative. This confirms that 70 percent will be a good estimate.

## EQUIPMENT FOR DISTILLATION AND GAS ABSORPTION: PACKED COLUMNS

Packings are generally divided into three classes:

1. *Random or dumped packings* (Figs. 14-48 and 14-49) are discrete pieces of packing, of a specific geometric shape, that are "dumped" or randomly packed into the column shell.
2. *Structured or systematically arranged packings* (Fig. 14-50) are crimped layers of corrugated sheets (usually) or wire mesh. Sections of these packings are stacked in the column.
3. *Grids.* These are also systematically arranged packings, but instead of wire mesh or corrugated sheets, these use an open-lattice structure.

Random and structured packings are common in commercial practice. The application of grids is limited primarily to heat-transfer and wash services and/or where a high fouling resistance is required. Grids are discussed in detail elsewhere (Kister, *Distillation Design,* McGraw-Hill, New York, 1992).

Figure 14-51 is an illustrative cutaway of a packed tower, depicting typical internals. This tower has a structured-packed top bed and a random-packed bottom bed. Each bed rests on a support grid or plate. The lower bed has a holddown grid at its top to restrict packing uplift. Liquid to each of the beds is supplied by a liquid distributor. An intermediate distributor, termed a *redistributor*, is used to introduce feed and/or to remix liquid at regular height intervals. The intermediate distributor in Fig. 14-51 is not self-collecting, so a chevron collector is used to collect the liquid from the bed above. An internal pipe passes this liquid to the distributor below. The collected liquid is mixed with the fresh feed (not shown) before entering the distributor. The reboiler return enters behind a baffle above the bottom sump.

As illustrated, the packing needs to be interrupted and a distributor added at each point where a feed enters or a product leaves. A simple

distillation tower with a single feed will have a minimum of two beds, a rectifying bed and a stripping bed.

## PACKING OBJECTIVES

The objective of any packing is to maximize efficiency for a given capacity, at an economic cost. To achieve these goals, packings are shaped to

1. *Maximize the specific surface area, that is, the surface area per unit volume.* This maximizes vapor–liquid contact area, and, therefore, efficiency. A corollary is that efficiency generally increases as the random packing size is decreased or as the space between structured packing layers is decreased.
2. *Spread the surface area uniformly.* This improves vapor–liquid contact, and, therefore, efficiency. For instance, a Raschig ring (Fig. 14-48*a*) and a Pall® ring (Fig. 14-48*c*) of an identical size have identical surface areas per unit volume, but the Pall® ring has a superior spread of surface area and therefore gives much better efficiency.
3. *Maximize the void space per unit column volume.* This minimizes resistance to gas upflow, thereby enhancing packing capacity. A corollary is that capacity increases with random packing size or with the space between structured packing layers. Comparing with the first objective, a tradeoff exists; the ideal size of packing is a compromise between maximizing efficiency and maximizing capacity.
4. *Minimize friction.* This favors an open shape that has good aerodynamic characteristics.
5. *Minimize cost.* Packing costs, as well as the requirements for packing supports and column foundations, generally rise with the weight per unit volume of packing. A corollary is that packings become cheaper as the size increases (random packing) and as the space between layers increases (structured packing).

## RANDOM PACKINGS

Historically, there were four generations of evolution in random packings. The first generation (1907 to the 1950s) produced two basic simple shapes—the Raschig ring and the Berl saddle (Fig. 14-48*a, b*) that became the ancestors of modern random packings. These packings have been superseded by more modern packing and are seldom used in modern distillation practice.

The second generation (late 1950s to the early 1970s) produced two popular geometries—the Pall® ring, which evolved from the Raschig ring, and the Intalox® saddle (Fig. 14-48*c–f*), which evolved from the Berl saddle. BASF developed the Pall® ring by cutting windows in the Raschig ring and bending the window tongues inward. This opened up the ring, lowering the aerodynamic resistance and dramatically enhancing capacity. The bent tongues improved area distribution around the particle, giving also better efficiency.

These improvements made the first-generation Raschig rings obsolete for distillation. Berl saddles (ceramics) are still used due to their good breakage resistance. The second-generation packings are still popular and extensively used in modern distillation practice. The Pall® ring is still a standard random packing up to now in many applications and serves as a benchmark packing for comparison.

The third generation (the mid-1970s to the late 1990s) has produced a multitude of popular geometries, most of which evolved from the Pall® ring and Intalox® saddle, featuring a more open ("lattice") structure to reduce pressure drop and slightly enhance capacity while retaining the same surface area per unit volume and therefore the efficiency. The IMTP® (Figure 14-49*a*) and similar shapes have been the dominant metal random packing in the last two decades. The CMR® (Figure 14-49*b*) and similar shapes are another popular third-generation packing both in metal and plastic. A more comprehensive description of the various packings is given elsewhere (Kister, *Distillation Design,* McGraw-Hill, New York, 1992). The third generation of packing was a significant, yet not large, improvement over the second generation.

The fourth generation (late 1990s to date) opened the lattice structures of the third-generation packings even more (Fig. 14-49*c–e*), providing relatively small additional pressure drop and capacity improvements, compared to the third-generation packings of the same efficiency. At present, both the third- and fourth-generation packings are popular.

## STRUCTURED PACKINGS

Structured packings have been around since as early as the 1940s. The very early structured packings, such as Panapak, never became popular, and they are seldom used nowadays.

The first generation of modern structured packings began in the late 1950s with high-efficiency wire-mesh packings such as Goodloe®, Hyperfil®, and the Sulzer® (wire-mesh) packings. By the early 1970s, these packings had made substantial inroads into vacuum distillation, where their low pressure drop per theoretical stage is a major advantage. In these services, they are extensively used today. Their high cost, high sensitivity to solids, and low capacity hindered their application outside vacuum distillation.

The corrugated-sheet packing, first introduced by Sulzer in the late 1970s, started a second generation of structured packings. With a high capacity, lower cost, and lower sensitivity to solids, while still retaining a high efficiency, these corrugated-sheet packings became competitive with conventional internals, especially for revamps. The 1980s saw an accelerated rise in the popularity of structured packings, to the point of their becoming one of the most popular column internals in use today.

Corrugated structured packings are fabricated from thin, corrugated (crimped) metal sheets, arranged parallel to one another. The corrugated sheets are assembled into an element (Figs. 14-50*a, c* and 14-51). The sheets in each element are arranged at a fixed angle to the vertical. Table 14-14 contains geometric data for several corrugated packings.

**Geometry (Fig. 14-52)** The crimp size defines the opening between adjacent corrugated layers. Smaller *B, h,* and *S* yield narrower openings, more sheets (and, therefore, greater surface area) per unit volume, and more efficient packing, but higher resistance to gas upflow, lower capacity, and enhanced sensitivity to plugging and fouling.

The corrugations spread gas and liquid flow through a single element in a series of parallel planes. To spread the gas and liquid uniformly in all radial planes, adjacent elements are rotated so that sheets of one element are at a

(*e*) A sheet of Flexipac HC™, a third-generation structured packing showing a 45° inclination angle in the element and near-vertical inclination at the element-to-element top and bottom transitions. (*Parts a, d, courtesy of Sulzer Chemtech; parts b, c, e, courtesy of Koch-Glitsch LP.*)

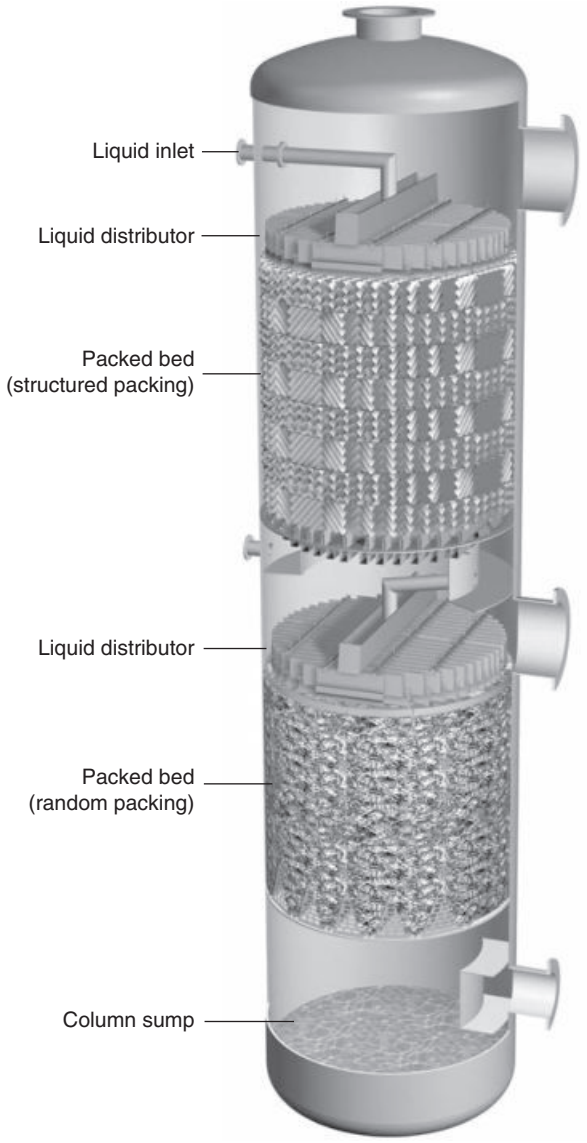

**FIG. 14-51** Illustrative cutaway of a packed tower, depicting an upper bed of structured packing and a lower bed of random packing. (*Courtesy of Sulzer Chemtech.*)

fixed angle to the layer below (Fig. 14-51). For good spread, element height is relatively short (typically 200 to 300 mm, 8 to 12 in), and the angle of rotation is around 90°.

The surfaces of a few structured packings (especially those used in highly fouling environments) are smooth. Most structured packings have a roughened or enhanced surface that assists the lateral spread of liquid, promotes film turbulence, and enhances the area available for mass transfer. Texturing commonly employed is embossing and grooving (Fig. 14-50*a, b*).

The surfaces of most (but not all) structured packings contain holes that serve as communication channels between the upper and lower surfaces of each sheet. If the holes are too small, or nonexistent, both sides of a sheet will be wet only at low liquid rates. At high liquid rates, *sheeting* or *blanking* will cause liquid to run down the top surface with little liquid wetting the bottom surface [Chen and Chuang, *Hydroc. Proc.* **68**(2): 37 (1989)], which may lower efficiency. Usually, but not always, the holes are circular (Fig. 14-50*a, b*), about 4 mm in diameter. Olujic et al. (*Distillation 2003: Topical Conference Proceedings*, AIChE Spring National Meeting, New Orleans, La., 2003, p. 523) showed that the hole diameter has a complex effect, strongly dependent on packing size, on both capacity and efficiency.

**Inclination Angle** In each element, corrugated sheets are most commonly inclined at about 45° to the vertical (typically indicated by the letter Y following the packing size). This angle is large enough for good drainage of liquid, avoiding stagnant pockets and regions of liquid accumulation, and small enough to prevent gas from bypassing the metal surfaces. In some packings, the inclination angle to the vertical is steepened to 30° (typically indicated by the letter X following the packing size). This improves drainage, and therefore capacity, but at the expense of reduced gas–liquid contact, and therefore efficiency.

A recent development followed the realization that liquid drainage was restricted at the element-to-element transition rather than inside elements [Lockett, Victor, and Billingham, *IChemE Symp. Ser.* **152:** 400 (2006)]. This means that the liquid accumulation leading to flood initiates at the transition region. A third generation of structured packing started, often referred to as *high-performance packings*, in which the main body of each element has layers inclined at 45°, but the ends of each element are vertical or almost vertical to permit drainage at this end region (Fig. 14-50*d, e*; but keep in mind that successive elements are rotated 90° rather than continuous, as shown in Fig. 14-50*d*). These high-performance packings offer greater capacity and lower pressure drop compared to equivalent 45° inclined packings, with efficiency the same with some (Pilling and Haas, *Topical Conference Proceedings*, AIChE Spring Meeting, New Orleans, March 10–14, 2002, p. 132; McNulty and Sommerfeldt in "Distillation: Horizons for the New Millennium," *Topical Conference Proceedings*, AIChE Spring Meeting, Houston, Tex., March 1999, p. 89) and lower with others [Olujic et al., *Chem. Eng. and Proc.* **42:** 55 (2003)].

## PACKED-COLUMN FLOOD AND PRESSURE DROP

Pressure drop of a gas flowing upward through a packing countercurrently to liquid flow is characterized graphically in Fig. 14-53. At very low liquid rates, the effective open cross section of the packing is not appreciably different from that of dry packing, and pressure drop is due to flow through a series of variable openings in the bed. Thus, pressure drop is proportional

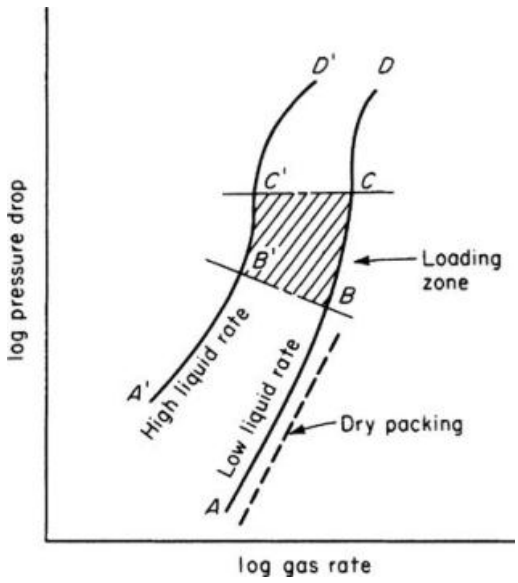

**FIG. 14-53** Pressure-drop characteristics of packed columns.

approximately to the square of the gas velocity, as indicated in the region *AB*. At higher liquid rates, the effective open cross section is smaller because of the presence of liquid (region *A′B′*). The pressure drop is higher, but still proportional to the square of the gas velocity.

At higher gas rates, a portion of the energy of the gas stream is used to support an increasing quantity of liquid in the column. For all liquid rates, a zone is reached where pressure drop is proportional to a gas flow rate to a power distinctly higher than 2; this zone is called the *loading zone*. The increase in pressure drop is due to the liquid accumulation in the packing voids (region *BC* or *B′C′*).

As the liquid holdup increases, the effective orifice diameter may become so small that the liquid surface becomes continuous across the cross section of the column. Column instability occurs concomitantly with a rising continuous-phase liquid body in the column. Pressure drop shoots up with only a slight change in gas rate (condition *C* or *C′*). The phenomenon is called *flooding* and is analogous to entrainment flooding in a tray column.

Alternatively, a phase inversion occurs, and gas bubbles through the liquid. The column is not unstable and can be brought back to gas-phase continuous operation by merely reducing the gas rate. A stable operating condition beyond flooding (region *CD* or *C′D′*) may form with the liquid as the continuous phase and the gas as the dispersed phase [Lerner and Grove, *Ind. Eng. Chem.* **43:** 216 (1951); Teller, *Chem. Eng.* **61**(9): 168 (1954); Leung et al., *Ind. Eng. Chem. Fund.* **14**(1): 63 (1975); Buchanan, *Ind. Eng. Chem. Fund.* **15**(1): 87 (1976)].

For total-reflux distillation in packed columns, regions of loading and flooding are identified by their effects on mass-transfer efficiency, as shown in Fig. 14-54. Gas and liquid rate increase together, and a point is reached at which liquid accumulates rapidly (point *B*) and effective surface for mass transfer decreases rapidly.

**Flood-Point Definition** In 1966, Silvey and Keller [*Chem. Eng. Progr.* **62**(1): 68 (1966)] listed 10 different flood point definitions that have been used by different literature sources. A later survey (Kister and Gill, *Proceedings of Chemeca 92*, Canberra, Australia, 1992, p. 185-2) listed twice that many. As Silvey and Keller pointed out, the existence of so many definitions puts into question what constitutes flooding in a packed tower, and at what gas rate it occurs. Symptoms used to identify flood in these definitions include the appearance of liquid on top of the bed, excessive entrainment, a sharp rise in pressure drop, a sharp rise in liquid holdup, and a sharp drop in efficiency. The survey of Kister and Gill suggests that most flood point definitions describe the point of flooding initiation (*incipient flooding*; point *C* or *C′* on Figs. 14-53 and 14-54). The different incipient flooding definitions gave surprisingly little scatter of flood point data ( for a given packing under similar operating conditions). It follows that any definition describing flooding initiation should be satisfactory.

The author believes that due to the variations in the predominant symptom with the system and the packing, the use of multiple symptoms is most appropriate. The author prefers the following definition by Fair and Bravo [*Chem. Eng. Symp. Ser.* **104:** A183 (1987)]: "A region of rapidly increasing pressure drop with simultaneous loss of mass-transfer efficiency. Heavy entrainment is also recognized as a symptom of this region." An almost identical definition was presented earlier by Billet (*Distillation Engineering,* Chem. Publishing Co., New York, 1979).

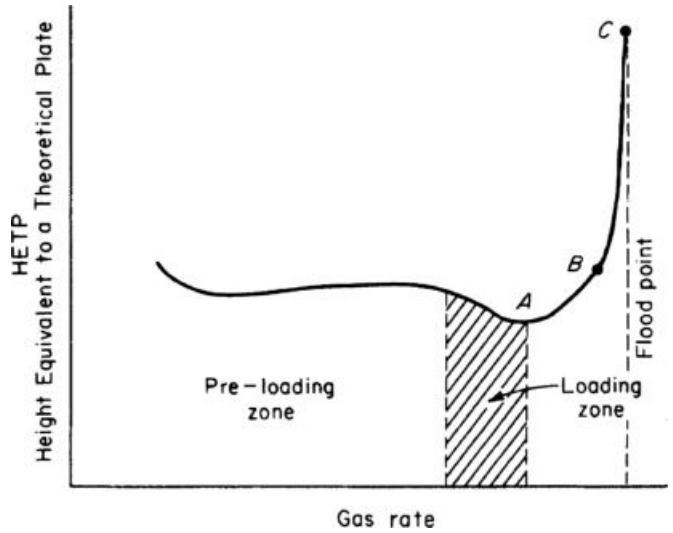

**FIG. 14-54** Efficiency characteristics of packed columns (total-reflux distillation.)

The maximum useful capacity (MUC, often also referred to as maximum efficient capacity, or maximum operational capacity) is defined as the "maximum vapor rate that provides normal efficiency of a packing when approaching flood" (i.e., point B in Fig. 14-54) (Strigle, *Packed Tower Design and Applications,* 2d ed., Gulf Publishing, Houston, Tex., 1994; Cai, chap. 3 in Gorak and Schoenmakers *Distillation Operation and Application*, Academic Press, New York, 2014). The MUC is clear-cut in Fig. 14-54. On the other hand, locating the MUC in other cases is difficult and leaves a lot of room for subjectivity.

In most cases [Kister and Gill, *Chem. Eng. Progr.* **87**(2): 32 (1991)], the velocity at which MUC is reached is related to the flood point velocity by

$$u_{S,\mathrm{MUC}} = 0.95\, u_{S,\mathrm{Fl}} \tag{14-139}$$

**Flood and Pressure Drop Prediction** The first generalized correlation of packed-column flood points was developed by Sherwood, Shipley, and Holloway [*Ind. Eng. Chem.* **30:** 768 (1938)] on the basis of laboratory measurements primarily on the air–water system with random packing. Later work with air and liquids other than water led to modifications of the Sherwood correlation, first by Leva [*Chem. Eng. Progr. Symp. Ser.* **50**(1): 51 (1954)], who also introduced the pressure drop curves, and later in a series of papers by Eckert. The generalized flooding–pressure drop chart by Eckert [*Chem. Eng. Progr.* **66**(3): 39 (1970)], included in previous editions of this handbook, was modified and simplified by Strigle (*Packed Tower Design and Applications,* 2d ed., Gulf Publishing, Houston, Tex., 1994) (Fig. 14-55). It is often called the generalized pressure drop correlation (GPDC). The ordinate is a capacity parameter [Eq. (14-140)] related to the Souders-Brown coefficient used for tray columns.

$$\mathrm{CP} = C_s\, F_p^{0.5} \nu^{0.05} = U_s \left( \frac{\rho_G}{\rho_L - \rho_G} \right)^{0.50} F_p^{0.5} \nu^{0.05} \tag{14-140}$$

where $U_S$ = superficial gas velocity, ft/s
$\rho_G$, $\rho_L$ = gas and liquid densities, lb/ft$^3$ or kg/m$^3$
$F_p$ = packing factor, ft$^{-1}$
$\nu$ = kinematic viscosity of liquid, cS
$C_S$ = *C*-factor, Eq. (14-77), based on tower superficial cross-sectional area, ft/s
CP = capacity factor, dimensional [units consistent with Eq. (14-140) and its symbols]

The abscissa scale term is the same flow parameter used for trays (dimensionless):

$$F_{LG} = \frac{L}{G} \left( \frac{\rho_G}{\rho_L} \right)^{0.5} \tag{14-141}$$

For structured packing, Kister and Gill [*Chem. Eng. Symp. Ser.* **128:** A109 (1992)] noticed a much steeper rise of pressure drop with flow parameter than that predicted from Fig. 14-55, and they presented a modified chart (Fig. 14-56).

The GPDC charts in Figs. 14-55 and 14-56 do not contain specific flood curves. Both Strigle and Kister and Gill recommend calculating the flood point from the flood pressure drop, $\Delta P_{\mathrm{flood}}$ (inch of water per foot of packings) given by the Kister and Gill equation

$$\Delta P_{\mathrm{flood}} = 0.12 F_p^{0.7} \tag{14-142}$$

Equation (14-142) permits finding the pressure drop curve in Fig. 14-55 or 14-56 at which incipient flooding occurs.

For low-capacity random packings, such as the small first-generation packings and those smaller than 1-in diameter ($F_p$ > 60 ft$^{-1}$), calculated flood pressure drops are well in excess of the upper pressure drop curve in Fig. 14-55. For these packings only, the original Eckert flood correlation [*Chem. Eng. Prog.* **66**(3): 39 (1970)] found in pre-1997 editions of this handbook and other major distillation texts is suitable.

The packing factor $F_p$ is empirically determined for each packing type and size. Values of $F_p$, together with general dimensional data for individual packings, are given for random packings in Table 14-13 (to go with Fig. 14-55) and for structured packings in Table 14-14 (to go with Fig. 14-56).

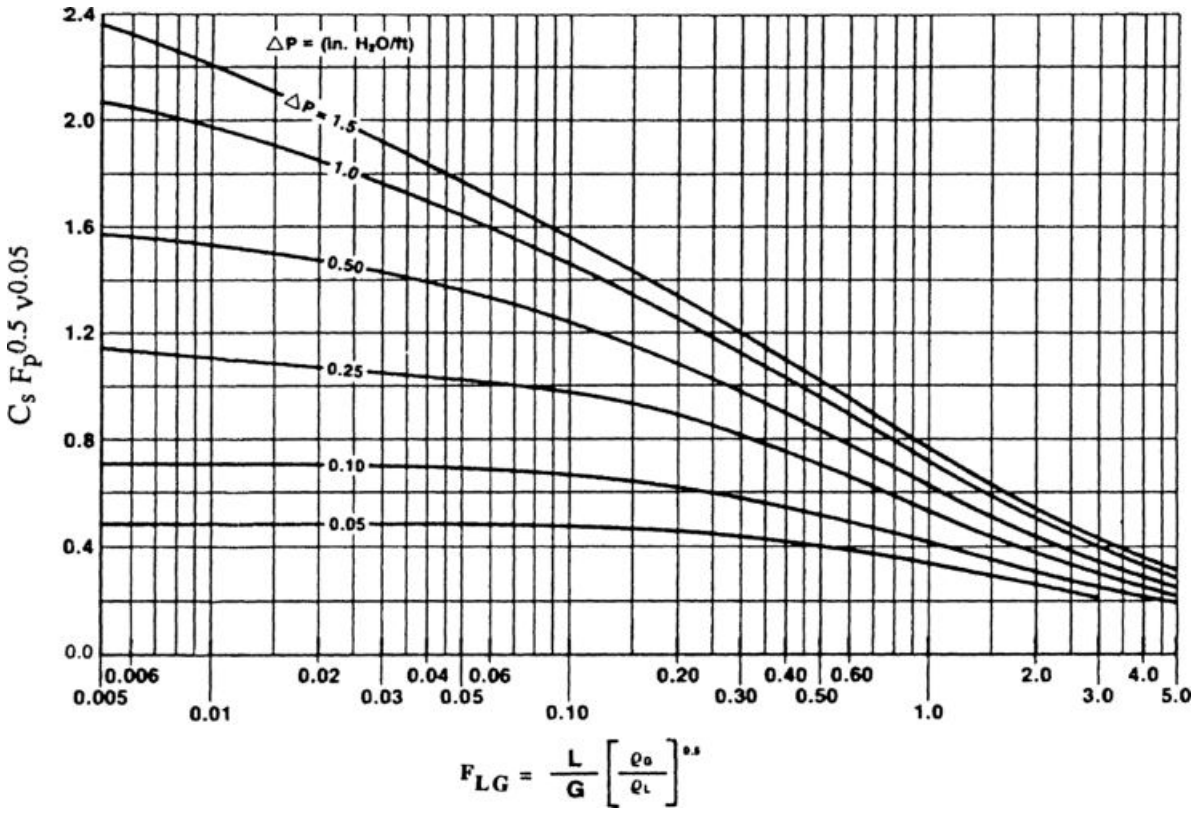

**FIG. 14-55** Generalized pressure drop correlation of Eckert as modified by Strigle. To convert inches $H_2O$ to mm $H_2O$, multiply by 83.31. (*From* Packed Tower Design and Applications by *Ralph E. Strigle, Jr. Copyright © 1994 by Gulf Publishing Co., Houston, Texas. Used with permission. All rights reserved.*)

Packing flood and pressure drop correlations should always be used with caution. Kister and Gill [*Chem. Eng. Progr.* **87**(2): 32 (1991)] showed that deviations from the GPDC predictions tend to be systematic and not random. To avoid regions in which the systematic deviations lead to poor prediction, they superimposed experimental data points for each individual packing on the curves of the GPDC. Figure 14-57 is an example. This method requires a single chart for each packing type and size. It provides the highest possible accuracy as it interpolates measured data and identifies uncertain regions. A set of charts is in Chapter 10 of Kister's book (*Distillation Design,* McGraw-Hill, New York, 1992) with updates in Kister, Larson, and Gill, (Paper presented at the AIChE Spring National Meeting, Houston, Tex., March 19–23, 1995) and in Kister, Scherffius, Afshar, and Abkar (*Distillation 2007: Topical Conference Proceedings,* 2007 AIChE Spring National Meeting, Houston, Tex., April 22–27, 2007, p.445). The latter reference also discusses correct and incorrect applications of those interpolation charts.

There are many alternative methods for flood and pressure drop prediction. The Billet and Schultes [*IChemE Symp. Ser.* **104:** A171, B255 (1987);

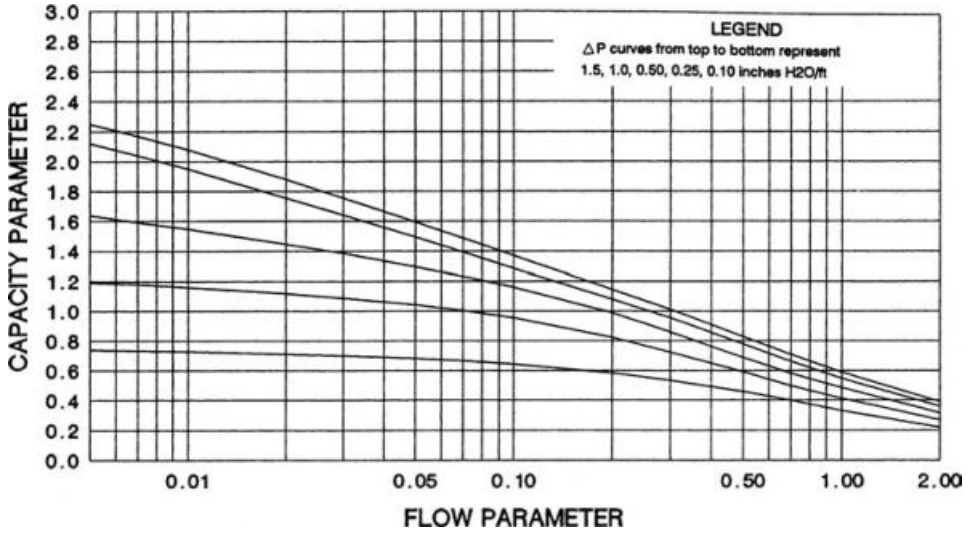

**FIG. 14-56** The Kister and Gill GPDC (SP) chart for structured packings only. Abscissa and ordinate same as in Fig. 14-55. (*From Kister, H. Z., and D. R. Gill,* IChemE Symp. Ser. *128: p. A109, 1992. Reprinted courtesy of IChemE.*)
