Z.,* Distillation Design*, copyright © McGraw-Hill, 1992; used with permission.*)

*Trans. IChemE.* **77:** Part A, p. 498 (September 1999)] and the Maćkowiak (*Fluid Dynamics of Packed Columns*, Springer/Heidelberg, New York, 2010) correlations are versions of the GPDC that take the liquid holdup into account. The Eiden and Bechtel correlation [*IChemE Symp. Ser.* **142:** 757 (1997)] is a version of the GPDC in which accuracy is improved by using constants representative of packing shape instead of packing factors. The Lockett and Billingham correlation [*IChemE Symp. Ser.* **152:** 400 (2006)] uses a Wallis correlation

$$C_G^{0.5} + mC_L^{0.5} = C_{LG} \tag{14-143}$$

where

$$C_L = u_L[\rho_L/(\rho_L - \rho_G)]^{0.5} \tag{14-144}$$

and was shown to work well for high-surface-area (> 400 $m^2/m^3$) structured packings. Here $C_G$ is the gas *C*-factor, Eq. (14-77), based on the tower superficial cross-sectional area, and $m$ and $C_{LG}$ are constants, available from the cited reference for some packing.

A drawback of most of these correlations (except that of Eiden and Bechtel) is the unavailability of constants for many, often most, of the modern popular packings.

The preceding methods apply to nonfoaming systems. Foaming systems can be handled either by applying additional derating (system) factors to the flood correlation (see Table 14-9) or by limiting the calculated pressure drop to 0.25 in of water per foot of packing (Hausch, in *Distillation Tools for the Practicing Engineer*, Topical Conference Proceedings, AIChE Spring Meeting, New Orleans, March 10–14, 2002, p. 119).

**Derating ("System") Factors** A review of some design criteria by Kooijman and Taylor (chap. 5 in Gorak and Schoenmakers, *Distillation Operation and Application*, Academic Press, New York, 2014) argued that the system factors in Table 14-9 can be extended to random packings by raising the relevant derating factor to the power of 0.7, or for a conservative design to a power of 0.8. The author prefers the more cautious approach of applying the same system factors as in Table 14-9. Comments in the tray section regarding the application of derating factors also extend to random packings.

**Pressure Drop** The GPDC discussed above (Figs. 14-55 and 14-56) and the Kister and Gill interpolation charts provide popular methods for calculating packing pressure drops. An alternative popular method that is particularly suitable for lower liquid loads was presented by Robbins.

For gas flow through dry packings, pressure drop may be estimated by the use of an orifice equation. For irrigated packings, pressure drop increases because of the presence of liquid, which effectively decreases the available cross section for gas flow (Fig. 14-53). Robbins (*Chem. Eng. Progr.*, May 1991, p. 87) uses the approach of correcting the dry pressure drop for the presence of liquid. The total pressure drop then becomes

$$\Delta P_t = \Delta P_d + \Delta P_L \tag{14-145}$$

where $\Delta P_t$ = total pressure drop, inches $H_2O$ per foot of packing

$$\Delta P_d = \text{dry pressure drop} = C_3 G_f^2 10^{(C_4 L_f)} \tag{14-146}$$

$\Delta P_L$ = pressure drop due to liquid presence

$$= 0.4[L_f/20{,}000]^{0.1}[C_3 G_f^2 10^{(C_4 L_f)}]^4 \tag{14-147}$$

$$G_f = \text{gas loading factor} = 986 F_s (F_{pd}/20)^{0.5} \tag{14-148}$$

$$L_f = \text{liquid loading factor} = L(62.4/\rho_L)(F_{pd}/20)^{0.5}\mu_L^{0.1} \tag{14-149}$$

The term $F_{pd}$ is a dry packing factor, specific for a given packing type and size. Values of $F_{pd}$ are given in Tables 14-13 and 14-14. For operating pressures above atmospheric, and for certain packing sizes, $L_f$ and $G_f$ are calculated differently:

$$G_f = 986 F_s (F_{pd}/20)^{0.5} 10^{0.3\rho_G} \tag{14-150}$$

$$L_f = L(62.4/\rho_L)(F_{pd}/20)^{0.5}\mu_L^{0.2} \qquad F_{pd} > 200 \tag{14-151a}$$

$$L_f = L(62.4/\rho_L)(20/F_{pd})^{0.5}\mu_L^{0.1} \qquad F_{pd} < 15 \tag{14-151b}$$

The Robbins equations require careful attention to dimensions. However, the use of the equations has been simplified through the introduction of

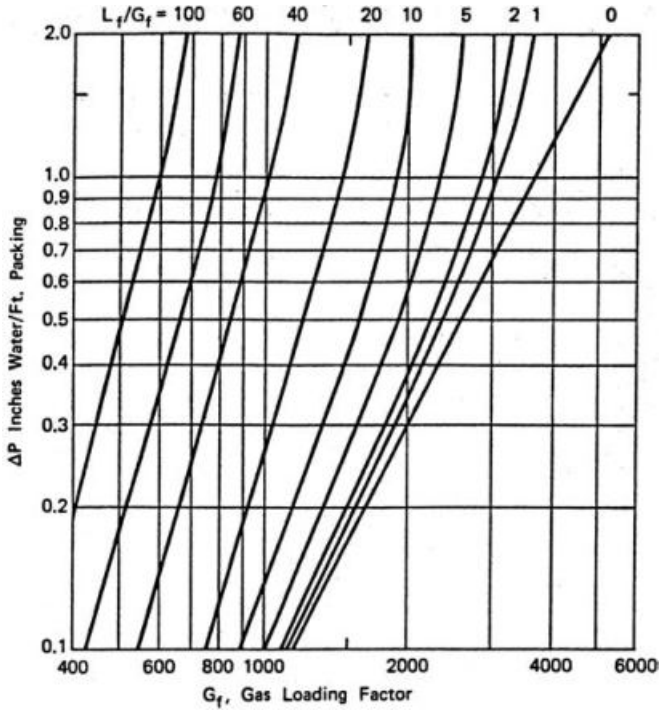

**FIG. 14-58** The Robbins generalized pressure-drop correlation. (*From L. A. Robbins. Chem* Eng. Progr., *May 1991, p. 87, reprinted courtesy of the American Institute of Chemical Engineers.*)

Fig. 14-58. The terms $L_f$ and $G_f$ are evaluated, and the $\Delta P_L$ is obtained directly from the chart. Basic nomenclature for the Robbins method follows:

$C_3 = 7.4(10)^{-8}$

$C_4 = 2.7(10)^{-5}$

$F_{pd}$ = dry packing factor, $ft^{-1}$

$F_s$ = superficial *F*-factor for gas, $U_t\rho_G^{0.5}$, $ft/s(lb/ft^3)^{0.5}$

$G$ = gas mass velocity, $lb/hr \cdot ft^2$

$G_f$ = gas loading factor, $lb/hr \cdot ft^2$

$L$ = liquid mass velocity, $lb/hr \cdot ft^2$

$L_f$ = liquid loading factor, $lb/hr \cdot ft^2$

$\Delta P$ = pressure drop, inches $H_2O$/ft packing (× 83.3 = mm $H_2O$/m packing)

$\rho_G$ = gas density, $lb/ft^3$

$\rho_L$ = liquid density, $lb/ft^3$

$\mu_L$ = liquid viscosity, cP

The Robbins correlation applies near atmospheric pressure and under vacuum, but it is not suitable above 3 bar absolute. For high (>0.3) flow parameters [Eq. (14-141)], the correlation has only been tested with air–water data.

For flood and MOC predictions, Robbins recommends his pressure drop method together with Eqs. (14-142) ( flood) and (14-139) (MUC).

The GPDC and Robbins correlations are empirical. Fundamental correlations are also available. Most of these use the channel model, which attributes the pressure drop to the resistance to flow in a multitude of parallel channels. The channels may have bends, expansions, and contractions. Popular applications of this approach are the Rocha et al. correlation [Rocha, Bravo, and Fair, *Ind. Eng. Chem. Res.* **32:** 641 (1993)] for structured packing and the Maćkowiak (*Fluid Dynamics of Packed Columns*, Springer-Verlag, Berlin Heidelberg, 2010) and Billet (*Packed Column Analysis and Design*, Ruhr University, Bochum, Germany, 1989) methods. Stichlmair et al. (*Distillation Principles and Practices*, Wiley, New York, 1998; *Gas Sep. Purif.* **3:** March 1989, p. 19) present alternative correlations using the particle model, which attributes packing pressure drop to friction losses due to drag of a particle. This is similar to the Ergun model for single-phase flow [*Chem. Eng. Prog.* **48**(2): 89 (1952)].

Duss (chap. 4 in Gorak, A., and Z. Olujic, eds., *Distillation Equipment and Processes,* Elsevier, New York, 2014; AIChE *Distillation Topical Conference Proceedings,* San Antonio, Tex., April 2013) notes that at very low gas Reynolds numbers, experienced in deep vacuum distillation, typically below 3 to 10 mbar, the gas flow regime changes to laminar, causing the friction factor to rise. This is accounted for in the fundamental models described previously, but it is often unaccounted for by empirical and many vendor methods that are based on turbulent flow. When applying an empirical or vendor correlation for structured packings under deep vacuum, Duss recommends checking the gas Reynolds number

$$\mathrm{Re}_G = 1000\, F\, \rho_G^{0.5}\, D_p / \mu_G$$

where $\mathrm{Re}_G$ is the gas Reynolds number, dimensionless; $F$ is the $F$-factor, defined by Eq. (14-76), m/s $(\mathrm{kg/m^3})^{0.5}$; $D_p$ is the packing hydraulic diameter, m; $\mu_G$ is the gas viscosity, cP, and other symbols are as described above. For structured packings, Duss uses $D_p = 4/a_p$. Values of $a_p$ are listed in Table 14-14. Maćkowiak (*Fluid Dynamics of Packed Columns*, Springer/Heidelberg, New York, 2010) states that random packings 25 mm and larger are always operated in the turbulent range. Duss gives the critical gas Reynolds numbers for changing from turbulent flow to laminar flow at 300 and 500 for structured packings with corrugation angles of 45° and 30° from the vertical, respectively.

***Example 14-13 Packed-Column Pressure Drop*** Air and water are flowing countercurrently through a bed of 2-in metal Pall rings. The air mass velocity is 2.03 $\mathrm{kg/s \cdot m^2}$ (1500 $\mathrm{lbs/hr \cdot ft^2}$), and the liquid mass velocity is 12.20 $\mathrm{kg/s \cdot m^2}$ (9000 $\mathrm{lbs/hr \cdot ft^2}$). Calculate the pressure drop by the generalized pressure drop (GPDC, Fig. 14-55) and the Robbins methods. Properties: $\rho_G = 0.074$ $\mathrm{lbs/ft^3}$; $\rho_L = 62.4$ $\mathrm{lbs/ft^3}$, $\mu_L = 1.0$ cP, $\nu = 1.0$ cS. The packing factor $F_p = 27$ $\mathrm{ft^{-1}}$. For Robbins, $F_{pd} = 24$ $\mathrm{ft^{-1}}$. The flow parameter $F_{LG} = L/G\,(\rho_G/\rho_L)^{0.5} = (9000/1500)\,(0.074/62.4)^{0.5} = 0.207$. The $F$-factor $= F_s = U_t \rho_G^{0.5} = G/(\rho_G^{0.5} 3600) = 1500/[(0.074)^{0.5}\,(3600)] = 1.53$ $\mathrm{ft/s(lb/ft^3)^{0.5}}$.

Using the GPDC method, the capacity parameter [by Eq. (14-140)] $= U_t[\rho_G/(\rho_L - \rho_G)]^{0.5} F_p^{0.5} \nu^{0.05}$, which is roughly equivalent to

$$\frac{F_S}{\rho_L^{0.5}} F_p^{0.5} \nu^{0.05} = \frac{1.53}{62.4^{0.5}} 27^{0.5}\,(1.0) = 1.01$$

Referring to Fig. 14-55, the intersection of the capacity parameter and the flow parameter lines gives a pressure drop of 0.38 in $H_2O$/ft packing.

Using the Robbins method, $G_f = 986 F_s\,(F_{pd}/20)^{0.5} = 986(1.53)(24/20)^{0.5} = 1653$. $L_f = L\,(62.4/\rho_L)(F_{pd}/20)^{0.5}\,\mu^{0.1} = 9000\,(1.0)(1.095)(1.0) = 9859$. $L_f/G_f = 5.96$.

From Fig. 14-58, pressure drop = 0.40 in $H_2O$/ft packing.

***Example 14-14 Does the Reynolds Number Matter?*** For the column in Example 14-13, would the pressure drop depend on Reynolds number if the packing used is a structured packing of 250 $\mathrm{m^2/m^3}$?

Converting to metric, the $F$-factor is $F$ (metric) $= 1.221 \times 1.53 = 1.87$ m/s $(\mathrm{kg/m^3})^{0.5}$, and the gas density is $0.074 \times 16.018 = 1.19$ $\mathrm{kg/m^3}$. From Duss's criterion, the hydraulic diameter is $4/250 = 0.016$ m. Using a viscosity of 0.018 cP gives $\mathrm{Re}_G = 1000 \times 1.87 \times 1.19^{0.5} \times 0.016/0.0181 = 1800$, well above the critical Reynolds number of 300.

## PACKING EFFICIENCY

**HETP versus Fundamental Mass Transfer** The two-film model gives the following transfer unit relationship:

$$H_{OG} = H_G + \lambda H_L \tag{14-152}$$

where $H_{OG}$ = height of an overall transfer unit, gas concentration basis, m
$H_G$ = height of a gas-phase transfer unit, m
$H_L$ = height of a liquid-phase transfer unit, m
$\lambda = m/(L_M/G_M)$ = slope of equilibrium line/slope of operating line

In design practice, a less rigorous parameter, HETP, is used to express packing efficiency. The HETP is the height of packed bed required to achieve a theoretical stage. The terms $H_{OG}$ and HETP may be related under certain conditions:

$$\mathrm{HETP} = H_{OG}\left[\frac{\ln \lambda}{(\lambda - 1)}\right] \tag{14-153}$$

and since

$$Z_p = (H_{OG})(N_{OG}) = (\mathrm{HETP})(N_t) \tag{14-154}$$

$$N_{OG} = N_t[\ln \lambda/(\lambda - 1)] \tag{14-155}$$

Equations (14-153) and (14-155) have been developed for binary mixture separations, and they hold for cases where the operating line and equilibrium line are straight. Thus, when there is curvature, the equations should be used for sections of the column where linearity can be assumed. When the equilibrium line and operating line have the same slope, HETP $= H_{OG}$ and $N_{OG} = N_t$ (theoretical stages).

An alternative parameter popular in Europe is the NTSM (number of theoretical stages per meter), which is simply the reciprocal of the HETP.

**Factors Affecting HETP: An Overview** Generally, packing efficiency increases (HETP decreases) when the following occur:

- Packing surface area per unit volume increases. Efficiency increases as the particle size decreases (random packing, Fig. 14-59) or as the channel size narrows (structured packing, Fig. 14-60).
- The packing surface is better distributed around a random packing element.

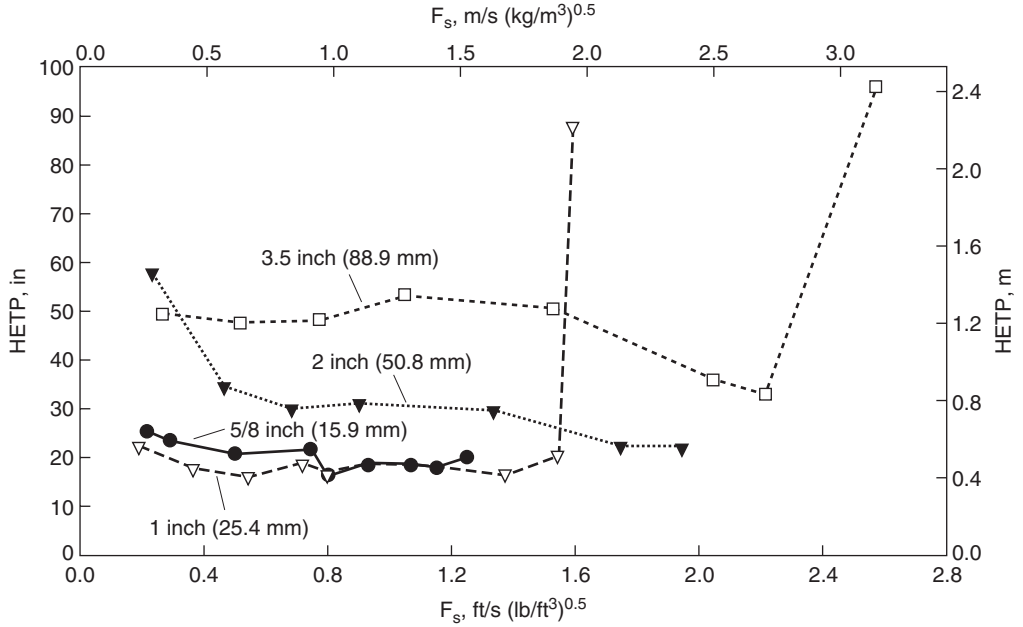

**FIG. 14-59** HETP values for four sizes of metal Pall rings, vacuum operation. Cyclohexane/*n*-heptane system, total reflux, 35 kPa (5.0 psia). Column diameter = 1.2 m (4.0 ft). Bed height = 3.7 m (12 ft). Distributor = tubed drip pan, 100 streams/$\mathrm{m^2}$. [*Adapted from Shariat and Kunesh,* Ind. Eng. Chem. Res. ***34:*** *1273 (1995). Reproduced with permission. Copyright © 1995 American Chemical Society.*]

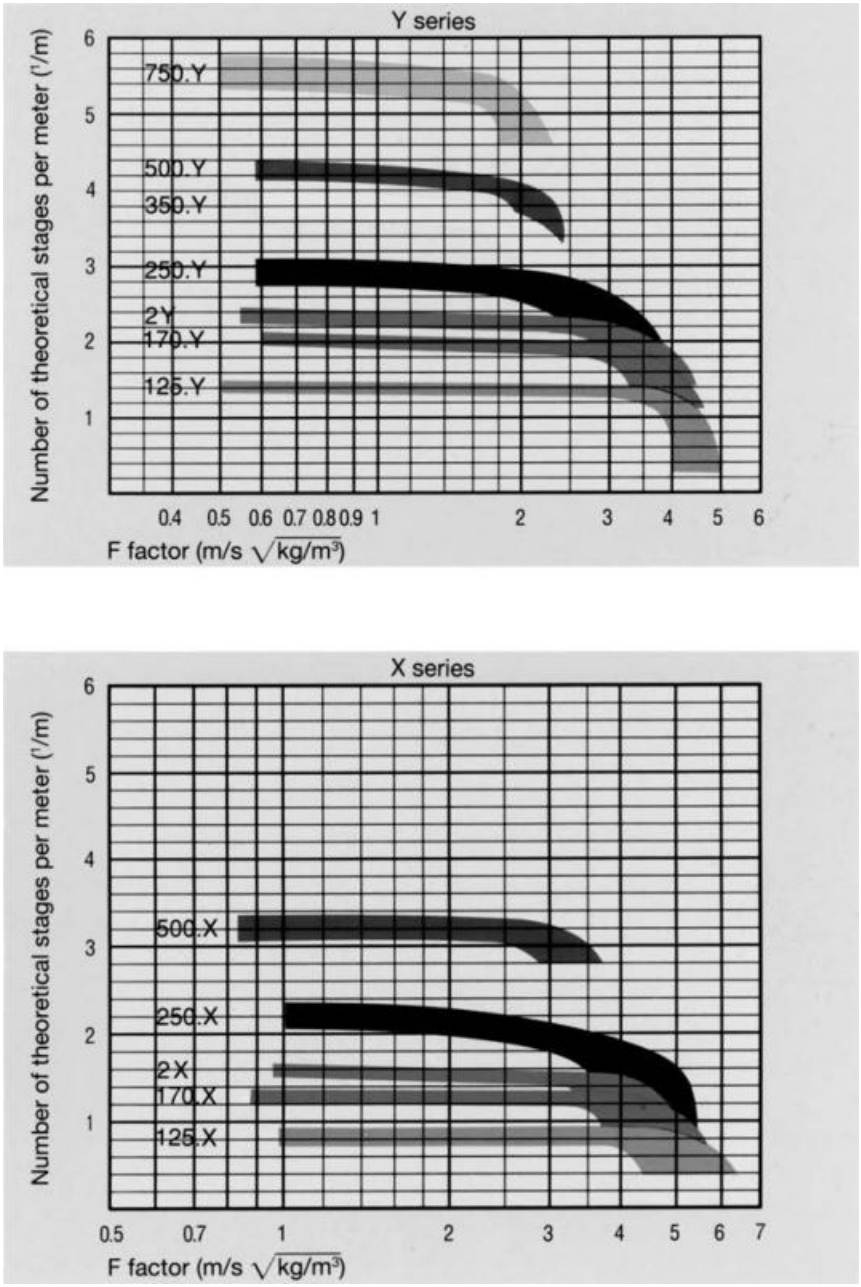

**FIG. 14-60** Effect of structured packing surface areas, loads, and inclination angle on packing efficiency. Efficiency expressed as number of theoretical stages per meter, the reciprocal of HETP. Sulzer data, chlorobenzene–ethylbenzene, 100 mbar, at total reflux; 250-mm-diameter test column. (*Reprinted courtesy of Sulzer Chemtech.*)

- Y-structured packings (45° inclination) give better efficiencies than X-structured packings (60° inclination to the horizontal) of the same surface areas (Fig. 14-60).
- High-performance structured packings (45° inclination) give much the same efficiencies as the Y-structured packings.
- For constant *L/V* operation in the preloading regime, generally liquid and vapor loads have little effect on random and most corrugated sheet structured packings (Figs. 14-59 and 14-60). HETP increases with loadings in some wire-mesh structured packing.
- Liquid and vapor are well distributed. Both liquid and vapor maldistribution have a major detrimental effect on packing efficiency.
- Other. These include *L/V* ratio (lambda), pressure, and physical properties. These come into play in some systems and situations, as discussed below.

**HETP Prediction** HETP can be predicted from mass-transfer models, rules of thumb, and data interpolation.

***Mass-Transfer Models*** Development of a reliable mass-transfer model for packing HETP prediction has been inhibited by a lack of understanding of the complex two-phase flow that prevails in packings, by the shortage of commercial-scale efficiency data for the newer packings, and by difficulty in quantifying the surface generation in modern packings. Bennett and Ludwig (*Chem. Eng. Prog.*, April 1994, p. 72) point out that the abundant air–water data cannot be reliably used for assessing real system mass-transfer resistance due to variations in turbulence, transport properties, and interfacial areas. More important, the success and reliability of rules of thumb for predicting packing efficiency made it difficult for mass-transfer models to compete.

For random packings, the Bravo and Fair correlation [*Ind. Eng. Chem. Proc. Des. Dev.* **21:** 162 (1982)] has been one of the most popular theoretical correlations. It was shown (e.g., McDougall, *Chem SA*, October 1985, p. 255) to be better than other theoretical correlations, yet it produced large

discrepancies when compared to test data [Shariat and Kunesh, *Ind. Eng. Chem. Res.* **34**(4): 1273 (1995)]. For structured packings, the Bravo, Fair, and Rocha correlation [*Chem. Eng. Progr.* **86**(1): 19 (1990); *Ind. Eng. Chem. Res.* **35:** 1660 (1996)] is one of the most popular theoretical correlations. This correlation is based on the two-film theory. Interfacial areas are calculated from the packing geometry and an empirical wetting parameter.

Alternate popular theoretical correlations for random packings, structured packings, or both [e.g., Billet and Schultes, *Trans. IChemE* **77:** Part A, p. 498 (September 1999); Maćkowiak, *Chem. Eng. Res. Des.* **99:** 28 (2015)] are also available.

***Rules of Thumb*** Since in most circumstances packing HETP is sensitive to only few variables, and due to the unreliability of even the best mass-transfer model, it has been the author's experience that rules of thumb for HETP are more accurate and more reliable than mass-transfer models. A similar conclusion was reached by Porter and Jenkins (*IChemE Symp. Ser.* **56,** Summary paper, London, 1979).

The majority of published random packing rules of thumb closely agree with one another. They are based on second-, third-, and fourth-generation random packings and should not be applied to the obsolete first-generation packings. Porter and Jenkins's (*IChemE Symp. Ser.* **56,** Summary paper, London, 1979), Frank's (*Chem. Eng.*, March 14, 1977, p. 40), Harrison and France's (*Chem. Eng.*, April 1989, p. 121), Chen's (*Chem. Eng.*, March 5, 1984, p. 40), and Walas' (*Chem. Eng.*, March 16, 1987, p. 75) general rules of thumb are practically the same, have been successfully tested against an extensive data bank, and are slightly conservative, and therefore suitable for design.

For small-diameter columns, the rules of thumb presented by Frank (*Chem. Eng.*, March 14, 1977, p. 40), Ludwig (*Applied Process Design for Chemical and Petrochemical Plants,* vol. 2, 2d ed., Gulf Publishing, Houston, Tex., 1979), and Vital et al. [*Hydrocarbon Processing* **63**(12): 75 (1984)] are identical. The author believes that for small columns, the more conservative value predicted from either the Porter and Jenkins or the Frank-Ludwig-Vital rule should be selected for design. Summarizing:

$$\text{HETP} = 18D_P \tag{14-156}$$

$$\text{HETP} > D_T \quad \text{for } D_T < 0.67 \text{ m} \tag{14-157}$$

where $D_P$ and $D_T$ are the packing and tower diameters, m, respectively, and the HETP is in meters. In high-vacuum columns (<100 mbar), and when $\lambda = mG_M/L_M$ is outside the range of 0.5 to 2.0, the preceding rules may be optimistic (see below).

The preceding rules of thumb were based on experience with Pall rings. The packing diameter may be difficult to establish for some of the modern packings, especially those of saddle or flat shape. For these, Kister and Larson (in Schweitzer, *Handbook of Separation Techniques for Chemical Engineers,* 3d ed., McGraw-Hill, 1997) extended Eq. (14-156) by expressing the packing diameter in terms of the more fundamental surface area per unit volume $a_P$, $m^2/m^3$. For Pall rings, it can be shown that

$$a_P = 5.2/D_P \tag{14-158}$$

and Eq. (14-156) becomes

$$\text{HETP} = 93/a_P \tag{14-159}$$

Harrison and France (*Chem. Eng.*, April 1989, p. 121) presented the only published rule of thumb for structured packings efficiency as a function of packing crimp. Kister and Larson reexpressed it in terms of the surface area per unit volume to accommodate a wider range of packing geometries. The final expression is

$$\text{HETP} = 100C_{XY}/a_P + 0.10 \tag{14-160}$$

Specific surface areas are listed in Tables 14-13 and 14-14.

The preceding rules of thumb apply to organic and hydrocarbon systems, whose surface tensions are relatively low ($\sigma < 25$ mN/m). For higher surface tensions, the liquid does not adhere well to the packing surfaces (*underwetting*), causing higher HETPs. In a water-rich system ($\sigma$ = 70 mN/m or so), HETPs obtained from Eqs. (14-156), (14-159), and (14-160) need to be doubled. For intermediate surface tension systems (some amines and glycols, whose surface tension at column conditions is 40 to 50 mN/m), HETPs obtained from Eqs. (14-156), (14-159), and (14-160) need to be multiplied by 1.5.

For random packings, Eqs. (14-156) and (14-159) apply for packings of 25-mm diameter and larger. For smaller packings, use of the $a_p$ at 25 mm often gives a slightly conservative HETP estimate. For structured packing, $C_{XY}$ in Eq. (14-160) reflects the effect of the inclination angle (Fig. 14-60). $C_{XY} = 1$ for Y-type, S-type, or high-performance packings, and $C_{XY} = 1.45$ for the larger (<300 $m^2/m^3$) X-type packings. There are insufficient data to determine $C_{XY}$ for high specific area X-type packings, but Fig. 14-60 suggests it is somewhat lower than 1.45.

Compared to experimental data, the preceding rules of thumb are slightly conservative. Since packing data are usually measured with perfect distribution, a slight conservative bias is necessary to extend these data to the good, yet imperfect, distributors used in the real world. For poor distributors, these rules of thumb will usually predict well below the HETPs measured in the field.

Lockett (*Chem. Eng. Progr.*, January 1998, p. 60) simplified the fundamental Bravo-Fair-Rocha correlation [*Ind. Eng. Chem. Res.* **35:** 1660 (1996)] to derive an alternative rule of thumb for structured packing efficiency. This rule of thumb predicts HETPs under perfect distribution conditions. Lockett recommends caution when applying this rule of thumb for aqueous systems because it does not predict the effects of underwetting.

***Service-Oriented Rules of Thumb*** Strigle (*Packed Tower Design and Applications,* 2d ed., Gulf Publishing, Houston, Tex., 1994) proposed a multitude of rules of thumb as a function of the service, column pressure, and physical properties. These rules are based on the extensive experience of Strigle and the Norton Company (now merged with Koch-Glitsch LP).

***Data Interpolation*** Interpolation of experimental HETP data is the most reliable means of obtaining design HETP values. This is hardly surprising in an area where our understanding of the theory is so poor that rules of thumb can do better than theoretical models. The author believes that it is best to derive HETP from experimental data, and to check it against a rule of thumb.

Eckert [*Chem. Eng. Progr.* **59**(5): 76 (1963)], Chen (*Chem. Eng.*, March 5, 1984, p. 40), and Vital et al. [*Hydroc. Proc.* **63**(12): 75 (1984)] tabulated experimental HETP data for various random packings. Kister (*Distillation Design,* McGraw-Hill, 1992) extended these tabulations and included published HETP data and a detailed procedure for interpolating such HETP data. A prerequisite to any interpolation of packing data is thorough familiarity with the factors that affect HETP. Overlooking any of the factors listed can easily lead to poor interpolation and grossly incorrect design. In particular, it is imperative to recognize that the quality of distribution in pilot towers is generally superior to the quality of distribution in commercial towers.

**Underwetting** Laboratory- and pilot-scale distillation experiments with systems that exhibit large differences in surface tension along the column such as methanol-water showed a sharp drop in efficiency at the high-surface-tension end of the column [Ponter et al., *Trans. Instn. Chem. Engineers [London]* 45: T345 (1967)]. There appeared to be a critical methanol composition below which performance deteriorated rapidly. The poor performance at the low-methanol-concentration end appeared independent of the type and size of packing. Visual observations with disk columns attributed these effects to underwetting.

Underwetting is a packing surface phenomenon, which breaks up liquid film. The tendency of the liquid film to break (the degree of wetting) is expressed by the contact angle (Fig. 14-61). A contact angle of 0° indicates perfect wetting; an angle of 180° indicates no wetting. Mersmann and Deixler [*Chem. Ing. Tech.* **58**(1): 19 (1986)] provide a preliminary chart for estimating contact angles. The contact angle depends on both the surface and the liquid and is a strong function of composition. In systems with large surface tension gradients, both contact angles and minimum wetting rates may vary rapidly with changes of composition or surface tension. Extensive studies by Ponter et al. [*Trans. Instn. Chem. Engineers [London]* **45:** T345 (1967); also, Ponter and Au-Yeung, *Chem. Ing. Tech.* **56**(9): 701 (1984)] and experiences reported by Niggemann et al. (chap. 7, in Gorak and Schoenmakers, *Distillation Operation and Application*, Academic Press, New York, 2014) showed that

- Underwetting is most significant in aqueous-organic systems, and it tends to occur at the high-surface-tension (aqueous) end of the composition range. Liquid viscosity may also have an effect.
- Underwetting may be alleviated by changing the material and surface roughness of the packing.

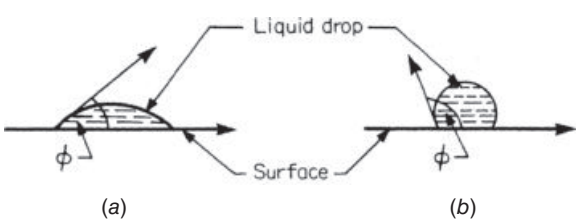

**FIG. 14-61** Contact angles. (*a*) Acute, good wetting. (*b*) Obtuse, poor wetting.

- In systems susceptible to underwetting, column efficiency can sometimes (but not always) be improved by the addition of small amounts of surfactants, or it may deteriorate in service due to deposition that increases the contact angle (e.g., hydrophobic deposits in an aqueous system).
- The flow rates needed to wet a surface are higher than those at which dewetting occurs.

**Effect of Lambda** Most packed-column efficiency testing has been at total reflux. Some tests for both random and structured packings [Billet, *Packed Towers Analysis and Design*, Ruhr University, Bochum, Germany, 1989; Meier, Hunkeler, and Stocker, *IChemE Symp. Ser.* 56: 3.3/1 (1979); Eckert and Walter, *Hydroc. Proc.* **43**(2): 107 (1964)] suggest that efficiencies at finite reflux are similar to those at total reflux when lambda ($\lambda = mG_M/L_M$, which is the ratio of the slope of the equilibrium curve to the slope of the operating line) ranges between 0.5 and 2.0. This range is typical for most distillation systems.

Koshy and Rukovena [*Hydroc. Proc.* **65**(5): 64 (1986)], experimenting with methanol-water and water-DMF using #25 IMTP packing in a pilot-scale column, observed a sharp efficiency drop when λ was greater than 2 or lower than 0.5. The efficiency loss escalated as λ deviated more from this range. Koshy and Rukovena recognized that surface tension gradients and underwetting may have influenced some of their findings, but they argued that the lambda effect is the major cause for the efficiency differences observed in their tests. High-relative-volatility systems are those most likely to be affected by λ because at low volatility, λ ranges from 0.5 to 2. Strigle (*Packed Tower Design and Applications*, 2d ed., Gulf Publishing, Houston, Tex., 1994) quantified the lambda effect on HETP using the following equation:

$$\text{Actual HETP/standard HETP} = 1 + 0.278[\text{ABS}(\ln \lambda)^3] \qquad (14\text{-}161)$$

For $0.5 < \lambda < 2$, Eq. (14-161) gives a ratio of less than 1.1; that is, it has little influence on HETP.

**Pressure** Generally, pressure has little effect on HETP of both random and structured packing, at least above 100 mbar abs. At deep vacuum (<100 mbar), there are data to suggest that efficiency decreases as pressure is lowered for random packings [Zelvinski, Titov, and Shalygin, *Khim Tekhnol. Topl. Masel.* **12**(10) (1966)], but most of these data can also be explained by poor wetting or maldistribution. When reducing the pressure steeply lowers temperatures, rapid liquid viscosity escalation can reduce efficiency [Bratmöller and Scholl, *Chem. Eng. Res. Design* **99:** 75 (2015)].

At high pressures (>15 to 20 bar), and high liquid rates, best characterized as high flow parameters, above 0.2 [Eq. (14-141)], structured packing efficiency diminishes as pressure is raised (Kister, Larson, and Yanagi, *Chem. Eng. Progr.,* February 1994, p. 23; Chambers, McCarley, Cai, and Vennavelli, *Kister Distillation Symposium Proceedings*, AIChE Spring Meeting, Austin, Tex., 2015, p. 364).

With structured packings (only), FRI's high-pressure (10 to 30 bar; flow parameters >0.25) distillation tests measured maxima, termed *humps* in the HETP versus load plot, typically at 65 to 90 percent of flood [Fitz, Shariat, and Kunesh, *IChemE Symp. Ser.* **142:** 829 (1997); Cai et al., *Trans IChemE* **81:** Part A, p. 85 (2003); Chambers, McCarley, Cai, and Vennavelli, *Kister Distillation Symposium Proceedings*, AIChE Spring Meeting, Austin, Tex., 2015, p. 364]. These humps (Fig. 14-62) were not observed with lower-pressure distillation ( flow parameters <0.2), and they appeared to intensify with higher pressure. The humps did not always occur; some tests at different distributor positioning and with larger packing showed no humps.

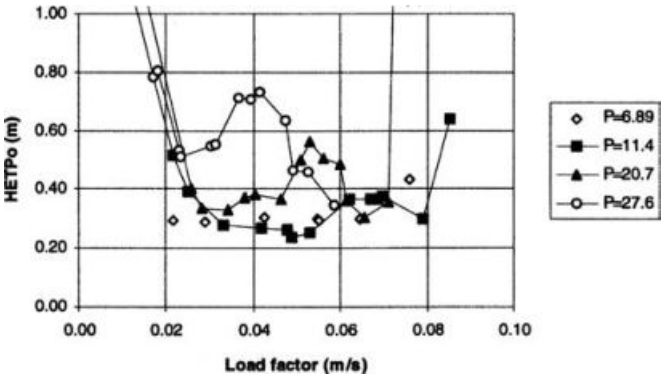

**FIG. 14-62** HETP data as measured in the FRI column for the $iC_4/nC_4$ system at different pressures (bara), showing efficiency humps. (*From J. L. Nooijen, K. A. Kusters, and J. J. B. Pek*, IChemE Symp. Ser. ***142:** p. 885, 1997. Reprinted courtesy of IChemE.*)

Zuiderweg et al. [*IChemE Symp. Ser.* **142:** 865 (1997); *Trans. IChemE* **81:** Part A, p. 85 (January 2003)] and Nooijen et al. [*IChemE Symp. Ser.* **142:** 885 (1997)] explain the humps by two-phase backmixing. At the high liquid loads in high-pressure distillation, flow unevenness prematurely floods some of the packing channels, carrying vapor bubbles downward and recirculating liquid upward. Chambers et al. applied observations from Kerst, Judat, and Schlünder's experiments with falling films [*Chem. Eng. Sci.* **55:** 4189 (2000)] to shed more light on the humps. As pressure increases, the smooth liquid films on the packing progressively turn to wavy, then to troughs, crests, coarse drops, and finally fine drops. The backmixing of the liquid drops reduces the efficiency leading to the hump formation. In addition, as liquid flow rate and pressure are raised, the falling liquid chokes an increasing proportion of the corrugation channels, forcing vapor to ascend through the less loaded channels, reducing contact and capacity.

**Physical Properties** Data presented by a number of workers [e.g., Vital, Grossel, and Olsen, *Hydroc. Proc.* **63**(12): 75 (1984)] suggest that, generally, random packing HETP is relatively insensitive to system properties for nonaqueous systems. A survey of data in Chapter 11 of Kister's *Distillation Design* (McGraw-Hill, New York, 1992) leads to a similar conclusion for structured packings. For water-rich systems, packing HETPs tend to be much higher than for nonaqueous systems due to their high lambda or surface underwetting, as discussed previously. High hydrogen concentrations (>30 percent or so in the gas) have also led to low packing efficiencies (Kister et al., *Proc. 4th Ethylene Producers Conference,* AIChE, New Orleans, La., p. 283, 1992), possibly due to the fast-moving hydrogen molecule dragging heavier molecules with it as it diffuses from a liquid film into the vapor.

**Errors in VLE and Reflux Ratios** These affect packing HETP in the same way as they affect tray efficiency. The discussions and derivation earlier in this subsection apply equally to tray and packed towers.

**Comparison of Various Packing Efficiencies for Absorption and Stripping** In past editions of this handbook, extensive data on absorption/stripping systems were given. Emphasis was given to the following systems:

| | |
|---|---|
| Carbon dioxide–1 N caustic | Liquid phase chemical reaction controlling |
| Ammonia–air–water | Liquid and gas phases contributing; chemical reaction contributing |
| Air–water | Gas phase controlling |
| Sulfur dioxide–air–water | Liquid and gas phase controlling |
| Carbon dioxide–air–water | Liquid phase controlling |

The reader may refer to the data in the 5th edition of this handbook.

**Summary** In the preloading regime, packing size, type, and distribution affect HETP. With aqueous-organic systems, HETP may be sensitive to underwetting and composition. A lambda value ($\lambda = mG_M/L_M$) outside the range of 0.5 to 2.0 causes HETP to rise, and so does a high hydrogen concentration. HETP of structured packings may also be affected by pressure (at high pressure) and vapor and liquid loads.

## MALDISTRIBUTION AND ITS EFFECTS ON PACKING EFFICIENCY

**Modeling and Prediction** Maldistribution may drastically reduce packing efficiency. HETP may increase by a factor of as high as 2 or 3 due to maldistribution. Shariat and Kunesh [*Ind. Eng. Chem. Res.* **34**(4): 1273 (1995)] provide a good demonstration.

Early models [Mullins, *Ind. Chem. Mfr.* **33:** 408 (1957); Manning and Cannon, *Ind. Eng. Chem.* **49**(3): 347 (1957)] expressed the effect of liquid maldistribution on packing efficiency in terms of a simple channeling model. A portion of the liquid bypasses the bed, undergoing negligible mass transfer, and then rejoins and contaminates the rest of the liquid. Huber et al. [*Chem. Ing. Tech.* **39:** 797 (1967); *Chem. Eng. Sci.* **21:** 819 (1966)] and Zuiderweg et al. [*IChemE Symp. Ser.* **104:** A217 (1987)] replaced the simple bypassing with variations in the local $L/V$ ratios. The overirrigated parts have a high $L/V$ ratio, the underirrigated parts a low $L/V$ ratio. Regions with low $L/V$ ratios experience pinching and, therefore, produce poor separation.

Huber et al. [*Chem. Ing. Tech.* **39:** 797 (1967)] and Yuan and Spiegel [*Chem. Ing. Tech.* **54:** 774 (1982)] added lateral mixing to the model. Lateral deflection of liquid by the packing particles tends to homogenize the liquid, thus counteracting the channeling and pinching effect.

A third factor is the nonuniformity of the flow profile through the packing. This nonuniformity was observed as far back as 1935 [Baker, Chilton, and Vernon, *Trans. Instn. Chem. Engrs.* **31:** 296 (1935)] and was first modeled by Cihla and Schmidt [*Coll. Czech. Chem. Commun.* **22:** 896 (1957)]. Hoek (Ph.D. thesis, The University of Delft, The Netherlands, 1983) combined all three factors into a single model, leading to the zone-stage model described next.

***The Zone-Stage Model*** Zuiderweg, Kunesh, et al. [*IChemE Symp. Ser.* **104:** A217, A233 (1987)] extended Hoek's work combining the effects of local $L/V$ ratio, lateral mixing, and flow profile into a model describing the effect of liquid maldistribution on packing efficiency. This work was performed at Fractionation Research Inc. (FRI) and at The University of Delft in the Netherlands. The model postulates that, in the absence of maldistribution, there is a "basic" (or "true" or "inherent") HETP that is a function of the packing and the system only. This HETP can be inferred from data for small towers, in which lateral mixing is strong enough to offset any pinching. For a given initial liquid distribution, the model uses a diffusion-type equation to characterize the splitting and recombining of liquid streams in the horizontal and vertical directions. The mass transfer is then calculated by integrating the liquid flow distribution at each elevation and the basic HETP. Zuiderweg et al. successfully applied the model to predict measured effects of maldistribution on packing efficiency. However, this model is difficult to use and has not gained industrywide acceptance.

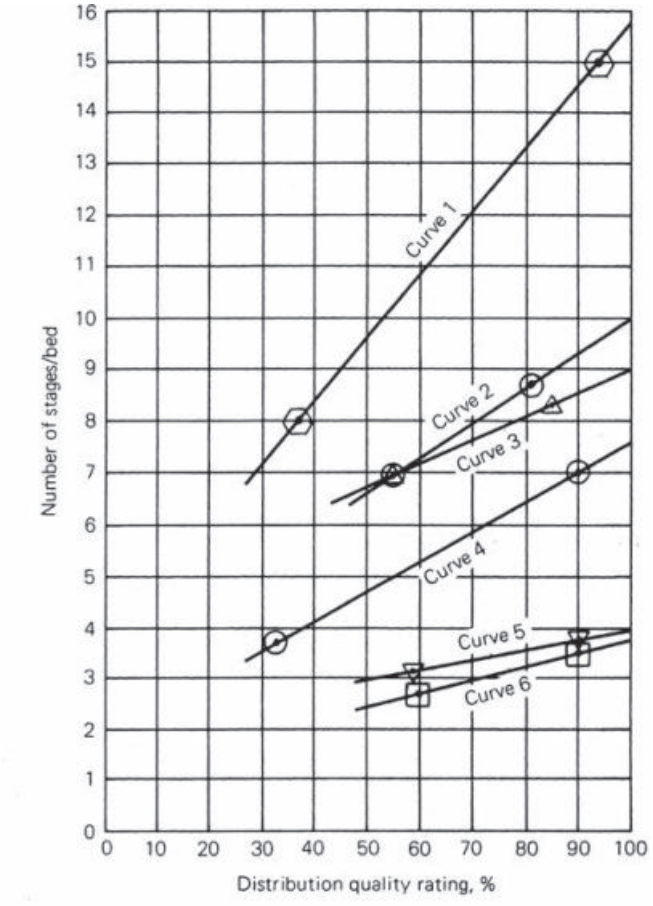

**FIG. 14-63** Effect of irrigation quality on packing efficiency. (*a*) Case histories demonstrating efficiency enhancement with higher distribution quality rating. (*b*) Correlation of the effect of irrigation quality on packing efficiency. (*From F. Moore and F. Rukovena,* Chemical Plants and Processing, *Europe edition, Aug. 1987; reprinted courtesy of* Chemical Plants and Processing.)

***Empirical Prediction*** Moore and Rukovena [*Chemical Plants and Processing* (European edition), August 1987, p. 11] proposed the empirical correlation in Fig. 14-63 for efficiency loss due to liquid maldistribution in packed towers containing Pall® rings or IMTP® packing. This correlation was shown to work well for several case studies (Fig. 14-63), is simple to use, and is valuable, at least as a preliminary guide.

To quantify the quality of liquid irrigation, the correlation uses the distribution quality rating index. Typical indexes are 10 to 70 percent for most standard commercial distributors, 75 to 90 percent for intermediate-quality distributors, and over 90 percent for high-performance distributors. Moore and Rukovena present a method for calculating a distribution-quality rating index from distributor geometry. Their method is described in detail in their paper as well as in Kister's book (*Distillation Operation,* McGraw-Hill, New York, 1990). For structured packing, the Moore and Rukovena method does not credit the liquid spreading performed by the top layer of packings, and therefore it may penalize distributors that irrigate the packings in the form of a drip line like in Fig. 14-68*e* (Spiegel, *Chemical Engineering and Processing*, 2006, p. 1011). Spiegel proposed a "wetting index," defined as the fraction of area wetted by liquid after the first layer of packing to the tower cross-sectional area, which accounts for the liquid spread at the top layer of packing. Unfortunately, generic guidelines for the compilation and application of the wetting index method have not been published.

***Maximum Liquid Maldistribution Fraction*** $\mathbf{f}_{max}$ To characterize the sensitivity of packed beds to maldistribution, Lockett and Billingham [*Trans. IChemE* **80:** Part A, p. 373, (May 2002); *Trans. IChemE* **81:** Part A, p. 134 (January 2003)] modeled maldistribution as two parallel columns, one receiving more liquid $(1 + f)L$, the other receiving less $(1 - f)L$. The vapor was assumed to be equally split (Fig. 14-64) without lateral mixing. Because of the different $L/V$ ratios, the overall separation is less than is obtained at uniform distribution. A typical calculated result (Fig. 14-65) shows the effective number of stages from the combined two-column system decreasing as the maldistribution fraction $f$ increases. Figure 14-65*a* shows that the decrease is minimal in short beds (e.g., 10 theoretical stages) or when the maldistribution fraction is small. Figure 14-65*a* shows that there is a limiting fraction $f_{max}$ that characterizes the maximum maldistribution that still permits achieving the required separation. Physically, $f_{max}$ represents the maldistribution fraction at which one of the two parallel columns in the model becomes pinched. Figure 14-65*b* highlights the steep drop in packing

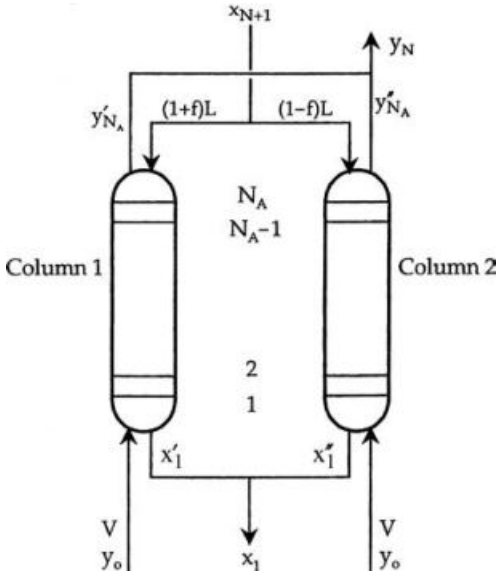

**FIG. 14-64** Parallel-columns model. (*From Lockett and Billingham,* Trans. IChemE ***80:*** *Part A, p. 373, May 2002; reprinted courtesy of IChemE.*)

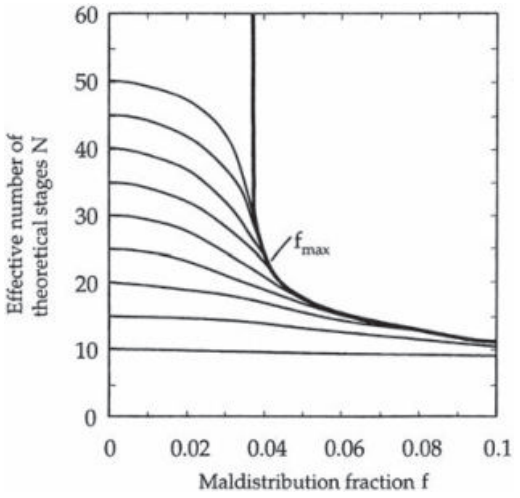
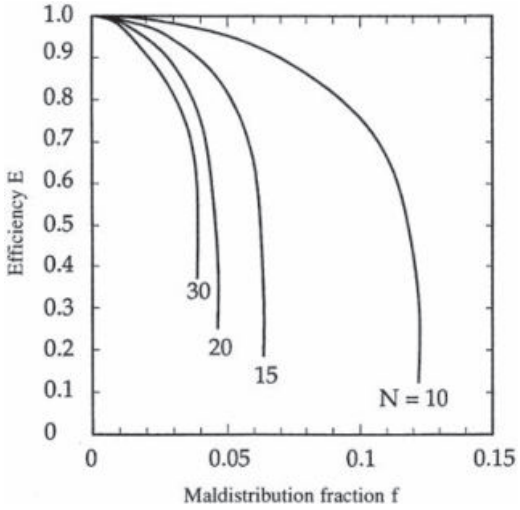


(*a*)



(*b*)

**FIG. 14-65** Loss of efficiency due to maldistribution as a function of maldistribution fraction *f* and the number of stages per bed for a given case study. (*a*) $f_{max}$ and reduction in number of stages. (*b*) Showing larger efficiency loss at higher number of stages per bed and higher *f*. The steep drops indicate pinching associated with $f_{max}$. (*From Lockett and Billingham,* Trans. IChemE ***80:*** *Part A, p. 373, May 2002; reprinted courtesy of IChemE.*)

efficiency upon the onset of this pinch. Billingham and Lockett derived the following equation for $f_{max}$ in a binary system:

$$f_{max} = \frac{y_{N+1} - y_N}{y_N - y_\circ} + \frac{x_1 - x_\circ}{x_{N+1} - x_\circ} - \left(\frac{y_{N+1} - y_N}{y_N - y_\circ}\right)\left(\frac{x_1 - x_\circ}{x_{N+1} - x_\circ}\right) \qquad (14\text{-}162)$$

This equation can be used to calculate $f_{max}$ directly without the need for a parallel column model. Billingham and Lockett show that the various terms in Eq. (14-162) can be readily calculated from the output of a steady-state computer simulation. Multicomponent systems are represented as binary mixtures, either by lumping components together to form a binary mixture of pseudolight and pseudoheavy components, or by normalizing the mole fractions of the two key components. Once $f_{max}$ is calculated, Billingham and Lockett propose the following guidelines:

- $f_{max} < 0.05$, extremely sensitive to maldistribution. The required separation will probably not be achieved.
- $0.05 < f_{max} < 0.10$, sensitive to maldistribution, but separation can probably be achieved.
- $0.10 < f_{max} < 0.20$, not particularly sensitive to maldistribution.
- $f_{max} > 0.20$ insensitive to maldistribution.

Figure 14-65*b* shows that shortening the bed can increase $f_{max}$. Relative volatility and $L/V$ ratio also affect $f_{max}$. The bed length and $L/V$ ratio can often be adjusted to render the bed less sensitive to maldistribution.

**Implications of Maldistribution to Packing Design Practice** These are discussed at length with extensive literature citation in Kister's book *Distillation Operation,* McGraw-Hill, New York, 1990. Following are the highlights:

1. Three factors appear to establish the effect of maldistribution on efficiency:

   *a. Pinching.* Regional changes in $L/V$ ratio cause regional composition pinches.

   *b. Lateral mixing.* Packing particles deflect both liquid and vapor laterally. This promotes mixing of vapor and liquid and counteracts the pinching effect.

   *c. Liquid nonuniformity*. Liquid flows unevenly through the packing and tends to concentrate at the wall.

2. At small tower-to-packing diameter ratios ($D_T/D_p < 10$), the lateral mixing cancels out the pinching effect, and a greater degree of maldistribution can be tolerated without a serious efficiency loss. At high ratios ($D_T/D_p > 40$), the lateral mixing becomes too small to offset the pinching effect. The effects of maldistribution on efficiency are therefore most severe in large-diameter columns and small-diameter packings.

A good design practice is to seek a packing size that gives a $D_T/D_p$ between 10 and 40. This is often impractical, and higher ratios are common. When $D_T/D_p$ exceeds 100, avoiding efficiency loss due to maldistribution is challenging. Either ratios exceeding 100 should be avoided, or a special allowance should be made for loss of efficiency due to maldistribution.

3. A large-diameter packed bed cannot return to health from any severe maldistribution [Olujic and Jansen, *Chem. Eng. Res. Des.* **99:** 2 (2015)].

4. Wall flow effects become large when $D_T/D_p$ falls below about 10. Packing diameter should be selected so that $D_T/D_p$ exceeds 10.

Commercial structured packings come with integral wall wipers at regular vertical intervals. These redirect liquid running down the wall into the packings and prevent gas from bypassing the bed at the wall region, and they need to be adequately stretched out during packing installation. Experiments by Olujic and Jansen [*Chem. Eng. Res. Des.* **99:** 2 (2015)] showed that the amount of wall flow differs to a certain extent, depending on the number and effectiveness of the wall wipers used.

5. Columns containing fewer than five theoretical stages per bed are relatively insensitive to liquid maldistribution. With 10 or more stages per bed, efficiency can be extremely sensitive to maldistribution (Strigle, *Packed Tower Design and Applications,* 2d ed., Gulf Publishing, Houston, Tex., 1994) (Fig. 14-66). Beds consisting of small packings or structured packings, which develop more theoretical stages per bed, are therefore more sensitive to maldistribution than equal-depth beds of larger packings. This is clearly demonstrated by FRI's experiments [Shariat and Kunesh, *Ind. Eng. Chem. Res.* **34**(4): 1273 (1995)]. Lockett and Billingham [*Trans. IChemE* **81:** Part A, p. 131 (January 2003)] concur with these comments when their procedure (above) indicates high sensitivity to maldistribution, but they allow a higher number of stages per bed when the sensitivity is low.

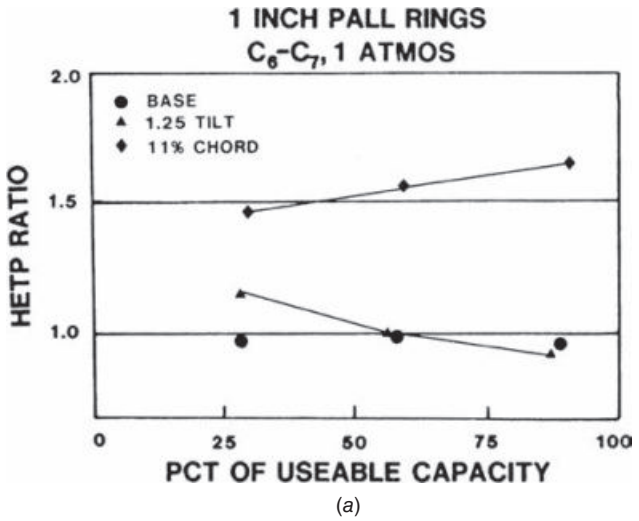
6. Maldistribution tends to be a greater problem at low liquid flow rates than at high liquid flow rates [Zuiderweg, Hoek, and Lahm, *IChemE Symp. Ser.* **104:** A217 (1987)]. The tendency to pinch and to spread unevenly is generally higher at the lower liquid flow rates.

7. A packed column has reasonable tolerance for a uniform or smooth variation in liquid distribution and for a variation that is totally random (*small-scale maldistribution*). The impact of discontinuities or zonal flow (*large-scale maldistribution*) is much more severe [Zuiderweg et al. 1987; Kunesh, *Chem. Eng.*, December 7, 1987, p. 101; Kunesh, Lahm, and Yanagi, *Ind. Eng. Chem. Res.* **26**(9): 1845 (1987); Olujic and Jansen, *Chem. Eng. Res. Des.* **99:** 2 (2015)]. This is so because the local pinching of small-scale maldistribution is evened out by the lateral mixing and therefore causes few ill effects. In contrast, the lateral mixing either is powerless to rectify a large-scale maldistribution or takes considerable bed length to do so (meanwhile, efficiency is lost).

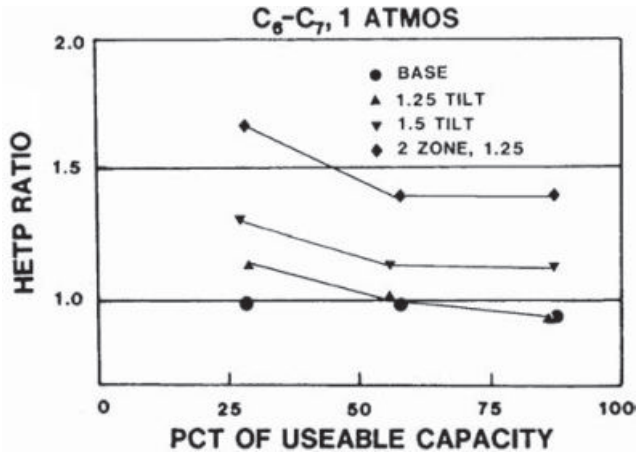
Figure 14-65 shows HETPs measured in tests that simulate various types of maldistribution in FRI's 1.2-m column containing a 3.6-m bed of 1-in Pall® rings. The *y* axis is the ratio of measured HETP in the maldistribution tests to the HETP obtained with an excellent distributor. Analogous measurements with structured packing were reported by Fitz, King, and Kunesh [*Trans. IChemE* **77:** Part A, p. 482 (1999)]. Generally, the response of the structured packings resembled that of the Pall® rings, except as noted below.

Figure 14-66*a* shows virtually no loss of efficiency when a distributor uniformly tilts, such that the ratio of highest to lowest flow is 1.25 (i.e., a 1.25 tilt). In contrast, an 11 percent chordal blank of a level distributor causes packing HETP to rise by 50 percent.

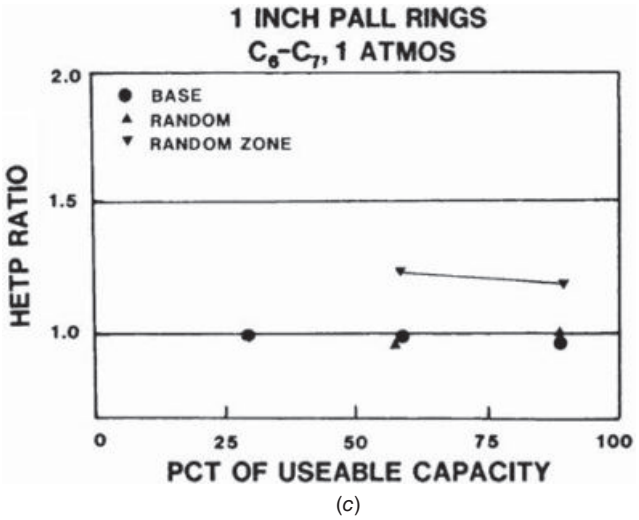
Figure 14-66*b* compares continuous tilts with ratios of highest to lowest flow of 1.25 and 1.5 to a situation where one-half of the distributor passes



(*a*)



(*b*)



(*c*)

**FIG. 14-66** Comparing the effects of "small-scale" and "large-scale" maldistribution on packing HETP. (*a*) Comparing the effect of a simulated continuous tilt (max/min flow ratio = 1.25) with the simulated effect of blanking a chordal area equal to 11 percent of the tower area. (*b*) Comparing the effects of simulated continuous tilts (max/min flow ratios of 1.25 and 1.5) with the effects of a situation where one-half of the distributor passes 25 percent more liquid than the other half. (*c*) Comparing the effects of random maldistribution with those of zonal maldistribution. (*Reprinted with permission from J. G. Kunesh, L. Lahm, and T. Yahagi,* Ind. Eng. Chem. Res. ***26:** p. 1845; copyright © 1987, American Chemical Society.*)

25 percent more liquid than the other half. The latter ("zonal") situation causes a much greater rise in HETP than a "uniform" maldistribution with twice as much variation from maximum to minimum.

Figure 14-66*c* shows results of tests in which flows from individual distributor drip points were varied in a gaussian pattern (maximum/mean = 2). When the pattern was randomly assigned, there was no efficiency loss. When the variations above the mean were assigned to a "high zone," and those below the mean to a "low zone," HETP rose by about 20 percent.

With structured packing, both random and zonal maldistribution caused about the same loss of efficiency at the same degree of maldistribution. Olujic and Jansen [*Chem. Eng. Res. Des.* **99:** 2 (2015)] provide a detailed survey on large-scale maldistribution tests with structured packings. With large surface area structured packings, even a relatively small degree of zonal maldistribution can be detrimental to HETP. In tests by Pavlenko et al. [*Theor. Found. Chem. Eng.* **43:** 1 (2009)], chordal blanking of as little as 10 percent of a tower cross section area, which gave no visible deterioration of liquid distribution, reduced bed efficiency by one-third in 450 $m^2/m^3$ structured packings.

8. A packed bed appears to have a "natural distribution," which is an inherent and stable property of the packings. An initial distribution that is better than natural will rapidly degrade to it, and one that is worse will finally achieve it, but sometimes at a slow rate. If the rate is extremely slow, recovery from a maldistributed pattern may not be observed in practice (Zuiderweg et al. 1987). Even though the volumetric distribution improves along the bed, the concentration profile could have already been damaged, and pinching occurs (Bonilla, *Chem. Eng. Prog.*, March 1993, p. 47).

9. Liquid maldistribution lowers packing turndown. The 2-in Pall rings curve in Fig. 14-59 shows HETP rise upon reaching the distributor turndown limit.

10. The major source of gas maldistribution is undersized gas inlet and reboiler return nozzles, leading to the entry of high-velocity gas jets into the tower. These jets persist through low-pressure-drop devices such as packings. Installing gas distributors and improving gas distributor designs, even inlet baffles, have alleviated many of these problems. Vapor distribution is most troublesome in large-diameter columns. Strigle (*Packed Tower Design and Applications,* 2d ed., Gulf Publishing, Houston, Tex., 1994) recommends considering a gas distributing device whenever the gas nozzle *F*-factor ($F_N = u_N \rho_G^{0.5}$) exceeds 27 m/s $(kg/m^3)^{0.5}$, or the kinetic energy of the inlet gas exceeds eight times the pressure drop through the first foot of packing, or the pressure drop through the bed is less than 0.65 mbar/m. Gas maldistribution is best tackled at the source by paying attention to the gas inlet arrangements.

11. A poor initial liquid maldistribution may cause gas maldistribution in the loading region, that is, at high gas rates [Stoter, Olujic, and de Graauw, *IChemE Symp. Ser.* **128:** A201 (1992); Kouri and Sohlo, *IChemE Symp. Ser.* **104:** B193 (1987)]. At worst, initial liquid maldistribution may induce local flooding, which would channel the gas. The segregation tends to persist down the bed. Outside the loading region, the influence of the liquid flow on gas maldistribution is small or negligible. Similarly, in high-gas-velocity situations, the liquid distribution pattern in the bottom structured packing layers is significantly influenced by a strongly maldistributed inlet gas flow [Olujic et al., *Chem. Eng. and Processing* **43:** 465 (2004)]. Duss [*IChemE Symp. Ser.* **152:** 418 (2006)] suggests that high liquid loads such as those experienced in high-pressure distillation also increase the susceptibility to gas maldistribution.

12. The effect of gas maldistribution on packing performance is riddled with unexplained mysteries. FRI's (Cai, paper presented at the AIChE Annual Meeting, Reno, Nev., 2001) commercial-scale tests show little effect of gas maldistribution on both random and structured packing efficiencies. The Cai et al. [*Trans IChemE* **81:** Part A, p. 85 (2003)] distillation tests in a 1.2-m-diameter tower showed that blocking the central 50 percent or the chordal 30 percent of the tower cross-sectional area beneath a 1.7-m-tall bed of 250 $m^2/m^3$ structured packing had no effect on packing efficiency, pressure drop, or capacity. The blocking did not permit gas passage but allowed the collection of the descending liquid. Simulator tests with similar blocking with packing heights ranging from 0.8 to 2.4 m [Olujic et al., *Chemical Engineering and Processing* **43:** 465 (2004); *Distillation 2003: Topical Conference Proceedings,* AIChE Spring National Meeting, New Orleans, La., AIChE, 2003, p. 567] differed, showing that a 50 percent chordal blank raised pressure drop, gave a poorer gas pattern, and prematurely loaded the packing. They explain the difference by the ability of liquid to drain undisturbed from the gas in the blocked segment in the FRI tests. Olujic et al. found that while gas maldistribution generated by collectors and by central blockage of 50 percent of the cross-sectional areas was smoothed after two to three layers of structured packing, a chordal blockage of 30 to 50 percent of cross-sectional area generated maldistribution that penetrated deeply into the bed.

13. Computational fluid dynamics (CFD) has been an effective tool for analyzing the effects of gas inlet geometry on gas maldistribution in packed beds. Using CFD, Wehrli et al. [*Trans. IChemE* **81:** Part A, p. 116 (January 2003)]

found that a very simple device such as the V-baffle (see Fig. 14-69*b*) gives much better distribution than a bare nozzle, while a more sophisticated vane device such as a Schoepentoeter (see Fig. 14-70*c*) is even better. Implications of the gas inlet geometry to gas distribution in refinery vacuum towers was studied by Vaidyanathan et al. (*Distillation 2001: Topical Conference Proceedings*, AIChE Spring National Meeting, Houston, Tex., April 22–26, 2001, p. 287); Paladino et al. (*Distillation 2003: Topical Conference Proceedings*, AIChE Spring National Meeting, New Orleans, La., 2003, p. 241); Torres et al. (*Distillation 2003: Topical Conference Proceedings,* AIChE Spring National Meeting, New Orleans, La., 2003, p. 284); Waintraub et al. (*Distillation 2005: Topical Conference Proceedings*, AIChE Spring National Meeting, Atlanta, Ga., 2005, p. 79); and Wehrli et al. (*IChemE* Symp. Ser 152, London, 2006). Vaidyanathan et al., Torres et al., and Stemich and Spiegel [*Chem. Eng. Res. Des.* **89:** 1392 (2011)] examined the effect of the geometry of a chimney tray (e.g., see Fig. 14-71) above the inlet on gas distribution and liquid entrainment. Paladino et al. demonstrated that the presence of liquid in the feed affects the gas velocity profile and must be accounted for in modeling. Paladino et al. and Waintraub et al. used their two-fluid model to study the velocity distributions and entrainment generated by different designs of vapor horns (e.g., see Fig. 14-70). Wehrli et al. produced pilot-scale data simulating a vacuum tower inlet, which can be used in CFD model validation. Ali et al. [*Trans. IChemE* **81:** Part A, p. 108 (January 2003)] found that the gas velocity profile obtained using a commercial CFD package compared well to those measured in a 1.4-m simulator equipped with structured packing together with commercial distributors and collectors. Their CFD model effectively pointed them to a collector design that minimizes gas maldistribution.

14. Liquid maldistribution has little effect on pressure drop in the preloading regime, while tending to lower pressure drop in the loading regime [Olujic and Jansen, *Chem. Eng. Res. Des.* **99:** 2 (2015)].

## PACKED-TOWER SCALE-UP

**Process versus Equipment Scale-Up** The superb article on packing scale-up, Schoenmakers and Spiegel (chap. 10 in Gorak, A., and Olujic, Z., eds., *Distillation Equipment and Processes*, Elsevier, New York, 2014) and the classic book by Krell (*Handbook of Laboratory Distillation,* 2d ed., Elsevier, New York, 1982) guide many of the recommendations that follow, with full endorsement by the author. *Process scale-up*, which tests the feasibility of a proposed process, identifies azeotropes, reactions, component accumulation, fouling, and corrosive potential, compares separation sequences, and looks for unexpected reactions, can be distinguished from *equipment scale-up*, which focuses on the number of separation stages needed in order to avoid tower oversizing or undersizing. The demarcation between the two is not sharp and varies in different literature references.

**Process Scale-Up (Miniplants)** A miniplant generates a bench-scale plant as equivalent as possible to the intended production plant. Usually the column diameters are about 50 mm. It is essential to correctly set up the process steps, recycles, purges, side draws, and residence times that influence reactions, product decompositions, and fouling. Schoenmakers and Spiegel emphasize that steady state may be difficult to reach unless the miniplant operates around the clock, and that bench-scale batch distillation tests are unsuitable for generating process scale-up data for continuous distillation. Sampling, analyses, and controls are also very important.

***Minimizing Heat Losses*** Due to the high area-to-volume ratio, heat losses are much greater in bench-scale columns than in production plants. Good insulation, heating the column wall close to the internal temperature, and avoiding column diameters smaller than 50 mm are key.

***Residence Times*** Bench-scale columns usually have more residence time than plant columns, and this has a major impact on reactions and decomposition. Using packings rather than trays, adding glass balls to reduce the vessel volume, and side heating can help. Feed and drawoff piping need to correctly mimic the intended plant column because fast reactions may occur in the vapor or liquid.

***Packings for Process Scale-Up*** Here the emphasis is on packings that will do the job. The diameter and height effects, which are primary for equipment scale-up, are secondary for process scale-up. Laboratory packings are discussed in Krell's book and also in some vendor brochures (e.g., Cannon Instrument Co., *Pro-Pak Protruded Metal Distillation Packing* Bulletin, State College, Pa.; Sulzer Chemtech, *Structured Packings Bulletin,* Winterthur, Switzerland).

***Calibration and Precautions*** This step tests the tower using a standard system and is a prerequisite for both process and equipment scale-up. The standard system should be nonhazardous, of stable components, nonfoaming, and nonfouling, and its equilibrium, thermal, and transport properties should be well known. A constant relative volatility over the concentration range, such as that of the chlorobenzene-ethylbenzene system [Ottenbacher et al., *Chem. Eng. Res. Des.* **89:** 1427 (2011)], is desirable. Schoenmakers and Spiegel name chlorobenzene-ethylbenzene above 50 mbar and cis-trans decalin at lower pressures. Deibele, Goedecke, and Schoenmakers [*IChemE Symp. Ser.* **142:** 1021 (1997)], and Gann et al. [*Chem. Ing. Tech.* **64**(1): 6 (1992)] provide an extensive list of factors that can affect this scale-up, including test mixture, contaminants, packing pretreatment, column structure, packing installation, snug fit at the wall, column insulation, vacuum tightness, measurement and control, liquid distribution, reflux subcooling, prewetting, sampling, analysis, adjusting the number of stages to avoid pinches and analysis issues, evaluation procedure, and more. Data from laboratory columns can be particularly sensitive to some of these factors.

**Equipment Scale-Up** The considerations that follow are mostly important for equipment scale-up purposes.

***Diameter*** For random packings, there are many reports [Billet, *Distillation Engineering,* Chem Publishing Co., New York, 1979; Chen, *Chem. Eng.*, March 5, 1984, p. 40; Zuiderweg, Hoek, and Lahm, *IChemE Symp. Ser.* **104:** A217 (1987)] of an increase in HETP with column diameter. Billet and Mackowiak's (Billet, *Packed Column Analysis and Design*, Ruhr University, Bochum, Germany, 1989) scale-up chart for Pall® rings implies that efficiency decreases as column diameter increases.

Practically all sources explain the increase of HETP with column diameter in terms of enhanced maldistribution or issues with the scale-up procedure. Bench-scale and pilot columns seldom operate at column-to-packing diameter ratios ($D_T/D_p$) larger than 20; under these conditions, lateral mixing effectively offsets a loss of efficiency due to maldistribution pinch. In contrast, industrial-scale columns usually operate at $D_T/D_p$ ratios of 30 to 100; under these conditions, lateral mixing is far less effective for offsetting maldistribution pinch.

To increase $D_T/D_p$, it may appear attractive to perform the bench-scale tests using a smaller packing size than will be used in the prototype. Deibele, Goedecke, and Schoenmakers [*IChemE Symp. Ser.* **142:** 1021 (1997)], Goedecke and Alig (Paper presented at the AIChE Spring National Meeting, Atlanta, Ga., April 1994), and Gann et al. [*Chem. Ing. Tech.* **64**(1): 6 (1992)] studied scale-up from 50- to 75-mm-diameter packed columns directly to industrial columns. Goedecke and Alig show that for wire-mesh structured packing, bench-scale efficiency tends to be better than large-column efficiency, while for corrugated-sheet structured packing, the opposite is true, possibly due to excessive wall flow. For some packings, variation of efficiency with loads at bench scale completely differs from its variation in larger columns. For one structured packing, Kuhni Rombopak 9M (this packing is not currently available), there was little load effect, and there was good consistency between data obtained from different sources—at least for one test mixture. Deibele et al. present an excellent set of practical guidelines to improve scale-up reliability. So, it appears that great caution is required when scaling up packing data from bench-scale columns.

***Height*** Experimental data for random packings show that HETP slightly increases with bed depth [Billet, *Distillation Engineering*, Chemical Publishing Co., New York, 1979; *Packed Tower Analysis and Design,* Ruhr University, Bochum, Germany, 1989; Eckert and Walter, *Hydrocarbon Processing* **43**(2): 107 (1964)].

For structured packing, some tests with Mellapak 250Y [Meier, Hunkeler, and Stöcker, *IChemE Symp. Ser.* **56:** 3, 3/1 (1979)] showed no effect of bed height on packing efficiency, while others [Cai et al., *Trans IChemE* **81:** Part A, p. 89 (January 2003)] did show a significant effect.

The effect of bed depth on packing HETP is attributed to liquid maldistribution. Zuiderweg et al. [*IChemE Symp. Ser.* **104:** A217 (1987)] suggest that the uneven irrigation generates an uneven concentration profile and localized pinching near the bottom of the beds. The tests by Martin, Bravo, and Fair (Paper presented at the National AIChE Meeting, New Orleans, La., 1988) confirm that the problem area is near the bottom. According to the zone-stage and Lockett and Billingham models discussed previously, as well as the empirical correlation by Moore and Rukovena (Fig. 14-63), the more stages per bed, the greater is the rise in HETP with bed depth. The presence and extent of maldistribution play an important role in determining the bed-depth effect.

As the bed depth increases, end effects (i.e., mass transfer in the region of liquid introduction and in the region where liquid drips from the packing supports) become less important. Such end effects tend to lower the HETP observed in short columns, such as pilot-plant columns.

In summary, bed depth may significantly influence HETP. This adds uncertainty to scale-up. Shallow test beds should be avoided. Most investigators use beds at least 1.5 m tall, and often more than 3 m tall. The FRI sampling technique (discussed in the subsection Sampling that follows) can detect maldistribution along the bed height. Ottenbacher et al. [*Chem. Eng. Res. Des.* **89:** 1427 (2011)] recommend making bed heights at least 4 to 6 m and to apply efficiencies from shorter test beds with care because they may be too optimistic.

***Loadings*** For many random and corrugated-sheet structured packings, HETP is independent of vapor and liquid loadings (Figs. 14-59 and 14-60). For wire-mesh and some corrugated-sheet structured packings, HETP changes with gas and liquid loads.

Wu and Chen [*IChemE Symp. Ser.* **104:** B225 (1987)] recommend pilot testing over the entire range between the expected minimum and maximum operating rates and taking the highest measured HETP as the basis for scale-up. The author concurs. With structured packings, the load effect may be due to liquid rather than gas loads, and the pilot tests should cover the range of liquid loads (i.e., m/s based on column cross section) that is expected in the prototype.

***Wetting*** For operation at low liquid loads, the onset of minimum wetting can adversely affect scale-up, particularly with random packings and aqueous systems. Scale-up reliability at low liquid loads can be improved by pilot testing at the composition range expected in the prototype, and by using identical packing materials and surface treatment in the pilot tests and in the prototype.

***Underwetting*** At the aqueous end of aqueous-organic columns, underwetting is important. Rapid changes of concentration profiles and physical properties in organic-water separations complicate scale-up [Eiden and Kaiser, *IChemE Symp. Ser.* **142:** 757 (1997); also Schoenmakers and Spiegel, chap. 10 in Gorak, A., and Olujic, Z., eds., *Distillation Equipment and Processes*, Elsevier, New York, 2014]. Near the onset of underwetting, HETP becomes strongly dependent on composition, packing material and surface roughness, and the presence of surfactants. Scale-up reliability can be enhanced by pilot testing at the composition range expected in the prototype and by using identical packing material and surface treatment in the pilot tests and in the prototype.

***Preflooding*** For one structured packing test with an aqueous system, Billet (*Packed Column Analysis and Design,* Ruhr University, Bochum, Germany, 1989) measured higher efficiency for a preflooded bed than for a non-preflooded bed. Presumably, the preflooding improved either wetting or distribution. Billet and Schoenmakers and Spiegel recommend preflooding the packing, both in the prototype and in the pilot column, to ensure maximum efficiency.

***Sampling*** Fractionation Research Inc. (FRI) developed a sampling technique that eliminates the influence of "end effects" and detects a maldistributed composition profile. This technique [Silvey and Keller, *IChemE Symp. Ser.* **32:** 4:18 (1969)] samples the bed at frequent intervals, typically every 0.6 m or so. HETP is determined from a plot of these interbed samples rather than from the top and bottom compositions.

It is imperative that the interbed samplers catch representative samples, which are an average through the bed cross section. Caution is required when the liquid is highly aerated and turbulent (e.g., above 1300 kPa or above 1 m/min). The author highly recommends the FRI sampling technique for all other conditions.

***Aging*** Billet (*Packed Column Analysis and Design,* Ruhr University, Bochum, Germany, 1989) showed that for some plastic packings in aqueous systems, the efficiency after one week's operation was almost double the efficiency of new packings. Little further change was observed after one week. Billet explains the phenomenon by improved wetting. He recommends that data for plastic packings should only be used for scale-up after being in operation for an adequately long period.

## DISTRIBUTORS

**Liquid Distributors** A liquid distributor (or redistributor) should be used in any location in a packed column where an external liquid stream is introduced. Liquid redistributors are also used between packed beds to avoid excessive bed lengths that may impair packing efficiency or mechanical strength. It is best to have the packing supplier also supply the distributor, with the user critically reviewing the design. The user must provide the supplier with concise information about the plugging, corrosive, and foaming tendencies of the service as well as the range of liquid flow rates that it needs to handle and the physical properties of the liquid.

Olsson (*Chem. Eng. Progr.*, October 1999, p. 57) discussed the key for successful distributor design and operation. He states that it is critical to correctly evaluate the fouling potential of the service and to design for it (e.g., preventing small holes, filtering the feed); to avoid gas entry into liquid distributors (e.g., no flashing feed into a liquid distributor); to systematically check the irrigation pattern using a method such as the circle analysis of Moore and Rukovena [*Chem. Plants and Process* (European ed.), August 1987, p. 11; described in detail in Kister's *Distillation Operation,* McGraw-Hill, New York, 1990]; to water-test any liquid distributor (major suppliers have dedicated test stands, which provide qualitative observations as well as random sampling of liquid rates issuing from various irrigation points from which a statistical coefficient of variation CV is derived; CV < 5% is good); to ensure correct entry of a feed into a liquid distributor; and to thoroughly inspect a distributor. Kister [*Trans. IChemE* **81:** Part A, p. 5 (January 2003)] found that between 80 and 90 percent of the distributor failures reported in the literature in the last 50 years could have been prevented if users and suppliers had followed Olsson's measures.

A minimum of 40 irrigation points per square meter has been recommended, with 60 to 100 per square meter being ideal [Strigle, *Packed Tower Design and Applications,* 2d ed., Gulf Publishing, Houston, Tex., 1994; Kister, *Distillation Operation,* McGraw-Hill, New York, 1990]. Commercial-scale tests with both random and structured packings showed no improvement in packing efficiency by increasing the irrigation point density above 40 per square meter [Fitz, King, and Kunesh, *Trans. IChemE* **77:** Part A, p. 482 (1999); Olujic and Jansen, *Chem. Eng. Res. Des.* **99:** 2 (2015)]. So going to larger numbers of irrigation points per square meter provides little improvement while leading to smaller holes, which increases the plugging tendency. With high-surface-area structured packings, a larger irrigation point density was shown to help packing efficiency (Olujic and Jansen 2015), and the recommended irrigation point densities per square meter are >120 for 350 $m^2/m^3$ packings, >160 for 500 $m^2/m^3$ packings, and >200 for larger areas [Kooijman and Taylor, chap. 5 in Gorak and Schoenmakers, *Distillation Operation and Application,* Academic Press, New York, 2014].

In orifice-type distributors, which are the most common type, the head-flow relationship is given by the Torricelli orifice equation

$$Q = 3.96 \times 10^{-4} K_D n_D d_h^2 h^{0.5} \tag{14-163}$$

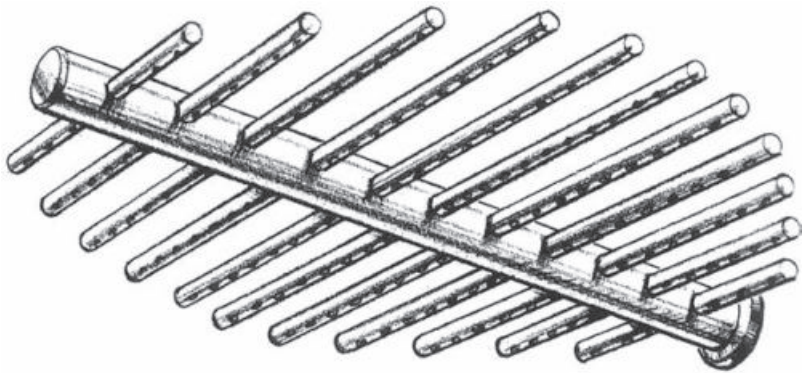
where $Q$ is the liquid flow rate, $m^3/h$; $K_D$ is the orifice discharge coefficient, with a recommended value of 0.707 (Chen, *Chem. Eng.*, March 5, 1984, p. 40); $n_D$ is the number of holes; $d_h$ is the hole diameter, mm; and $h$ is the liquid head, mm. Equation (14-163) shows that at a given $Q$, increasing $n$ leads to either smaller $d$ or smaller $h$.

Figures 14-67 and 14-68 show common distributor types used for distillation and absorption. An excellent detailed discussion of the types of distributors and their pros and cons was given by Bonilla (*Chem. Eng. Progr.*, March 1993, p. 47). The *perforated pipe* (or *ladder pipe*) distributor (Fig. 14-67*a*) has holes on the underside of the pipes. It is inexpensive, provides a large open area for vapor flow, and does not rely on gravity. On the debit side, it is typically designed for high-velocity heads, 500 to 1000 mm of water, which is 5 to 10 times more than gravity distributors, requiring [per Eq. (14-163)] either fewer irrigation points or the use of plugging-prone smaller holes. The high hole velocities make it prone to corrosion and erosion. These disadvantages make it relatively unpopular. A gravity variation of this distributor uses a liquid drum above the distributor that gravity-feeds it.

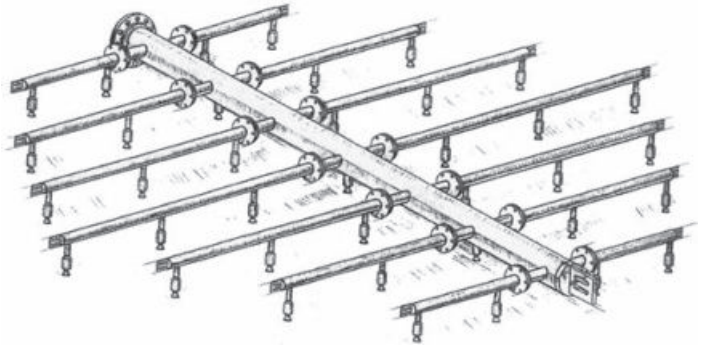
*Spray* distributors (Fig. 14-67*b*) are pipe headers with spray nozzles fitted on the underside. The spray nozzles are typically wide-angle (often 120°) full-cone. Spray distributors are unpopular in distillation but are common in heat transfer, in washing and scrubbing services (especially in refinery towers), and in small-diameter towers where a single spray nozzle can be used. They are inexpensive and offer a large open area for vapor flow and a robustness for handling of fouling fluids when correctly designed, and the sprays themselves contribute to mass and heat transfer. On the debit side, the spray cones often generate regions of over- and underirrigation, the sprays may not be homogeneous, and the spray nozzles are prone to corrosion, erosion, and damage. With highly subcooled liquids, the spray angle may collapse when pushed at high pressure drops (above 100 to 150 kPa) (Fractionation Research Inc., *A Spray Collapse Study,* motion picture 919, Stillwater, Okla., 1985). The design and spray pattern are highly empirical. Sprays also generate significant entrainment to the section above [Trompiz and Fair, *Ind. Eng. Chem, Res.* **39**(6): 1797 (2000)].

*Orifice pan* distributors (Fig. 14-68*a*) and *orifice tunnel* distributors (Fig. 14-68*b*) have floor holes for liquid flow and circular (Fig. 14-68*a*) or rectangular (Fig. 14-68*b*) risers for vapor passages. When they are used as redistributors, a hat is installed above each riser to prevent liquid from the bed above from dripping into the risers. Unlike the ladder pipe and spray distributors that operate by pressure drop, orifice distributors operate by gravity and therefore use a much smaller liquid head, typically 100 to 150 mm at maximum rates. Using Eq. (14-163), the lower head translates to either more distributions points ($n_D$), which helps irrigation quality, or larger hole diameters, which resists plugging. However, the low liquid velocities, large residence times, and open pans (or troughs) make them more prone to plugging than the pressure distributors. Leakage through cracks at the support ring may generate maldistribution, and it is problematic especially when thermal expansion to process temperatures is significant. A good hole pattern and avoidance of oversized risers are essential. Orifice distributors are self-collecting, a unique advantage for redistributors. Orifice distributors are one of the most popular types and are favored whenever the liquid loads are high enough to afford hole diameters large enough to resist plugging (>12 mm).

*Orifice trough* (or *orifice channel*) distributors (Fig. 14-68*c–f*) are some of the most popular types. The trough construction does away with the multitude of joints in the orifice pans, making them far more leak-resistant, a major advantage in large towers and low-liquid-rate applications. Liquid



(*a*)



(*b*)

**FIG. 14-67** Pressure liquid distributors. (*a*) Ladder pipe. (*b*) Spray. (*Courtesy of Koch-Glitsch LP.*)

from a central parting box (Fig. 14-68*c*, *e*) or middle channel (Fig. 14-68*d*) is metered into each trough. The troughs can have floor holes, but elevating the holes above the floor (Fig. 14-68*c*–*g*) is preferred because it enhances plugging resistance. Tubes (Fig. 14-68*c*, *d*, *f*) or baffles (Fig. 14-68*e*) direct the liquid issuing from the elevated holes downward onto the packings. Orifice trough distributors are not self-collecting. When used for redistribution, they require a liquid collector to be installed above them.

Turndown of orifice distributors is constrained to about 2:1 by Eq. (14-163). For example, a 100-mm liquid head at the design drops to 25 mm when the liquid rate is halved. Lower heads give poor irrigation and high sensitivity to levelness. Turndown is often enhanced by using two rows of side tubes (in the Fig. 14-68*c* type) or of side holes (in the Fig. 14-68*d* or *e* types). *Perforated drip tubes* (as in Fig. 14-68*d*) are popular in either orifice trough or orifice pan distributors. The lower, smaller hole is active at low liquid rates, with the larger upper hole becoming active at higher liquid rates. The use of perforated drip tubes is not recommended when the vapor dew point is much higher than the liquid bubble point because liquid may boil in the tubes, causing dryout underneath [Kister, Stupin, and Oude Lenferink, *IChemE Symp. Ser.* **152:** 409 (2006)].

A popular type of the orifice trough distributor is the *splash plate* distributor (Fig. 14-68*e*). The splash plates spread the issuing liquid over their lengths, making it possible to reduce the number of irrigation points. This is a special advantage with small liquid rates because fewer irrigation points (at a given head) translate to larger, more fouling-resistant hole diameters [Eq. (14-163)]. Lack of the drip tubes eliminates the possible in-tube boiling issue mentioned previously.

*Multistage* orifice trough distributors (Fig. 14-68*f*) also try to provide good irrigation at low liquid rates without resorting to plugging-prone small holes. The primary stage uses fewer irrigation points. Liquid from the primary stage is further split at the secondary stage. The secondary stage is small, so leveling and small flow variations are not of great concern. The secondary stage may use the same or a different liquid splitting principle from that of the primary stage. Even short layers of structured packings have been used as a secondary distribution stage.

*Notched trough* distributors (Fig. 14-68*g*) consist of parallel troughs with side V notches. These distributors obey the triangular notch equation instead of the orifice equation, which makes the flow proportional to $h^{2.5}$ [instead of $h^{0.5}$ in Eq. (14-163)]. This high power renders the distributor highly sensitive to out-of-levelness and hydraulic gradients and makes it difficult to incorporate a large number of distribution points. Since the liquid issues sideways, it is difficult to predict where the liquid will hit the packings. Baffles are sometimes used to direct the liquid downward. Overall, the quality of distribution is inferior to that of orifice distributors, making notched-trough distributors unpopular. Their strength is their insensitivity to fouling and corrosive environments and their ability to handle high liquid rates at good turndown.

With any trough distributor, and especially those with V notches, excessive hydraulic gradients must be avoided. This is often achieved by using more parting boxes.

The hydraulic gradient is highest where the liquid enters the troughs, approaching zero at the end of the trough. The hydraulic gradient (between entry point and trough end) can be calculated from [Moore and Rukovena, *Chemical Plants and Processing* (European ed.), August 1987, p. 11]

$$h_{hg} = 51\, v_H^2 \tag{14-164}$$

where $h_{hg}$ is the hydraulic gradient head, mm, and $v_H$ is the horizontal velocity in the troughs, m/s.

**Flashing Feed and Vapor Distributors** When the feed or reflux is a flashing feed, the vapor must be separated out of the liquid before the liquid enters a liquid distributor. At low velocities (only), this can be achieved by a *bare nozzle* (Fig. 14-69*a*). A *V baffle* (Fig. 14-69*b*) is sometimes installed as a primitive flashing feed or vapor distributor.

For better vapor-liquid separation and distribution, with smaller-diameter towers (<1.5 m), a *flash chamber* (Fig. 14-69*c*) separates the liquid from the vapor, with the collected liquid descending via downpipes to a liquid distributor below. The flash chamber can be peripheral (Fig. 14-69*c*) or central. In larger towers, *gallery distributors* (Fig. 14-69*d*) are preferred. The flashing feed enters the peripheral section of the upper plate (the gallery) where vapor disengages and flows up, with liquid descending through holes (Fig. 14-69*d*) or down pipes onto the liquid distributor below. Alternatively, an external knockout pot is sometimes used to give separate vapor and liquid feeds.

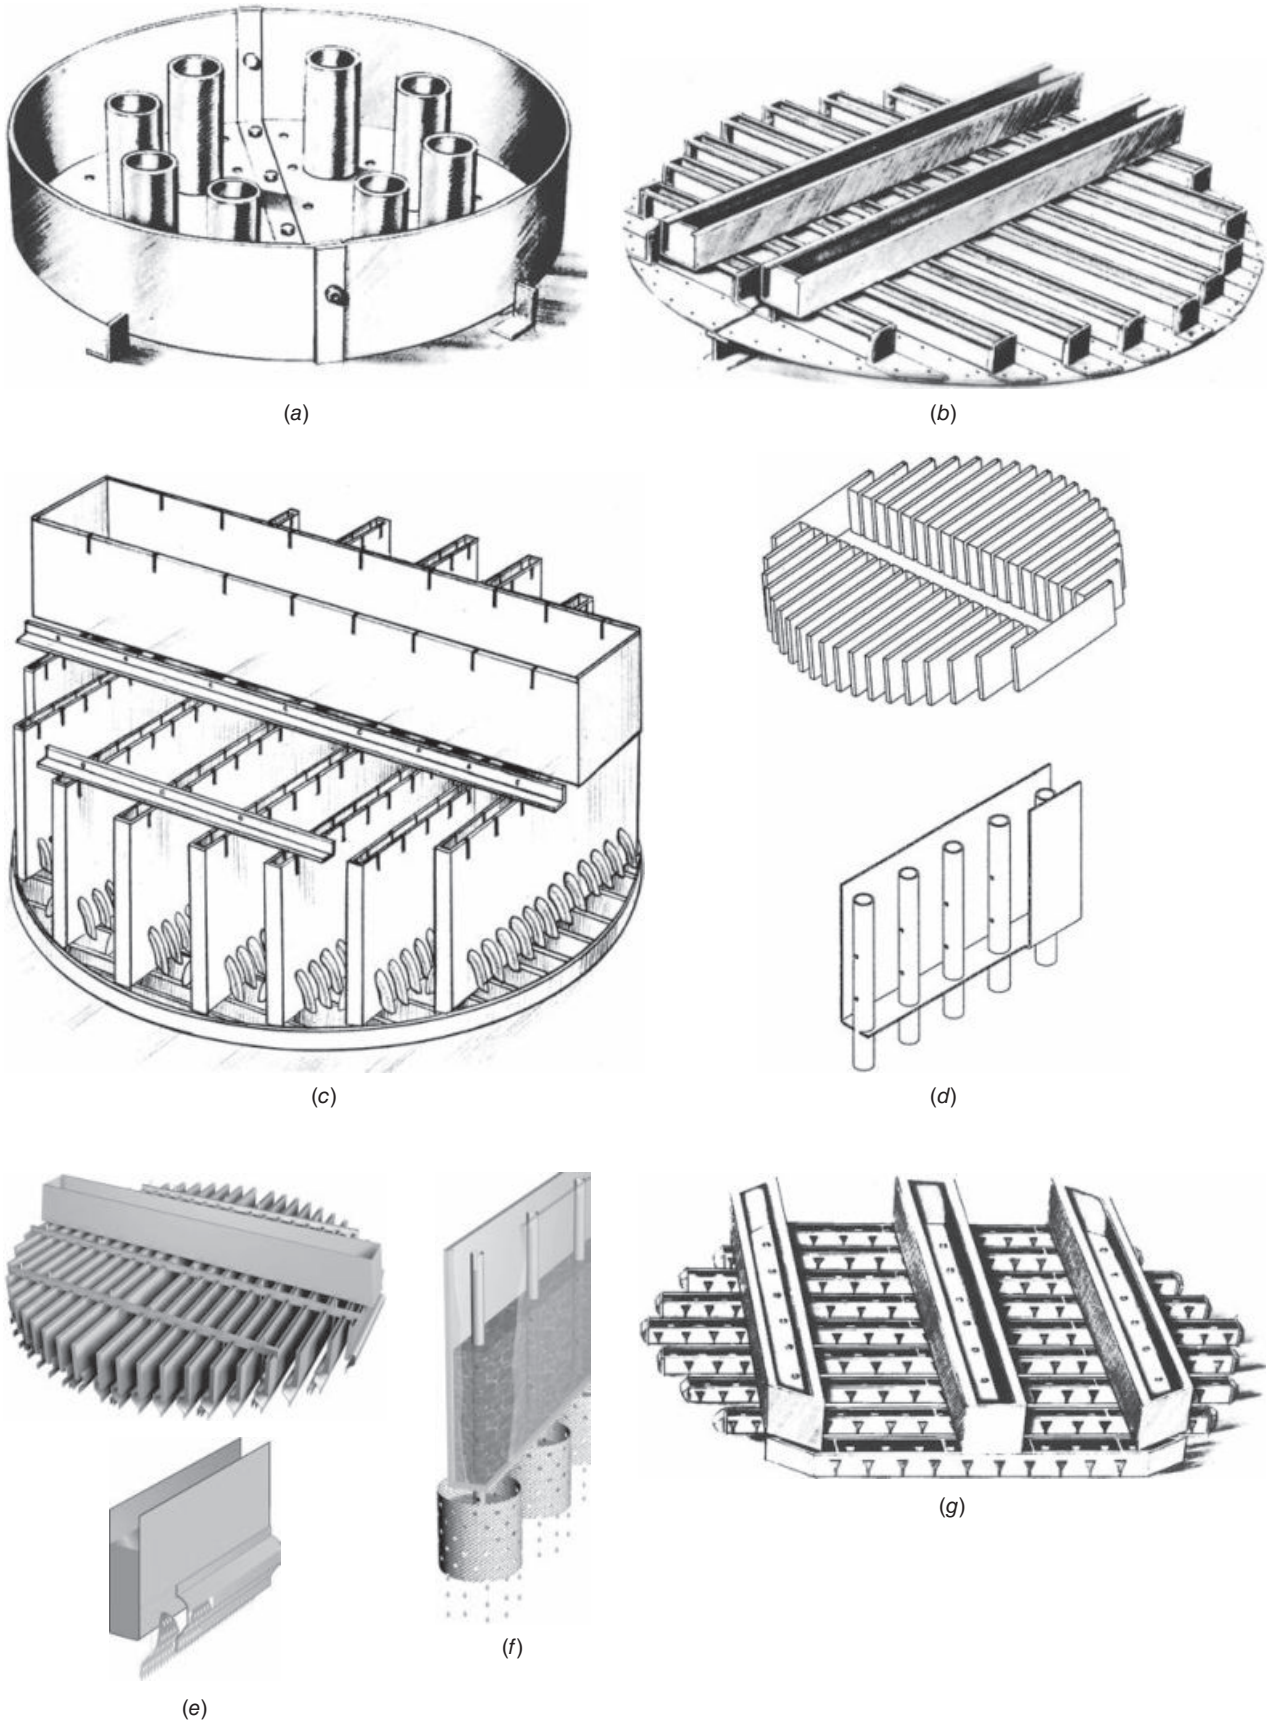


**FIG. 14-68** Gravity liquid distributors. (*a*) Orifice pan. (*b*) Orifice tunnel. (*c*) Orifice tube, using external drip tubes. (*d*) Orifice trough, using internal drip tubes. (*e*) Splash plate orifice trough. (*f*) Two-stage orifice trough. (*g*) Notched trough. (*Parts a–c, g, courtesy of Koch-Glitsch LP; parts d–f, courtesy of Sulzer Chemtech.*)

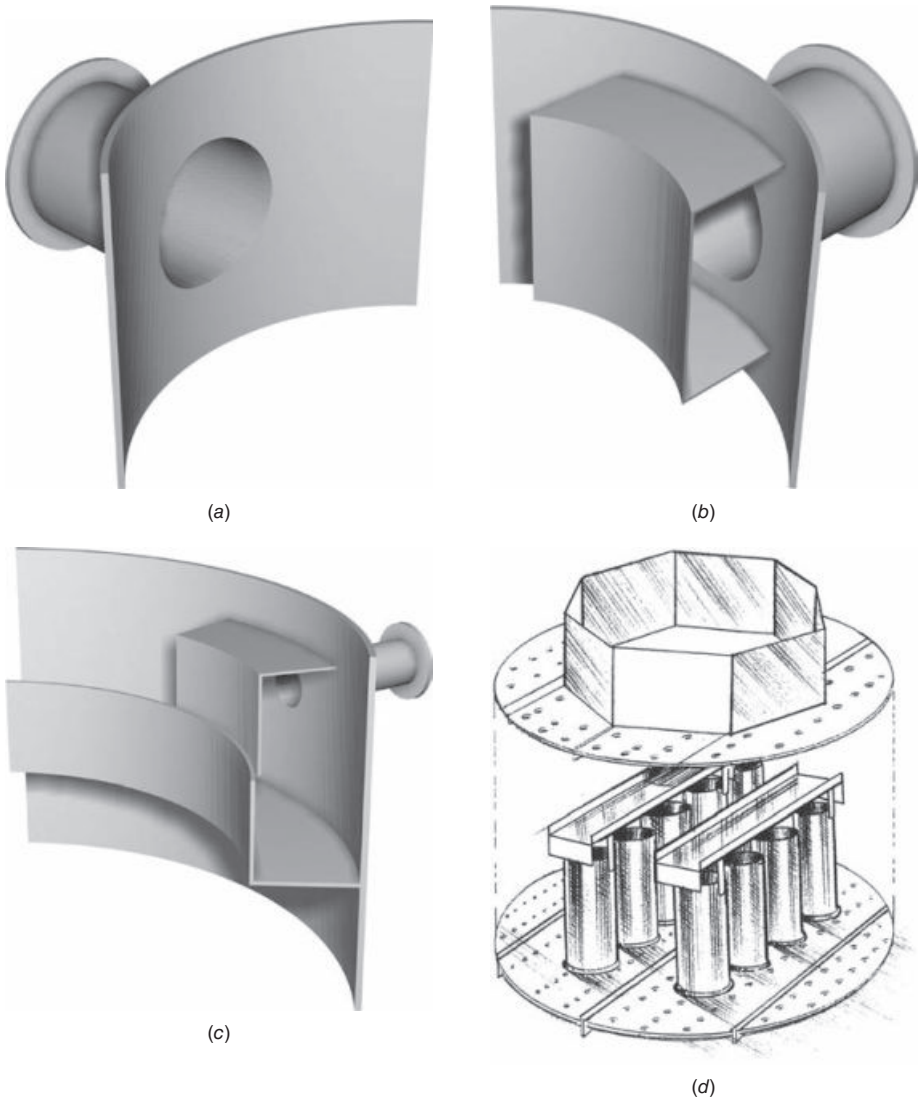

**FIG. 14-69** Flashing feed and vapor distributors. (*a*) Bare nozzle. (*b*) Rounded V baffle. (*c*) Peripheral flash box—the box extends right around the tower wall, with the collected liquid descending via downpipes to a liquid distributor below. (*d*) Gallery distributor—the feed enters the gallery area (upper plate). (*Parts a–c, courtesy of Sulzer Chemtech; part d, courtesy of Koch-Glitsch LP.*)

The *vapor horn* (Fig. 14-70*a*) is unique for high-velocity feeds in which vapor is the continuous phase with liquid present as suspended drops in the feed vapor. This is common when the feed makes up the bulk of the vapor traffic in the tower section above. Typical examples are feeds to refinery vacuum and crude towers and rich solution feeds to hot carbonate regenerators. A tangential helical baffle or vapor horn, covered at the top, open at the bottom, and spiraling downward, is used at the feed entry. This baffle forces the vapor to follow the contour of the vessel as it expands and decreases in velocity. Liquid droplets, due to their higher mass, tend to collide with the tower wall, which deflects them downward, thus reducing upward entrainment. Large forces, generated by hurricane-force winds and vapor flashing, are absorbed by the entire tower wall rather than by a small area. A wear plate is required at the tower wall. Some designs have vane openings on the inside wall.

Internal vanes to knock down the liquid and to deflect it downward may (Fig. 14-70*a*) or may not be included in the vapor horn design. If there are no vanes, the top of the horn typically goes down about ½ of the nozzle diameter for 180° horns and ¾ of nozzle diameter for 270° horns. The idea is that the vapor flow projection at 360° practically clears the inlet. The vapor horn with internal vanes is typically closed at the end and is not sloped.

Alternatively, multivane triangular diffusers (Fig. 14-70*b, c*) such as the Schoepentoeter™ have been successful for high-velocity vapor-rich feeds. These are used with radial (as distinct from tangential) nozzles. The vanes knock out the liquid and direct it downward while the vapor expands to the tower diameter. A recent development, the Schoepentoeter Plus,™ adds catching rims at the vane outlets to reduce liquid reentrainment.

Pilot-scale tests by Fan et al. [*IChemE Symp. Ser.* **142:** 899 (1997)] compared vapor distribution and entrainment from sparger, vapor horns, and multivane triangular diffusers. Vapor horns gave the best overall performance considering vapor distribution, entrainment, and pressure drop, with multivane distributors doing well, too. The designs of the inlets compared, however, were not optimized so the comparison could have reflected deviations from optimum rather than real differences between the devices.

Low-velocity vapor-only feeds often enter via bare nozzles or V baffles. At higher velocities, perforated vapor spargers are used. At high velocities, vapor horns and multivane triangular diffusers are often preferred. Alternatively or additionally, a vapor distributor may be mounted above the feed. The vapor distributor is a chimney tray (Fig. 14-71) where liquid is collected on the deck and flows via downcomers or is drawn out while vapor passes through the chimneys. To be effective as a vapor distributor, the pressure drop through the chimneys needs to be high enough to counter the maldistributed vapor. It was recommended to make the pressure drop through the chimneys at least equal to the velocity head at the tower inlet nozzle (Strigle, *Random Packings and Packed Towers*, Gulf Publishing, Houston, Tex., 1987), with common pressure drops ranging from 25 to 200 mm water.

## OTHER PACKING CONSIDERATIONS

**Liquid Holdup** Liquid holdup is the liquid present in the void spaces of the packing. Reasonable liquid holdup is necessary for good mass transfer and efficient tower operation, but beyond that, it should be kept low. High holdup increases tower pressure drop, the weight of the packing, the support load at the bottom of the packing and tower, and the tower drainage time. Most important, when distilling thermally unstable materials, excessive holdup raises product degradation and fouling, and with hazardous chemicals, it increases undesirable inventories.

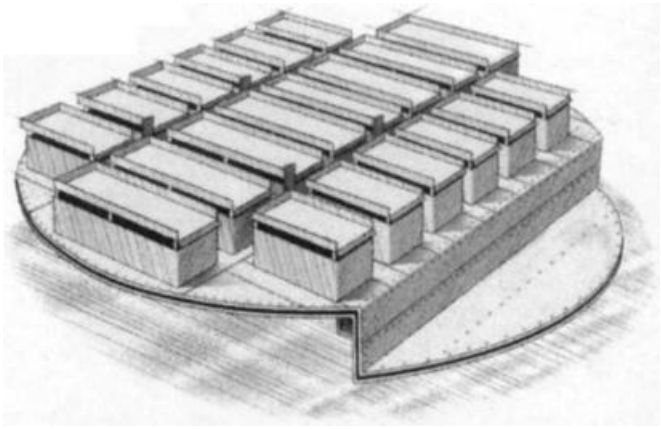

**FIG. 14-71** Chimney tray vapor distributor. (*Reprinted courtesy of Koch-Glitsch LP.*)

The effect of liquid and gas rates on the operating holdup is shown in Figs. 14-72 and 14-73. In the preloading regime, holdup is essentially independent of gas velocity, but it is a strong function of liquid flow rate and packing size. Smaller packings and high liquid rates tend to have greater holdup. Liquid holdup significantly increases with liquid viscosity above 2.5 cP, with only a slight effect below 2.5 cP [Zakeri, Einbu, and Svenden, *Chem. Eng. Res. Des.* **90:** 585 (2012); Bratmöller and Scholl, *Chem. Eng. Res. Design* **99:** 75 (2015); Alix and Raynal, *Chem. Eng. Res. Des.* **86:** 585 (2008)].

Maćkowiak (*Fluid Dynamics of Packed Columns*, Springer/Heidelberg, New York, 2010) characterizes holdup behavior according to the dimensionless liquid Reynolds number $\mathrm{Re}_L$ given by

$$\mathrm{Re}_L = 1000\, u_L\, \rho_L / a_p\, \mu_L \qquad (14\text{-}165)$$

where $u_L$ is the liquid superficial velocity, m/s, $a_p$ is the surface area per unit volume, $m^2/m^3$ (values listed in Tables 14-13 and 14-14), $\rho_L$ is the liquid density, $kg/m^3$, and $\mu_L$ is the liquid viscosity, cP. Reynolds numbers less than 1 indicate laminar flow; numbers above 10 indicate turbulent flow.

In the far most common turbulent flow regime, there is little viscosity effect and a smaller dependence on liquid velocity. In laminar flow, liquid holdup increases more strongly with smaller packing size and significantly increases with liquid viscosity.

Holdup can be estimated by using Buchanan's correlation [*Ind. Eng. Chem. Fund.* **6:** 400 (1967)], as recommended in previous editions of this handbook. More recent correlations by Billet and Schultes [*Trans.IChemE* **77:** Part A, p. 498 (1999)], by Maćkowiak (*Fluid Dynamics of Packed Columns*, Springer/Heidelberg, New York, 2010), and by Mersmann and Deixler [*Chem. Ing. Tech.*

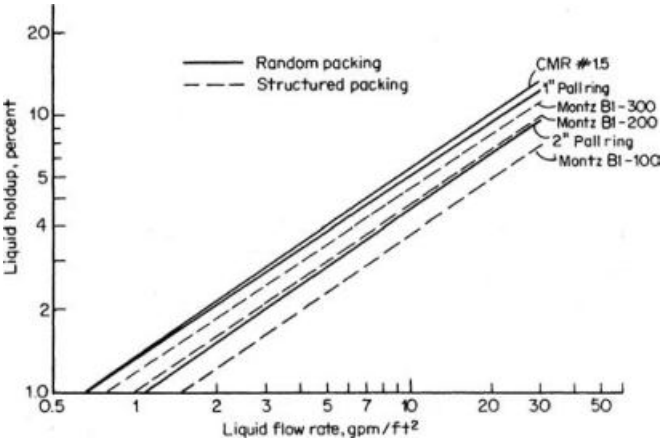

**FIG. 14-72** Liquid holdup, air-water data by Billet ("Packed Column Design and Analysis," Ruhr University, Bochum, Germany), preloading regime. (*From Kister, H. Z.,* Distillation Design, *copyright © by McGraw-Hill; reprinted with permission.*)

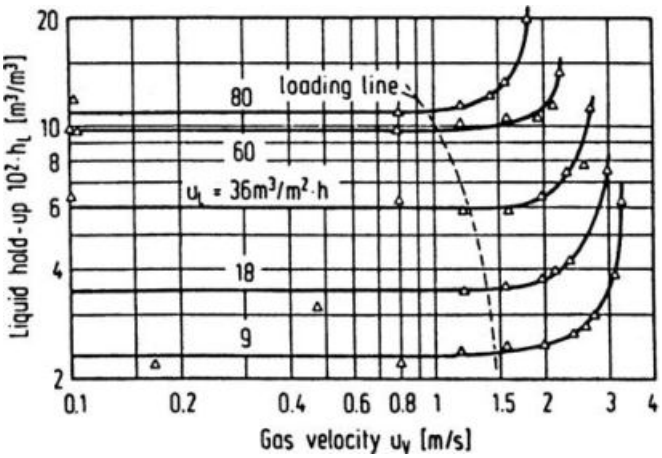

**FIG. 14-73** Effect of liquid and gas rates on the operating holdup of modern random packings (25-mm NorPac®). [*From R. Billet and M. Schultes,* IChemE Symp. Ser. ***104:*** *p. A159, 1987. Reprinted courtesy of the Institution of Chemical Engineers (UK).*]

**58**(1): 19 (1986)] apply to modern random packings as well as to some structured packings.

Stichlmair and Fair (*Distillation Principles and Practice*, Wiley-VCH, New York, 1998) show that liquid holdup is primarily a function of the liquid Froude number, the specific surface area of the packing, and physical properties. They recommend the correlation by Engel, Stichlmair, and Geipel [*Ind. Eng. Chem. Symp. Ser.* **142:** 939 (1997)].

$$h_{Lo} = 0.93\left(\frac{U_L^2 a_p}{g}\right)^{1/6}\left(\frac{\mu_L^2 a_p^3}{\rho_L^2 g}\right)^{1/10}\left(\frac{\sigma a_p^2}{1000\rho_L g}\right)^{1/8} \qquad (14\text{-}166)$$

where $h_{Lo}$ = liquid holdup, fractional
$U_L$ = liquid superficial velocity, m/s
$a_p$ = packing specific surface area, $m^2/m^3$
$g$ = acceleration due to gravity, m/s
$\mu_L$ = liquid viscosity, kg/(m · s)
$\sigma$ = surface tension, mN/m

The Engel, Stichlmair, and Geipel correlation applies only in the preloading regime. The packing geometry is represented in the correlation solely by the readily available specific surface area (Tables 14-13 and 14-14).

**Minimum Wetting Rate** The minimum wetting rate (MWR) is the lower stability limit of packings. Below this liquid load, the liquid film on the packing surfaces breaks up and dewetting occurs. The area available for mass transfer diminishes, and efficiency drops.

Hiller et al. [*Chem. Eng. Res. Des.* **99:** 220 (2015)] note a hysteresis between wetting and dewetting, reflected by the industrial practice of starting up low-liquid-load columns at higher liquid rates to achieve initial wetting.

Schmidt [*IChemE Symp. Ser.* **56:** 3.1/1 (1979)] described the MWR in terms of a force balance at a dry patch along the path of a falling liquid film. While the gravity and viscous forces resist dewetting, the surface tension and vapor shear forces tend to dewet the falling film. The MWR therefore rises with an increase in surface tension and liquid density and with a decrease in liquid viscosity. Large packing sizes and poor surface wetting characteristics also contribute to higher MWR.

Schmidt presented a fundamental correlation to predict minimum wetting for Raschig and Pall® rings. More popular have been the Glitsch rules of thumb [Table 14-15; Glitsch, Inc. (now Koch Glitsch), Bulletin 345, Dallas, Tex., 1986] for CMR® random packings with packing surface areas around 200 $m^2/m^3$. To extend these rules to other random packings, Kister (*Distillation Design*, McGraw-Hill, New York, 1992) applied Schmidt's model to give

$$Q_{MW} \approx (Q_{MW} \text{ from Table 14-15}) \times (200/a_p)^{0.5} \qquad (14\text{-}167)$$

The Glitsch brochure did not state the surface tension bases of Table 14-15. The author believes that they conservatively apply to organic and hydrocarbon systems ($\sigma < 25$ mN/m). For water ($\sigma = 70$ mN/m), the author believes that double the values from Table 14-15 is reasonable.

A more recent rule by Stichlmair and Fair (*Distillation Principles and Practice*, Wiley, New York, 1998) recommends higher MWR values than in Table 14-15, 2 and 10 $m^3/(h \cdot m^2)$ for organic and aqueous systems, respectively.

**TABLE 14-15 Glitsch's Rule of Thumb for Minimum Wetting**

Basis: CMR with $a_p > 150$ $m^2/m^3$

| Material | Minimum wetting rate, $m^3/(m^2 \cdot h)$ |
|---|---|
| Unglazed ceramic (chemical stoneware) | 0.5 |
| Oxidized metal (carbon steel, copper) | 0.7 |
| Surface-treated metal (etched stainless steel) | 1.0 |
| Glazed ceramic | 2.0 |
| Glass | 2.5 |
| Bright metal (stainless steel, tantalum, other alloys) | 3.0 |
| PVC-CPVC | 3.5 |
| Polypropylene | 4.0 |
| Fluoropolymers (PTFE type) | 5.0 |

Some surface treatments of the packing (e.g., oxidizing, sandblasting, etching) can substantially reduce the MWR. Chuang and Miller [*Can. J. Chem. Eng.* **66**(6): 377 (1988)] tested a metallic random packing with an aqueous system at low liquid rates [about 0.4 $m^3/(h \cdot m^2)$]. They used two alternative techniques for oxidizing the packing surfaces. The packings oxidized with the more effective technique gave a column efficiency twice as high as those oxidized by the others.

Superior wetting characteristics characterize structured packings. Satisfactory performance was reported down to 0.25 and 0.12 $m^3/(h \cdot m^2)$ in corrugated-sheet and wire-mesh metal structured packings, respectively, with organic systems. FRI's commercial-scale tests (Fitz and Kunesh, paper presented at the AIChE Annual Meeting, Chicago, November 1996) demonstrated good efficiencies for a hydrocarbon system in Mellapak® 250Y down to 0.5 $m^3/(h \cdot m^2)$ (no lower limit reached) with good liquid and vapor distribution. Hiller et al. [*Chem. Eng. Res. Des.* **99:** 220 (2015)] plotted operating points for 16 different industrial columns, successfully separating both organic and aqueous temperature-sensitive mixtures. About half of these were in the range of 0.2 to 1 $m^3/(h \cdot m^2)$. The *F*-factor [Eq. (14-76)] range for most was around 1.5 $Pa^{0.5}$. On this basis, Niggemann, Rix, and Meier (chap. 7 in Gorak and Schoenmakers, *Distillation Operation and Application*, Academic Press, New York, 2014) propose a minimum of 0.2 $m^3/(h \cdot m^2)$ and 1.0 $m^3/(h \cdot m^2)$ for organic and aqueous systems, respectively, with structured packings. They emphasize that the success of designs at such low liquid loads depends on achieving good liquid distribution.

**Two Liquid Phases** Two liquid phases often occur in heterogeneous distillation, in steam stripping, and in solvent recovery. Harrison (*Chem. Eng. Progr.*, November 1990, p. 80) and Meier et al. [*IChemE Symp. Ser.* **152:** 267 (2006)] saw no reason to expect unusual capacity or pressure drop limitations due to the presence of the second liquid phase, suggesting that standard correlations for these should apply.

In contrast, both expressed uncertainty in predicting packing efficiency. Harrison presented two case studies: In one, adding water to two water-insoluble organics had no effect on HETP; in another, a key component was soluble in both liquid phases, and HETP was about 50 percent above normal. Harrison argued that a second liquid phase leads to lower efficiency only when it impairs diffusion of the key species.

Extensive work by Wozny, Repke, et al. [*Ind. Eng. Chem. Res.* **49:** 822 (2010); *Chem. Eng. Res. Des.* **85**(A1): 50 (2007)] explained their findings and the earlier ones. Water tends to form rivulets or drops, while organics tend to flow as closed films on the packing. Both liquid phases overlay each other, causing strong interactions that are difficult to predict. Individual effective areas for the two liquid phases may be increased or decreased, depending on the flow characteristics on the packing. For example, one liquid phase may overflow the other and shield it from contact with the gas. Overall, the presence of a second liquid phase may increase, decrease, or not change the mass transfer efficiency. Meier et al. recommend obtaining efficiencies by scaling up laboratory-scale data using a similar type of packing.

Both Harrison and Meier et al. emphasize adequately distributing each liquid phase to the packing. Harrison noted that a well-designed ladder pipe distributor can maintain high velocities and low residence times that provide good mixing. With trough distributors that separate the phases and then distribute each to the packing, a light-to-heavy phase maldistribution may occur, especially when the phase ratio and separation vary. Meier et al. noted the existence of a cloudy two-liquid layer between the clear light and heavy liquid and recommend an additional middle distribution point for this layer. They also noticed that phase separation unevenness can have a large influence on the phase ratio irrigated to the packing.

**High Viscosity and Surface Tension** Bravo (Paper presented at the AIChE Spring National Meeting, Houston, Tex., 1995) studied a system that had 425-cP viscosity, 350 mN/m surface tension, and a high foaming

tendency. He found that efficiencies were liquid-phase-controlled and could be estimated from theoretical HTU models. Capacity was less than predicted by conventional methods, which do not account for the high viscosity. Design equations for orifice distributors extended well to the system once the orifice coefficient was calculated as a function of the low Reynolds number and the surface tension head was taken into account.

Böcker and Ronge [*Chem. Eng. Technol.* **28**(1) (2005)] verified Bravo's findings. Experimenting with chlorobenzene/ethylbenzene stripping in a 50-mm column, they raised the viscosity from 0.26 cP to 25 cP and 260 cP by adding up to 8 percent of polybutadiene to the feed. At the higher viscosities, liquid drainage deteriorated, which lowered flood points and raised pressure drops, especially at high liquid loads. Packing efficiency declined as liquid viscosity was raised, reaching 20 percent of the nonviscous efficiency at 260 cP, due to poorer wetting of the packing. Bratmöller and Scholl [*Chem. Eng. Res. Design* **99:** 75 (2015)] confirmed declining packing efficiency with higher liquid viscosity for a distillation system in a 50-mm column with structured packings at pressures from 950 to 20 mbar, over which there was a sixfold increase in liquid viscosity.

# OTHER TOPICS FOR DISTILLATION AND GAS ABSORPTION EQUIPMENT

## COMPARING TRAYS AND PACKINGS

Most separations can be performed either with trays or with packings. The following factors represent economic pros and cons that favor each and may be overridden. For instance, column complexity is a factor favoring trays, but gas plant demethanizers that often use one or more interreboilers are traditionally packed.

**Factors Favoring Packings**

*Vacuum systems.* Packing pressure drop is much lower than that of trays because the packing open area approaches the tower cross-sectional area, while the tray's open area is only 8 to 15 percent of the tower cross-sectional area. Also, the tray liquid head, which incurs substantial pressure drop (typically about 50 mm of the liquid per tray), is absent in packing. Typically, tray pressure drop is on the order of 10 mbar per theoretical stage, compared to 3 to 4 mbar per theoretical stage with random packings and about one-half of that with structured packings.

Consider a vacuum column with 10 theoretical stages, operating at 70-mbar top pressure. The bottom pressure will be 170 mbar with trays, but only 90 to 110 mbar with packings. The packed tower will have a much better relative volatility in the lower parts, thus reducing reflux and reboil requirements and bottom temperature. These translate to less product degradation, greater capacity, and smaller energy consumption, giving packings a major advantage.

*Lower-pressure-drop applications.* When the gas is moved by a fan through the tower, or when the tower is in the suction of a compressor, the smaller packing pressure drop is often a controlling consideration. This is particularly true for towers operating close to atmospheric pressure. Here excessive pressure drop in the tower increases the size of the fan or compressor (new plant), bottlenecks them (existing plant), and largely increases power consumption. Due to the compression ratio, pressure drop at the compressor discharge is far less important and seldom a controlling consideration.

*Revamps.* The pressure drop advantage is invaluable in vacuum column revamps and can be translated to a capacity gain, an energy gain, a separation improvement, or various combinations of these benefits. Likewise, for towers in the suction of compressors or when gas is moved through the tower by a fan, replacing trays with packings reduces the compression ratio or fan pressure drop and helps debottleneck the compressor or fan.

Packings also offer an easy tradeoff between capacity and separation. In the loaded sections of the tower, larger packings can overcome capacity bottlenecks at the expense of loss in separation. The separation loss can often be regained by retrofitting with smaller packings in sections of the tower that are not highly loaded. In tray towers, changing tray spacing gives similar results, but it is more difficult to do.

*Foaming (and emulsion).* The low gas and liquid velocities in packing suppress foam formation. The large open area of the larger random packing promotes foam dispersal. Both attributes make random packing excellent for handling foams. In many cases, recurrent foaming was alleviated by replacing trays with random packing, especially when tray downcomers were poorly designed.

Switching from trays to structured packing can aggravate foaming. While the low gas and liquid velocities help, the solid walls restrict the lateral movement of foams and give support to the foams.

*Small-diameter columns.* Columns with diameters less than 1 m (3 ft) are difficult to access from inside to install and maintain the trays. "Cartridge" trays or an oversized diameter are often used. Either option is expensive. Cartridge trays also run into problems with sealing to the tower wall, matching tower to tray hardware (Sands, *Chem. Eng.*, April 2006, p. 86) and being easy to dislodge. Packing is normally a cheaper and more desirable alternative.

*Corrosive systems.* The practical range of packing materials is wider. Ceramic and plastic packings are cheap and effective. Trays can be manufactured in nonmetals, but packing is usually a cheaper and more desirable alternative.

*Low liquid holdup.* Packings have lower liquid holdup than do trays. This is often advantageous for reducing polymerization, degradation, or the inventory of hazardous materials.

*Batch distillation.* Because of the smaller liquid holdup of packing, a higher percentage of the liquid can be recovered as top product.

**Factors Favoring Trays**

*Solids.* Trays handle solids much more easily than packing. Both gas and liquid velocities on trays are often an order of magnitude higher than through packing, providing a sweeping action that keeps tray openings clear. Solids tend to accumulate in packing voids. There are fewer locations on trays where solids can be deposited. Plugging in liquid distributors has been a common trouble spot. Cleaning trays is much easier than cleaning packings.

Not all trays are fouling-resistant. Floats on moving valve trays tend to "stick" to deposits on the tray deck. Fouling-resistant trays have large sieve holes or large fixed valves, and these should be used when plugging and fouling are the primary considerations.

There is much that can be done to alleviate plugging with random packing. Large, open packing with minimal pockets offers good plugging resistance. Distributors that resist plugging have large holes (>13-mm diameter). Such large holes are readily applied with high liquid flow rates, but they are often not practical for small liquid flow rates.

*Maldistribution.* The sensitivity of packing to liquid and gas maldistribution has been a common cause of failures in packed towers. Maldistribution issues are most severe in large-diameter towers, long beds, small liquid flow rates, and smaller packing. Structured packing is generally more prone to maldistribution than random packing. While good distributor design, water testing, and inspection can eliminate most maldistribution issues, it only takes a few small details that fall through the cracks to turn success into failure. Due to maldistribution, there are far more failures experienced with packing than in trays, and it takes more trials "to get it right" than with trays. This makes trays more robust.

*Complex towers.* Interreboilers, intercondensers, cooling coils, and side drawoffs are more easily incorporated in trays than in packed towers. In packed towers, every complexity requires additional distribution and/or liquid collection equipment.

*Feed composition variation.* One way of allowing for design uncertainties and feedstock variation is by installing alternate feed points. In packed towers, every alternate feed point requires expensive distribution equipment.

*Performance prediction.* Due to their sensitivity to maldistribution, there is greater uncertainty in predicting packed column performance.

*Chemical reaction, absorption.* Here the much higher liquid holdup on trays provides greater residence time for absorption or chemical reaction than does packing.

*Turndown.* Moving valve and bubble-cap trays normally give better turndown than packings. Unless very expensive distributors are used, packed tower turndown is usually limited by distributor turndown.

*Weight.* Tray towers usually weigh less than packed towers, saving on the cost of foundations, supports, and column shell.

**Trays versus Random Packings** The following factors generally favor trays compared to random packings, but not compared to structured packings.

*Low liquid rates.* With the aid of picket-fence weirs, splash baffles, reverse-flow trays, and bubble-cap trays, low liquid rates can be handled better in trays. Random packings suffer from liquid dewetting and maldistribution sensitivity at low liquid rates.

*Process surges.* Random packings are usually more troublesome than trays in services prone to process surges (e.g., those caused by slugs of water entering a hot oil tower, relief valve lifting, compressor surges, or instability of liquid seal loops). Structured packings are usually less troublesome than trays in such services.

**Trays versus Structured Packings** The following factors generally favor trays compared to structured packings, but not compared to random packings.

*Packing fires.* The thin sheets of structured packing (typically 0.1 mm) poorly dissipate heat away from hot spots. Also, cleaning, cooling, and washing of pyrophoric deposits can be difficult, especially when distributors or packing plug up. Many incidents of packing fires during turnarounds (while towers with structured packings were open to atmosphere) have been reported. Most of these fires were initiated by pyrophoric deposits, hot work (e.g., welding) above the packing, opening the tower while hot organics were still present, and packing metallurgy that was not fire-resistant. Detailed discussion can be found in Fractionation Research Inc. (FRI) Design Practices Committee, "Causes and Prevention of Packing Fires," *Chem. Eng.*, July 2007.

*Materials of construction.* Due to the thin sheets of structured packings (an order of magnitude thinner than trays), their materials of construction need to have better resistance to oxidation or corrosion. For a service in which carbon steel is usually satisfactory with trays, stainless steel is usually required with structured packings.

*Column wall inspection.* Due to their snug fit, structured packings are easily damaged during removal. This makes it difficult to inspect the column wall (e.g., for corrosion).

*Washing and purging.* Thorough removal of residual liquid, wash water, air, or process gas trapped in structured packings at start-up and shutdown is more difficult than with trays. Inadequate removal of these fluids may be hazardous.

*High liquid rates.* Multipass trays effectively lower the liquid load "seen" by each part of the tray. A similar trick cannot be applied with packings. The capacity of structured packings tends to rapidly fall off at high liquid rates.

**Capacity and Efficiency Comparison** Kister et al. [*Chem. Eng. Progr.* **90**(2): 23 (1994)] reported a study of the relative capacity and efficiency of conventional trays, modern random packings, and conventional structured packings. They found that, for each device optimally designed for the design requirements, a rough guide could be developed on the basis of flow parameter $L/G\,(\rho_G/\rho_L)^{0.5}$ (abscissa in Figs. 14-32, 14-55, and 14-56) and the following tentative conclusions could be drawn:

***Flow Parameter 0.02–0.1***

1. Trays and random packings have much the same efficiency and capacity.
2. Structured packing efficiency is about 1.5 times that of trays or random packing.
3. At a parameter of 0.02, the structured packing has a 1.3–1.4 capacity advantage over random packing and trays. This advantage disappears as the parameter approaches 0.1.

***Flow Parameter 0.1–0.3***

1. Trays and random packings have about the same efficiency and capacity.
2. Structured packing has about the same capacity as trays and random packings.
3. The efficiency advantage of structured packing over random packings and trays decreases from 1.5 to 1.2 as the parameter increases from 0.1 to 0.3.

***Flow Parameter 0.3–0.5***

1. The loss of capacity of structured packing is greatest in this range.
2. The random packing appears to have the highest capacity and efficiency with conventional trays just slightly behind. Structured packing has the least capacity and efficiency.

Experience indicates that the use of structured packings has capacity/efficiency disadvantages in the higher-pressure (higher-flow-parameter) region.

Zuiderweg and Nutter [*IChemE Symp. Ser.* **128:** A481 (1992)] explain the loss of capacity/efficiency by a large degree of backmixing and vapor recycle at high flow parameters, promoted by the solid walls of the corrugated packing layers.

## SYSTEM LIMIT: THE ULTIMATE CAPACITY OF FRACTIONATORS

Liquid drops of various sizes form in the gas–liquid contact zones of tray or packed towers. Small drops are easily entrained upward, but their volume is usually too small to initiate excessive liquid accumulation ( flooding). When the gas velocity is high enough to initiate a massive carryover of the larger drops to the tray above, or upward in a packed bed, liquid accumulation (entrainment flooding) takes place. This flood can be alleviated by increasing the tray spacing or using more hole areas on trays or by using larger, more open packings.

Upon further increase of gas velocity, a limit is reached when the superficial gas velocity in the gas–liquid contact zone exceeds the settling velocity of large liquid drops. At gas velocities higher than this, ascending gas lifts and carries over much of the tray or packing liquid, causing the tower to flood. This flood is termed *system limit* or *ultimate capacity*. This flood cannot be debottlenecked by improving packing size or shape, tray hole area, or tray spacing. The system limit gas velocity is a function only of physical properties and liquid flow rate. Once this limit is reached, the liquid will be blown upward. This is analogous to spraying water against a strong wind and getting drenched (Yanagai, *Chem. Eng.*, November 1990, p. 120). The system limit represents the ultimate capacity of the vast majority of existing trays and packings. In some applications, where very open packings (or trays) are used, such as in refinery vacuum towers, the system limit is the actual capacity limit.

The original work of Souders and Brown [*Ind. Eng. Chem.* **26**(1): 98 (1934), Eq. (14-80)] related the capacity of fractionators due to entrainment flooding to the settling velocity of drops. The concept of system limit was advanced by Fractionation Research Inc. (FRI), whose measurements and model have recently been published (Fitz and Kunesh, *Distillation 2001: Proceedings of Topical Conference,* AIChE Spring National Meeting, Houston, Tex., 2001; Stupin, FRI Topical Report 34, 1965, available through Special Collection Section, Oklahoma State University Library, Stillwater, Okla.). Figure 14-74 is a plot of FRI system limit data (most derived from tests with dual-flow trays with 29 percent hole area and 1.2- to 2.4-m tray spacing) against liquid superficial velocity for a variety of systems (Stupin 1965). The data show a constant-slope linear dependence of the system limit *C*-factor on the liquid load. There was a shortage of data at low liquid loads. Later data (Fig. 14-75) showed that as the liquid load was reduced, the system limit $C_{s,\text{ult}}$ stopped increasing and reached a limiting value. Based on this observation, Stupin and Kister [*Trans. IChemE* **81:** Part A, p. 136 (January 2003)] empirically revised the earlier Stupin/FRI correlation to give

$$C_1 = 0.445(1-F)\left(\frac{\sigma}{\Delta\rho}\right)^{0.25} - 1.4L_S \tag{14-168}$$

$$C_2 = 0.356(1-F)\left(\frac{\sigma}{\Delta\rho}\right)^{0.25} \tag{14-169}$$

$$C_{s,\text{ult}} = \text{smaller of } C_1 \text{ and } C_2 \tag{14-170}$$

where

$$F = \frac{1}{1+1.4(\Delta\rho/\rho_G)^{1/2}} \tag{14-171}$$

In Eqs. (14-168) through (14-171), $C_{s,\text{ult}}$ is the system limit *C*-factor based on the tower superficial area [see Eq. (14-77) for *C*-factor definition]; $L_S$ is the liquid superficial velocity, m/s; $\sigma$ is the surface tension, mN/m; $\Delta\rho$ is the difference between the liquid and gas densities, kg/m$^3$; and $\rho_G$ is the gas density, kg/m$^3$.

Stupin and Kister [*Trans. IChemE* **81:** Part A, p. 136 (January 2003)] relate the flattening of the curve in Fig. 14-75 at low liquid loads to the formation of more, smaller, easier-to-entrain liquid drops when the liquid load is lowered beyond the limiting liquid load. It follows that devices that can restrict the formation of smaller drops may be able to approach the system limit capacity predicted by Stupin's original equation [Eq. (14-168)] even at low liquid loads.

The only devices capable of debottlenecking a tray system-limit device are those that introduce a new force that helps disentrain the vapor space. Devices that use centrifugal force (see the subsection Centrifugal Force Deentrainment) are beginning to make inroads into commercial distillation and have achieved capacities as high as 50 percent above the system limit. Even the horizontal vapor push (see the subsection Truncated Downcomers/Forward-Push Trays) can help settle the entrained drops, but to a much lesser extent. It is unknown whether the horizontal push alone can achieve capacities exceeding the system limit.

## WETTED-WALL COLUMNS

Wetted-wall or falling-film columns are vertical tubes with liquid flowing as a thin film down a tube wall and vapor ascending through the hollow center. Because of the ease of modeling, wetted wall columns are popular as laboratory equipment, for example, to measure mass-transfer coefficients. In industry, wetted wall columns found application in services where high-heat-transfer-rate requirements are concomitant with the absorption process. Large areas of open surface are available for heat transfer for a given rate of mass transfer in this type of equipment because of the low mass-transfer rate inherent in wetted-wall equipment. In addition, this type of equipment lends itself to annular-type cooling devices.

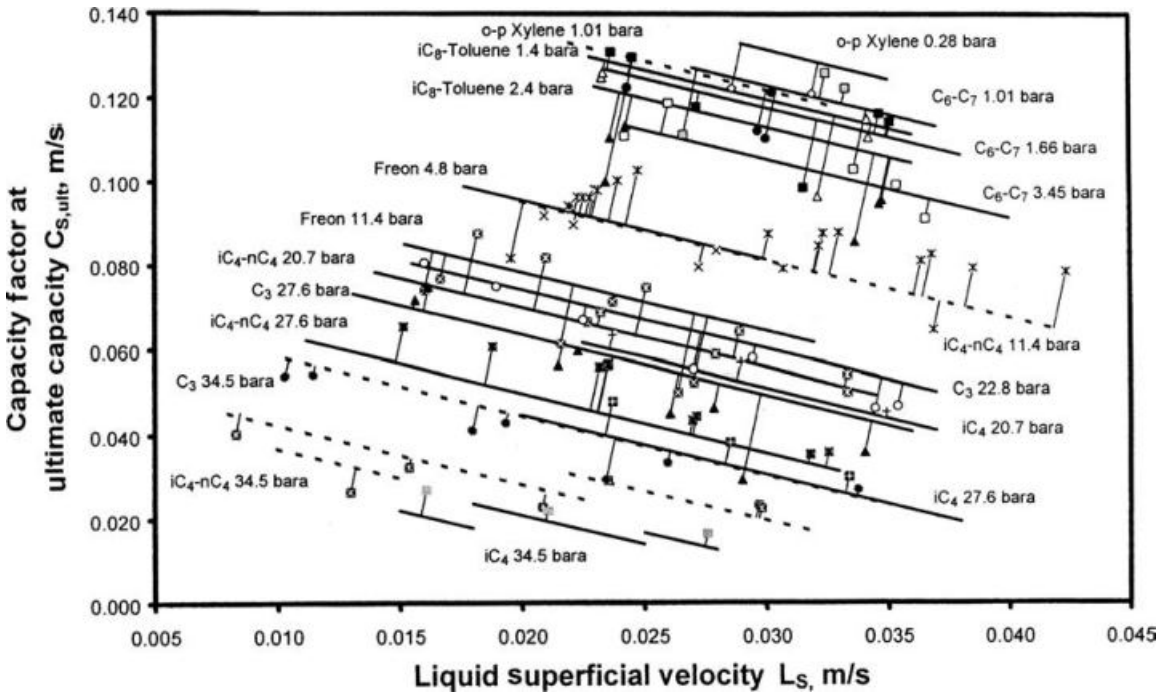

**FIG. 14-74** Effect of liquid rate on ultimate capacity at higher liquid rates. (*From Stupin, W. J., and H. Z. Kister,* Trans. IChemE, *vol. 81, Part A, p. 136, January 2003. Reprinted courtesy of IChemE.*)

The classic experimental work by Gilliland and Sherwood [*Ind. Eng. Chem.* **26:** 516 (1934)] used a falling-film column to study mass transfer for the vaporization of pure liquids in air streams for streamline flow. They obtained a correlation between the Sherwood number, Reynolds number, and Schmidt number.

$$\frac{k_g D_{\text{tube}}}{D_g}\frac{P_{BM}}{P} = 0.023 N_{\text{Re}}^{0.83} N_{\text{Sc}}^{0.44} \tag{14-172}$$

where $D_g$ = diffusion coefficient, ft²/h
$D_{\text{tube}}$ = inside diameter of tube, ft
$k_g$ = mass-transfer coefficient, gas phase, lb · mol/(h · ft²) (lb · mol/ft³)
$P_{BM}$ = logarithmic mean partial pressure of inert gas, atm
$P$ = total pressure, atm
$N_{\text{Re}}$ = Reynolds number, gas phase
$N_{\text{Sc}}$ = Schmidt number, gas phase

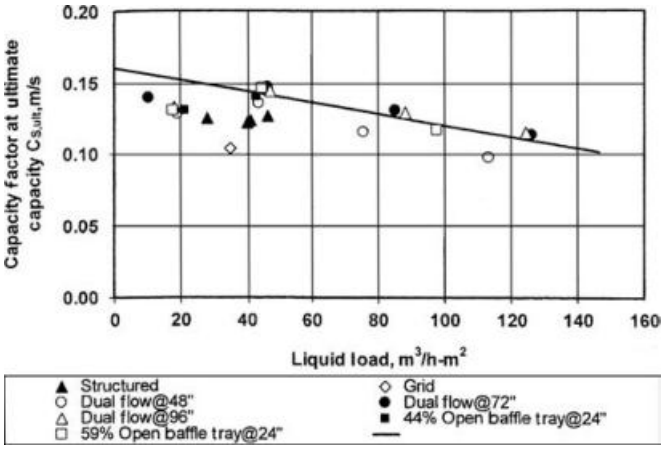

**FIG. 14-75** Comparison of original ultimate capacity correlation to test data, $C_6/C_7$, 1.66 bar. (*From Stupin, W. J., and H. Z. Kister,* Trans. IChemE, *vol. 81, Part A, p. 136, January 2003. Reprinted courtesy of IChemE.*)

Note that the group on the left side of Eq. (14-172) is dimensionless. When turbulence promoters are used at the inlet-gas section, an improvement in gas mass-transfer coefficient for the absorption of water vapor by sulfuric acid was observed by Greenewalt [*Ind. Eng. Chem.* **18:** 1291 (1926)]. A falling off of the rate of mass transfer below that indicated in Eq. (14-172) was observed by Cogan and Cogan (thesis, Massachusetts Institute of Technology, 1932) when a calming zone preceded the gas inlet in ammonia absorption.

Considerable work on wetted wall columns was reported in previous editions of *Perry's Handbook*. Many published contributions have been added since [for example, Nielsen, Kiil, Thomsen, and Dam-Johansen, *Chem. Eng. Sci.* **53**(3): 495 (1998); Erasmus and Nieuwoudt, *Ind. Eng. Chem. Res.* **40**(10): 2310 (2001); Spedding, *The Chemical Engineering Journal* **37**(3): 165 (1988); Strumillo and Porter, *AIChE J.* **11**(6): 1139 (1965)]. Due to the bulkiness of this work compared to the relatively low industrial usage of wetted wall columns, this work will not be addressed in detail in this edition of *Perry's Handbook*, and the reader is referred to the earlier editions and to the update articles.

## COLUMN COSTS

The estimation of column costs for preliminary process evaluations requires consideration not only of the basic type of internals but also of their effect on overall system cost. For a distillation system, for example, the overall system can include the vessel (column), attendant structures, supports, and foundations; auxiliaries such as reboiler, condenser, feed heater, and control instruments; and connecting piping. The choice of internals influences all these costs, but other factors influence them as well. A complete optimization of the system requires a full-process simulation model that can cover all pertinent variables influencing economics.

The cost estimation method presented here follows the guidelines of Peters, Timmerhaus, and West (*Plant Design and Economics for Chemical Engineers*, 5th ed., McGraw-Hill Education, 2003). Alternative methods were presented by Erwin (*Industrial Chemical Process Design*, 2d ed., McGraw-Hill, New York, 2014), and Towler and Sinnott (*Chemical Engineering Design—Principles, Practice, and Economics of Plant and Process Design*, 2d ed., Elsevier, Amsterdam, 2013).

**Cost of Internals** Purchased costs of trays may be estimated from Fig. 14-76, with corrections for tray material taken from Table 14-16. For two-pass trays, the cost is 15 to 20 percent higher. Figure 14-77 provides similar information for random packings. Note that for Figs. 14-76 and 14-77,

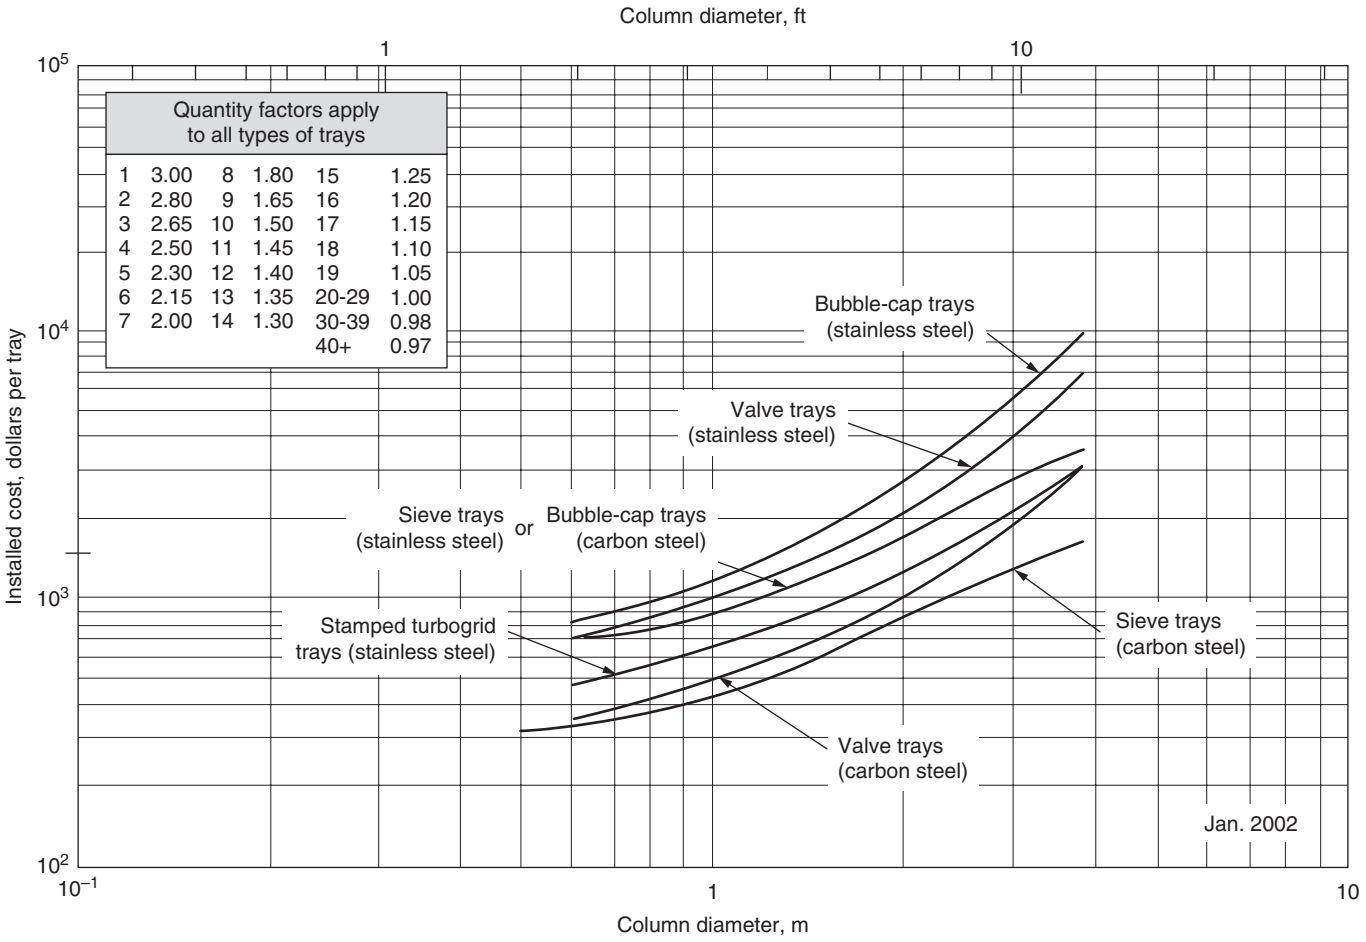

**FIG. 14-76** Purchased cost of trays in tray columns. Price includes tray decks, downcomers, and structural steel parts. (*Peters, Timmerhaus and West,* Plant Design and Economics for Chemical Engineers*, 5th Ed., McGraw-Hill Education, 2003. Reprinted with permission.*)

**TABLE 14-16 Relative Fabricated Cost for Metals Used in Tray-Tower Construction***

| Materials of construction | Relative cost per $ft^2$ of tray area (based on carbon steel = 1) |
|---|---|
| Sheet-metal trays | |
| Steel | 1 |
| 4–6% chrome—½ moly alloy steel | 2.1 |
| 11–13% chrome type 410 alloy steel | 2.6 |
| Red brass | 3 |
| Stainless steel type 304 | 4.2 |
| Stainless steel type 347 | 5.1 |
| Monel | 7.0 |
| Stainless steel type 316 | 5.5 |
| Inconel | 8.2 |
| Cast-iron trays | 2.8 |

*Peters and Timmerhaus, *Plant Design and Economics for Chemical Engineers*, 4th ed., McGraw-Hill, New York, 1991. To convert cost per square foot to cost per square meter, multiply by 10.76.

the effective cost date is January 2002, with the Marshall and Swift cost index being taken as 1167. Table 14-17 is based on 1990 cost data, but it only provides the relative costs between different materials.

In early 2017, costs of 0.2-mm-thick 410 SS corrugated sheet structured packings for a bed about 20 ft tall were on the order of \$40 to \$45 per cubic foot for Y packing of 125 $m^2/m^3$, rising to \$55 to \$60 per cubic foot and \$70 to \$75 per cubic foot for third-generation (high-performance) structured packings of 250 $m^2/m^3$ and 350 $m^2/m^3$, respectively, of the same material and thickness. Reducing the sheet thickness to the less-fire-resistant 0.1 mm in the same material reduces the costs to an order of \$40 to \$45 per cubic foot and \$50 to \$55 per cubic foot for third-generation (high-performance) packings of 250 $m^2/m^3$ and 350 $m^2/m^3$, respectively. See Table 14-14 for common packings of these surface areas. For third- and fourth-generation random packings, 410 SS and carbon steel, respectively, costs were on the order of \$100 to \$110 per cubic foot and \$85 to \$95 per cubic foot for 25-mm packings, declining to \$60 to \$65 and \$55 to \$60 per cubic foot, respectively, for 50-mm packings. These figures allow for distributors, collectors, and supports, but the need for special distributors and redistributors can double the cost of packings on a volumetric basis.

It should be recognized that, because of the requirement for distributors, redistributors, collectors, and holddowns, and because of competition, there are likely to be large variations in these costs from tower to tower and from supplier to supplier. Also, packings sold in very large quantities carry discounts. So the values in Figs. 14-76 and 14-77, as well as the numbers just cited, are far from reliable and are only suitable for a very preliminary indication, not for evaluation. The supplier should always be contacted for a reliable estimate.

**Cost of Columns** The fabricated cost of the vessel, including heads, skirt, nozzles, and ladderways, is usually estimated on the basis of weight. Figure 14-78 provides cost data for the shell and heads, and Fig. 14-79 provides cost data for connections. For very approximate estimates of complete columns, including internals, Fig. 14-80*a* and *b* may be used. As for Figs. 14-76 and 14-77, the effective cost date for Figs. 14-78 through 14-80 is January 2002, when the cost index was 1167.

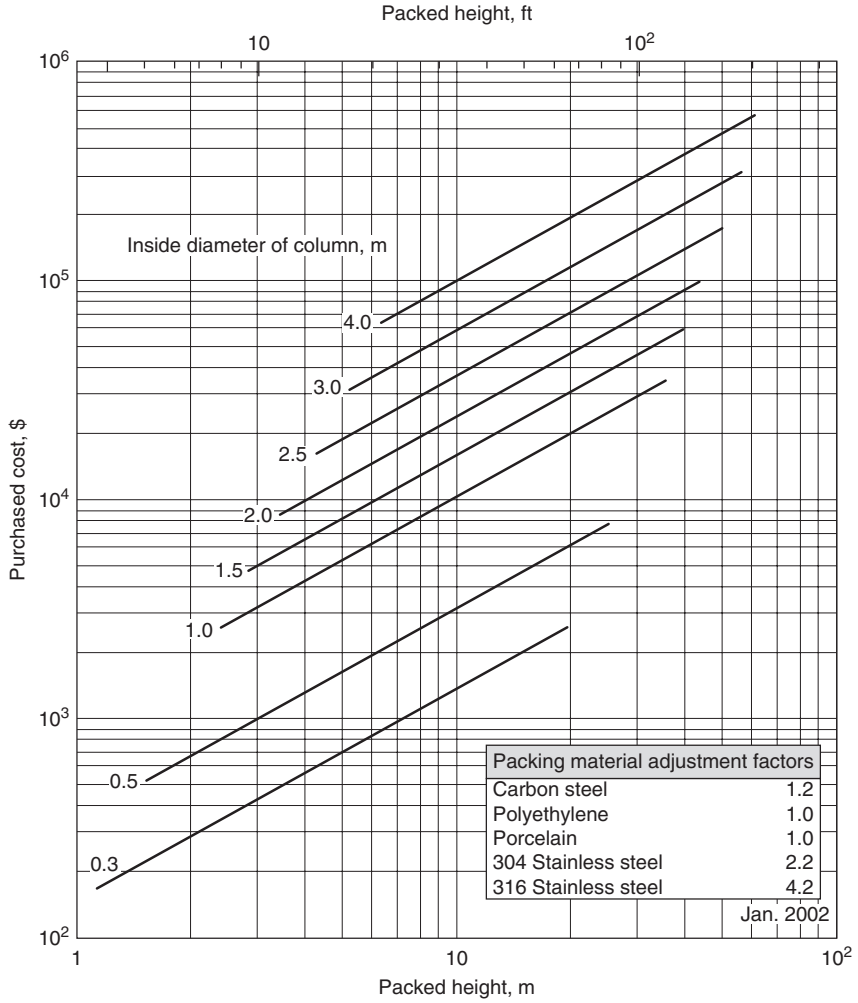

**FIG. 14-77** Purchased cost of random packings (price includes packing supports and distributors). (*Peters, Timmerhaus and West,* Plant Design and Economics for Chemical Engineers*, 5th Ed., McGraw-Hill Education, 2003. Reprinted with permission.*)

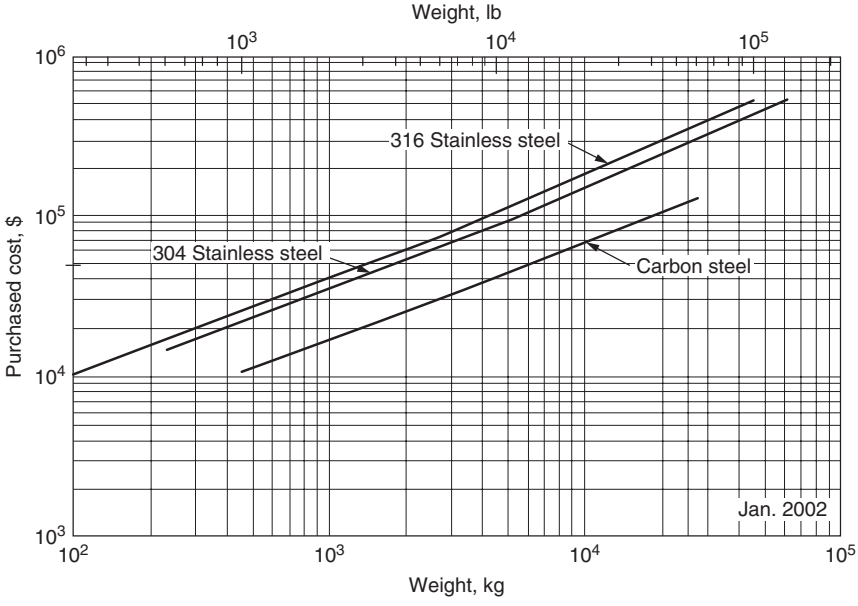

**FIG. 14-78** Purchased cost of columns. Costs are for shell with two heads and skirt, but without trays, packings, or connections. (*Peters, Timmerhaus and West,* Plant Design and Economics for Chemical Engineers*, 5th Ed., McGraw-Hill Education, 2003. Reprinted with permission.*)

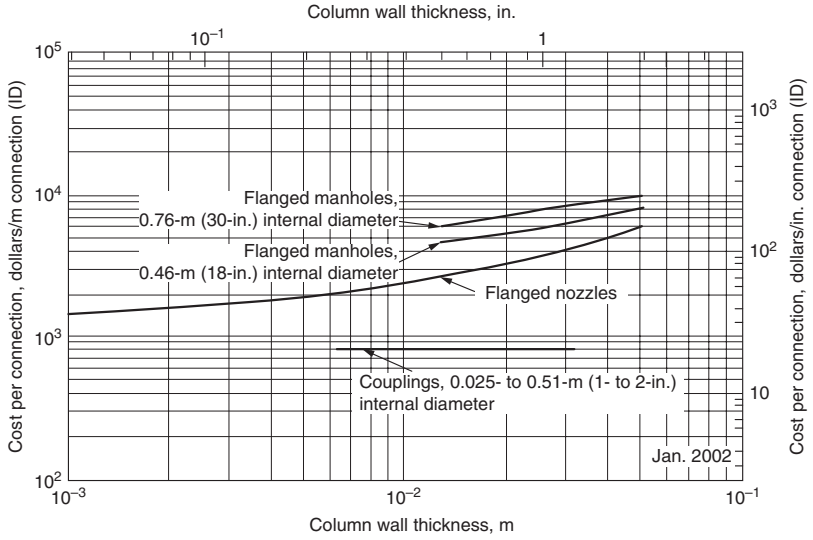

**FIG. 14-79** Approximate installed cost of steel-tower connections. Values apply to 136-kg (300-lb) connections. Multiply costs by 0.9 for 68 kg (150-lb) connections and by 1.2 for 272-kg (600-lb) connections. (*Peters, Timmerhaus and West,* Plant Design and Economics for Chemical Engineers*, 5th Ed., McGraw-Hill Education, 2003. Reprinted with permission.*)

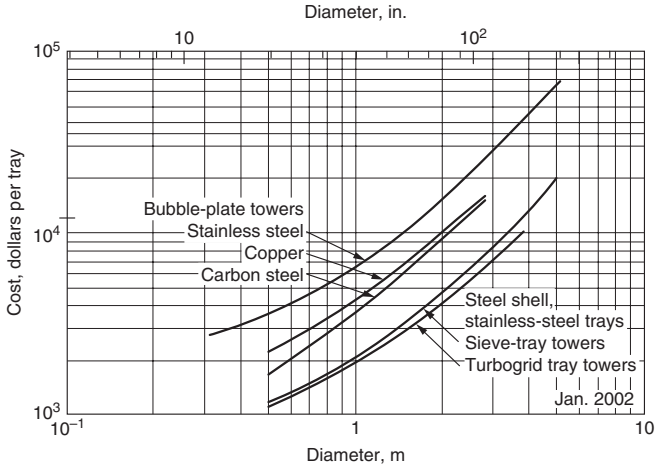

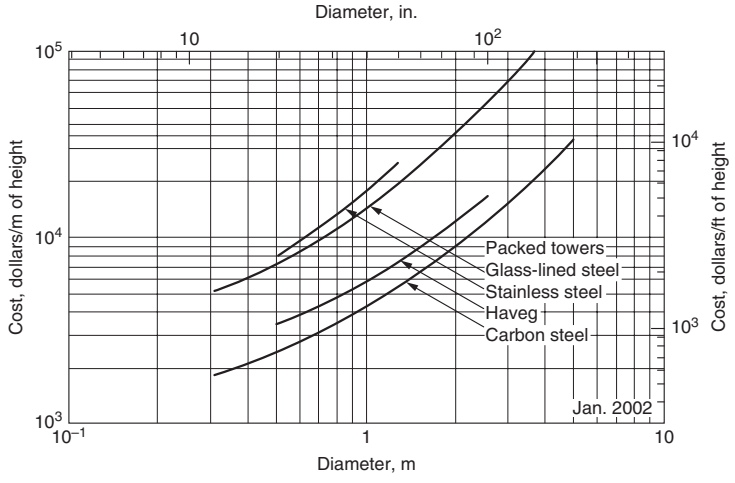

**FIG. 14-80** Purchased cost of towers, including installation and auxiliaries. (*a*) Tray towers. (*b*) Packed towers. (*Peters, Timmerhaus and West,* Plant Design and Economics for Chemical Engineers*, 5th Ed., McGraw-Hill Education, 2003. Reprinted with permission.*)

# PHASE DISPERSION

**General References:** For an overall discussion of gas–liquid breakup, see Brodkey, *The Phenomena of Fluid Motions,* Addison-Wesley, Reading, Mass., 1967. For a discussion of atomization devices and how they work, see Lipp, *Practical Spray Technology*, Lake Innovation LLC, Lake Junaluska, N.C., 2012. Prog.* **91**(7): 72–80 (1995)].

## BASICS OF INTERFACIAL CONTACTORS

**Steady-State Systems: Bubbles and Droplets** Bubbles are made by injecting vapor below the liquid surface. In contrast, droplets are commonly made by atomizing nozzles that inject liquid into a vapor. Bubble and droplet systems are fundamentally different, mainly because of the enormous difference in the density of the injected phase. There are situations where each is preferred. Bubble systems tend to have much higher interfacial area, as shown by comparing Example 14-17 to Examples 14-15 and 14-16. Because of their greater area, bubble systems will usually give a closer approach to equilibrium.

However, droplet systems can enable much higher energy input (via gas-phase pressure drop in cocurrent systems) and, as a result, can dominate applications where a quick quench is needed. See Examples 14-22 and 14-23. Conversely, droplet systems can also be designed for very low pressure drop, which is advantageous in applications such as vacuum condensers.

**Unstable Systems: Froths and Hollow-Cone Atomizing Nozzles** We usually think of interfacial contact as a steady-state system of raining droplets or rising bubbles, but some of the most efficient interfacial contactors take advantage of unstable interfacial geometry. The most common is the distillation tray, which operates with a wild mix of bubbles, jets, films, and droplets. The mix is often described as *froth.* Gas pressure drop provides the energy to create the froth.

A variant on the froth contact is the reverse jet contactor (see Example 14-23), which can be considered an upside-down distillation tray, operated above the flooding velocity in cocurrent flow of gas and liquid. It is limited to one stage.

An entirely different unstable contactor involves the thin expanding liquid film produced by a hollow-cone spray nozzle. Because of fresh surface and the thinness of the film, this can give very high transfer for liquid-limited systems. Two applications are direct contact condensation and the removal of volatile components from a high-boiling residual liquid.

**Surface Tension Makes Liquid Sheets and Liquid Columns Unstable** Surface tension is the energy required to make an increment of interfacial surface. A sheet or column of liquid has greater surface than a sphere, hence surface tension converts sheets and columns to droplets. See Fig. 14-81.

There are many different atomizers, but the underlying principle of all is the same—to first generate a flat sheet or a liquid column. Liquid sheets and columns are unstable; a small surface disturbance on either will propagate, and the liquid will reshape itself into droplets. The key property in controlling this process is surface tension. Surface tension gets a high exponent in all the atomization correlations.

**Little Droplets and Bubbles versus Big Droplets and Bubbles—Coalescence versus Breakup** When big drops are subjected to shear forces, as in falling rain, the droplets are distorted; and if the distortions are great enough, the big droplets break into little ones. This is why raindrops never exceed a certain size. A variant on this is breakup in highly turbulent systems such as that in high-velocity quench systems or pneumatic nozzles. Here the droplets are distorted by the energy of the turbulent eddies.

But little droplets and bubbles have greater surface per unit of liquid than big ones do. Hence little droplets tend to coalesce into big ones and will grow larger if given enough quiet time.

While the primary difficulty is estimating the interfacial area due to the unstable interface, a secondary problem is that freshly made, unstable surface gives higher transfer than older, more stable surface.

**Empirical Design Tempered by Operating Data** The net of these is that interfacial area is difficult to predict, and interfacial contactors are difficult to design. Prediction methods are given next, but they should always be tempered by operating experience.

## INTERFACIAL AREA—IMPACT OF DROPLET OR BUBBLE SIZE

Transfer is aided by increased interfacial area. Interfacial area per unit volume $a_D$ of a single droplet or bubble is inversely proportional to the diameter of the droplet or bubble $D$.

$$a_D = 6/D \tag{14-173a}$$

To estimate the total interfacial area in a given volume, the $a_D$ value is multiplied by the fractional holdup of dispersed phase in the total volume.

$$a = a_D(\Phi_D) \tag{14-173b}$$

where $a$ = interfacial area/volume and $\Phi_D$ = fraction of volume in dispersed phase = holdup.

Fractional holdup in a continuous process depends on the velocities of the two phases, as if they were flowing by themselves.

$$\Phi_D = \text{(dispersed phase volume)/(volume of dispersed and continuous phases)}$$

***Example 14-15 Interfacial Area for Droplets/Gas in Cocurrent Flow*** For equal mass flow of gas and liquid and with gas density 0.001 of liquid density, the gas velocity in cocurrent flow will be 1000 times the liquid velocity. This sets $\Phi_D$.

$$\Phi_D = 1/(1 + 1000) = 0.00099$$

If the droplets are 500 μm in diameter, Eqs. (14-173*a*) and (14-173*b*) give

$$a = (6/0.0005)(0.00099) = 12 \text{ m}^2/\text{m}^3$$

If the droplets are 100 μm in diameter, Eqs. (14-173*a*) and (14-173*b*) give

$$a = (6/0.0001)(0.00099) = 60 \text{ m}^2/\text{m}^3$$

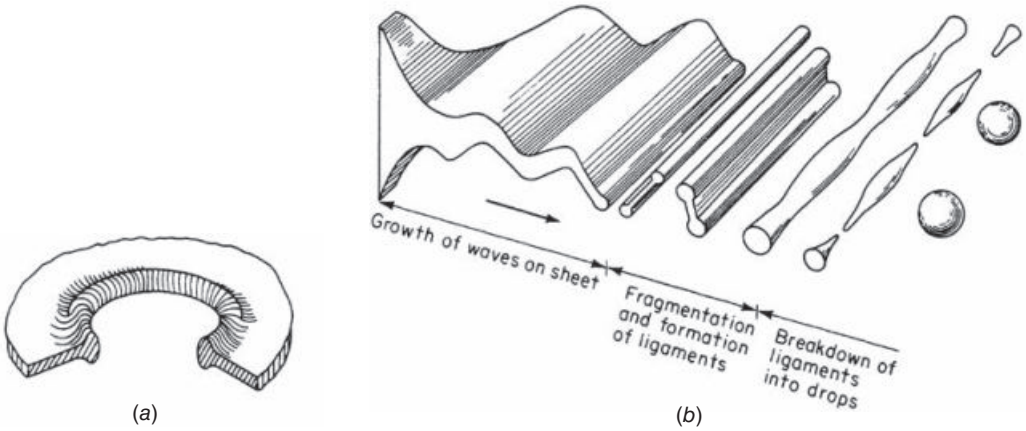

**FIG. 14-81** Sheet breakup. (*a*) By perforation. [*After Fraser et al.,* Am. Inst. Chem. Eng. J. ***8****(5): 672 (1962).*] (*b*) By sinusoidal wave growth. [*After Dombrowski and Johns,* Chem. Eng. Sci. ***18:*** *203 (1963).*]

***Example 14-16 Interfacial Area for Droplets Falling in a Vessel*** Droplet systems rarely exceed a $\Phi_D$ value of 0.01. At this low level, $\Phi_D$ in a low-velocity countercurrent contactor can be approximated by Eq. (14-174).

$$\Phi_D = U_L/(U_t - U_G) \tag{14-174}$$

where $U_L$ = liquid superficial velocity
$U_t$ = terminal velocity of droplet
$U_G$ = gas superficial velocity

With a gas superficial velocity of 1.5 m/s, for equal mass flow of gas and liquid, with gas density 0.001 of liquid density, and with 500-μm-diameter droplets falling at a vessel settling of 2.5 m/s, Eq. (14-174) gives a fractional holdup of liquid of

$$\Phi_D = (0.001)1.5/(2.5 - 1.5) = 0.0015$$

Equations (14-173*a*) and (14-173*b*) then give

$$a = (6/0.0005)(0.0015) = 18 \text{ m}^2/\text{m}^3$$

***Example 14-17 Interfacial Area for Bubbles Rising in a Vessel*** For bubble systems (gases dispersed in liquids), fractional holdup can approach 0.5, as shown by Fig. 14-82. However, before reaching this holdup, the bubble systems shift to an unstable mix of bubbles and vapor jets. Hence an exact comparison to Example 14-15 isn't possible because at the 1.5 m/s velocity of Example 14-15, the system becomes a froth. But at about one-fifth the velocity of Example 14-15, an estimate of interfacial area is possible.

If the bubble size is 10,000 μm and fractional holdup is 0.4, Eqs. (14-173*a*) and (14-173*b*) give an interfacial area of

$$a = (6/0.01)(0.4) = 240 \text{ m}^2/\text{m}^3$$

Measured interfacial area in distillation trays is consistent with this high value.

Note the much higher interfacial area than in the droplet systems of Examples 14-15 and 14-16. The higher interfacial area when the gas is dispersed explains why bubbling and froth systems often give better performance than droplet systems. The big difference in interfacial area stems from the much larger volume per unit of mass of gas, that is, the lower density of the gas than the liquid.

## RATE MEASURES, TRANSFER UNITS, APPROACH TO EQUILIBRIUM, AND BYPASSING

**What Controls Mass/Heat Transfer: Liquid or Gas Transfer or Bypassing** Either the gas side or the liquid side of the interface can be controlling.

**Liquid-Controlled** In fractionation systems with high viscosity or component relative volatility that greatly exceeds 1, the liquid side will be controlling. This is clearly illustrated by Fig. 14-47, which shows a sharp decline in efficiency with either a rise in liquid viscosity or a rise in *component relative volatility*.

Note that *high component relative volatility* means the same thing as *sparingly soluble*. Oxygen dissolving in a fermentation reactor is an example of a system being liquid controlled due to a *sparingly soluble gas*. Another application that is liquid controlled is the removal of *high relative volatility components* from residual oil.

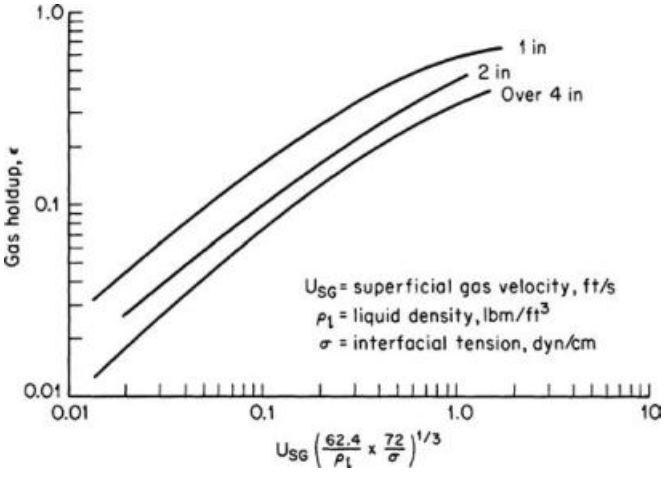

**FIG. 14-82** Gas holdup correlation. [Ind. Eng. Chem. Process Des. Dev. ***6:*** *218 (1967).*]

Still another case where liquid controls is in condensing a pure vapor, as in Example 14-24, or absorbing a pure gas, as in Example 14-25.

**Gas-Controlled** The gas side dominates in gas cooling applications. An example is the quenching of a furnace effluent with a vaporizing liquid. In this application, the liquid is nearly uniform in temperature. Restated, the reduction in driving force across the liquid side of the interface is unimportant.

Other applications that are gas-side-controlled include removal of a component such as $NH_3$ from a gas by using an acidic liquid, or removing a component such as $SO_2$ from a gas with a basic liquid. See Examples 14-20 through 14-23.

**Bypassing-Controlled** Trayed or packed columns operate with countercurrent flow and can achieve many equilibrium stages in series by good distribution of gas and liquid and careful control of details. Other devices such as sprays are vulnerable to bypassing and are limited to one equilibrium stage.

**Rate Measures for Interfacial Processes** The terminology used for reporting rate data can be confusing. Normally rate data are reported on a volumetric basis with transfer rate and effective area combined. For example, $k_La$ denotes mass-transfer data per unit volume. The subscript $L$ means it is referenced to the molar concentration difference between the interface and the bulk liquid. This is commonly used on data involving a sparingly soluble (high relative volatility) component. Note that the lowercase $k$ means the data deal only with the resistance in the liquid phase.

Less commonly, data are given as $k_Ga$. The subscript $G$ means it is referenced to the molar concentration difference between the interface and the gas. This might be used for data on absorbing a gas such as $NH_3$ by a highly acidic liquid. Note that $k_Ga$ only deals with the resistance in the gas phase.

When one is dealing with direct contact heat transfer, the corresponding terms are $h_La$ and $h_Ga$. Here the driving force is the temperature difference. The subscript $L$ means that we are dealing with a liquid-limited process such as condensing a pure liquid. How to convert $k_La$ data to an $h_La$ value is illustrated by Example 14-24.

There are ways to combine the liquid and gas resistance to get an overall transfer rate such as $K_Ga$ (as denoted by the uppercase $K$). However, data are rarely reported in this form.

**Approach to Equilibrium** Although rate measures such as $k_Ga$ and $h_Ga$ are often cited in the literature, they are often not as useful to designers as the simpler concept of approach to equilibrium. *Approach to equilibrium* compares the transfer between liquid and gas phases to the best possible that could be achieved in a single backmixed equilibrium stage.

Approach to equilibrium is easy to understand and easy to apply. Examples 14-18 through 14-23 illustrate its use.

***Example 14-18 Approach to Equilibrium—Perfectly Mixed, Complete Exchange*** This would be approximated by a very long pipeline contactor where an acidic aqueous stream is injected to cool the gas and remove $NH_3$.

If the adiabatic saturation temperature of the gas is 70°C, at the exit of the contactor, the gas would be cooled to 70°C.

Similarly, at the exit of the contactor, the $NH_3$ in the gas would be zero, regardless of the initial concentration.

***Example 14-19 Approach to Equilibrium—Complete Exchange but with 10 Percent Gas Bypassing*** A spray column is used, and an acidic liquid rains down on the gas of Example 14-18. If the initial $NH_3$ is 1000 ppm and 10 percent of the gas bypasses, the $NH_3$ in the exit gas would be

$$0.1(1000) = 100 \text{ ppm}$$

Similarly, if the gas enters at 120°C, at the exit we will find 10 percent of the differential above the adiabatic saturation temperature. For an adiabatic saturation temperature of 70°C, the exit gas temperature will be

$$70 + 0.1(120 - 70) = 75°\text{C}$$

**Approach to Equilibrium—Finite Contactor with No Bypassing** When there is no bypassing, the measure that sets the approach is the ratio of change to driving force. This ratio is called the *number of transfer units* $N_G$. It is dimensionless. For heat-transfer applications, it can be envisioned as a conventional heat exchanger where a vaporizing liquid cools a gas:

$$\text{No. of gas-phase transfer units} = \frac{T_{G,\text{out}} - T_{G,\text{in}}}{(T_G - T_L)_{\text{av}}} = N_G \tag{14-175}$$

where $T_G$ = gas temperature and $T_L$ = liquid temperature. The number of transfer units $N_G$ can also be calculated as the capability for change divided by the thermal capacitance of the flowing streams.

$$N_G = \frac{(\text{system volume})(h_G a)}{(\text{volumetric flow rate})\,\rho_G c_G} = \frac{(\text{gas contact time})(h_G a)}{\rho_G c_G} \tag{14-176}$$

where $a$ = interfacial area per unit volume
$h_G$ = heat-transfer coefficient from interface to gas
$\rho_G$ = gas density
$c_G$ = gas specific heat

Note that in this calculation, performance and properties all refer to the gas, which is appropriate when dealing with a gas-limited transfer process.

This leads to a way to estimate the approach to equilibrium.

$$E = 1 - e^{-N_G} \tag{14-177}$$

where $E$ = "approach to equilibrium" fractional removal of $NH_3$ or fractional approach to adiabatic liquid temperature
$N_G$ = number of transfer units calculated relative to gas flow

***Example 14-20 Finite Exchange, No Bypassing, Short Contactor*** A short cocurrent horizontal pipeline contactor gives 86 percent removal of $NH_3$. There is no bypassing because of the highly turbulent gas flow and injection of liquid into the center of the pipe. What would we expect the exit gas temperature to be?

Equation (14-177) says that the back-calculated $N_G$ is 2:

$$N_G = -\ln(1 - 0.86) = 2$$

For diffusing gases of similar molecular weight, the properties that control heat transfer follow the same rules as those that control mass transfer. As a result, the $NH_3$ scrubbing and gas cooling processes achieve similar approaches to equilibrium.

For an entry temperature of 120°C and an adiabatic saturation temperature of 70°C, the expected outlet temperature would be

$$70 + (1 - 0.86)(120 - 70) = 77°\text{C}$$

This looks like a powerful concept, but its value is limited due to uncertainty in estimating $h_G a$. Both $h_G$ and $a$ are difficult to estimate due to dependence on power dissipation, as discussed below. The primary value of the $N_G$ concept lies in estimating an expected change from baseline data as in the comparison of Example 14-20 with Example 14-21.

***Example 14-21 A Contactor That Is Twice as Long, No Bypassing*** If we double the length of the pipeline contactor, double the effective contact area, and double the number of transfer units to 4, what do we expect for performance?

For $N_G = 4$,

$$E = 1 - e^{-4} = 0.982$$

The $NH_3$ in the exit gas would be expected to drop to

$$(1 - 0.982)(1000) = 18 \text{ ppm}$$

and the expected outlet temperature would be

$$70 + (1 - 0.982)(120 - 70) = 70.9°\text{C}$$

If we double the length again, we increase the number of transfer units to 8 and achieve an approach of

$$E = 1 - e^{-8} = 0.9997$$

The outlet temperature would be

$$70 + (1 - 0.9997)(120 - 70) = 70.015°\text{C}$$

Similarly, the $NH_3$ in the exit gas would be

$$(1 - 0.9997)(1000) = 0.3 \text{ ppm}$$

Note that this approximates the exit condition of Example 14-18.

**Transfer Coefficient—Impact of Droplet Size** The transfer coefficients increase as the size of droplets decreases. This is so because the transfer process is easier if it only has to move mass or heat a shorter distance (i.e., as the bubble or droplet gets smaller).

In the limiting case of quiescent small bubbles or droplets, the transfer coefficients vary inversely with average bubble or droplet diameter. For example, in heat transfer from a droplet interface to a gas, the minimum value is

$$h_{G,\min} = \text{heat transfer coefficient from interface to gas} = 2k_G/D \tag{14-178}$$

where $k_G$ = gas thermal conductivity and $D$ = droplet diameter.

## IMPORTANCE OF TURBULENCE

The designer usually has control over the size of a droplet. As discussed next, several of the correlations show that droplet diameter varies with turbulent energy dissipation. For example, Eqs. (14-185) and (14-196) suggest that in droplet systems

$$D \propto \{1/(\text{gas velocity})\}^{1.2}$$

and hence from Eq. (14-173)

$$a \propto 1/D \propto (\text{gas velocity})^{1.2} \tag{14-179}$$

However, just looking at the impact of velocity on droplet size underestimates the velocity impact because turbulence gives higher transfer than Eq. (14-178) predicts. Transfer coefficients increase as the mixing adjacent to the surface increases. This mixing depends on the energy dissipated into the phases. To a first approximation this transfer from droplets increases with local power dissipation raised to the 0.2 power.

$$h_{G,\text{turbulent}} \propto (\text{power dissipated})^{0.2}$$

and since power dissipation per unit volume increases with velocity$^3$,

$$h_{G,\text{turbulent}} \propto (\text{velocity})^{0.6} \tag{14-180}$$

The combined effect on interfacial area and on the transfer coefficient is that the effective transfer increases greatly with gas velocity. From Eqs. (14-173) and (14-180)

$$h_G a_{\text{turbulent}} \propto (\text{velocity})^{1.8} \tag{14-181}$$

For quenching operations, this means that even though residence time is cut as gas velocity goes up, the effective approach to equilibrium increases. Since the volume for a given length of pipe falls with velocity$^{-1}$, the expected number of transfer units $N_G$ in a given length of pipe increases with velocity$^{0.8}$.

$$N_{G,\text{turbulent}} \propto (h_G a_{\text{turbulent}})(\text{volume}) \propto (\text{velocity})^{0.8} \tag{14-182}$$

See Example 14-22.

## EXAMPLES OF CONTACTORS

**High-Velocity Pipeline Contactors** High-velocity cocurrent flow can give greater power input than any other approach. This is critical when extremely high rates of reaction quenching are needed.

***Example 14-22 Doubling the Velocity in a Horizontal Pipeline Contactor—Impact on Effective Heat Transfer*** Velocity in pipeline quench systems often exceeds 62 m/s (200 ft/s). Note that this is far above the flooding velocity in distillation packing, distillation trays, or gas-sparged reactors. There are few data available to validate performance even though liquid injection into high-velocity gas streams has been historically used in quenching reactor effluent systems. However, the designer knows the directional impact of parameters as given by Eq. (14-182).

For example, if a 10-ft length of pipe gives a 90 percent approach to equilibrium in a quench operation, Eq. (14-177) says that the back-calculated $N_G$ is 2.303:

$$N_G - \ln(1 - 0.9) = 2.303$$

Equation (14-177) says if we double velocity but retain the same length, we expect an increase of $N_G$ to 4.0.

$$N_G = 2.303(2)^{0.8} = 4$$

and

$$E = 1 - e^{-4} = 0.982$$

Restated, the approach to equilibrium rises from 90 percent to greater than 98 percent even though the contact time is cut in half.

**Vertical Reverse Jet Contactor** A surprisingly effective modification of the liquid injection quench concept is to inject the liquid countercurrent *upward* into a gas flowing *downward*, with the gas velocity at some multiple of the flooding velocity defined by Eq. (14-198). The reverse jet contactor can be envisioned as an upside-down distillation tray. For large gas volumes, multiple injection nozzles are used. One advantage of this configuration is that it minimizes the chance of liquid or gas bypassing. Another advantage is that it operates in the froth region, which generates greater area per unit volume than the higher-velocity cocurrent pipeline quench.

The concept was first outlined in U.S. Patent 3,803,805 (1974) and was amplified in U.S. Patent 6,339,169 (2002). The 1974 patent presents data that clarify that the key power input is from the gas stream.

A more recent article discusses use of the reverse jet in refinery off-gas scrubbing for the removal of both $SO_2$ and small particles [*Hydrocarbon Processing* **84**(9): 99–106 (2005)]. This article cites downward gas velocities in the range of 10 to 37 m/s and notes gas pressure drop in the range of 6 to 20 in of water. Removals of $SO_2$ and fine particles were both close to 99 percent. The froth produced by the contactor reverses direction, flows down, and is largely disengaged in a vessel mounted below.

***Example 14-23 The Reverse Jet Contactor, U.S. Patent 6,339,169*** This patent deals with rapid cooling and removal of $NH_3$ from gas exiting an acrylonitrile reactor. Liquid is injected upward. The claims suggest downward-flowing gas velocity is between 20 and 25 m/s.

Gas cooling is reported to be largely complete in 0.1 s. $NH_3$ removal at the exit of the contactor is reported to be greater than 99 percent. The gas is cooled by water vaporizing from the injected liquid, with total water circulated being in the range of 100 times that evaporated.

Since the gas cooling and $NH_3$ scrubbing move in parallel, they would be expected to achieve nearly the same approach to equilibrium as long as the pH of all the liquid stays below a key threshold. The great excess of liquid enables this.

The key is high froth interfacial area per unit volume.

**Simple Spray Towers** The other extreme to the pipeline and reverse jet contactors is an open vessel where spray is injected down into upflowing gas to form a rain of liquid. The advantage of simple spray towers is that they give low gas pressure drop and also tend to be nonfouling.

Even though gas velocity is well below flooding velocity, the finer droplets of the spray will be entrained. Note the wide spectrum of particle sizes shown by Fig. 14-83.

However, as shown by Examples 14-24 and 14-25, they can be extremely effective in liquid-limited systems.

**Bypassing Limits Spray Tower Performance in Gas Cooling** As shown by Example 14-19, only modest performance is achieved in gas-limited systems. The modest efficiency is due to gas bypassing. Tall spray towers are not effective countercurrent devices. Even with nominally falling droplets, there is a great deal of backmixing because there is no stabilizing pressure drop as there would be in a column filled with packing or trays. A packet of droplets weighs more than a gas-filled space. The result is that the volume that is filled with the most droplets moves down relative to all other volumes. Similarly, the gas volume that has the fewest droplets moves up more quickly than other volumes. This generates bypassing of liquid and gas. The flows are driven by the rain of droplets themselves. Anything less than perfect distribution of liquid and gas will induce a dodging action between the flowing streams. Most designers limit expectations for spray contactors to some fraction of a single equilibrium stage regardless of height.

One approach that has been employed to get better distribution in spray systems is to mount a single large-capacity nozzle in the center of the vessel with radial discharge of large droplets. The droplets are discharged with enough velocity to penetrate to the vessel walls.

**Spray Towers in Liquid-Limited Systems—Hollow-Cone Atomizing Nozzles** If we follow an element of liquid leaving a hollow-cone hydraulic spray nozzle, the sequence is a rapidly thinning cone followed by wave development, followed by shedding of ligaments, followed by breakage of the ligaments into droplets. See Fig. 14-81. The sequence gives high transfer for liquid-limited systems. This results from the thin sheet of the hollow cone as well as the creation of fresh surface in the breakup process.

**Devolatilizers** Devolatilization systems are liquid-limited due to the combination of high liquid viscosity and removal of a component with high relative volatility. Simpson and Lynn [*AIChE J.* **23**(5): 666–673 (1977)] reported oxygen stripping from water at 98 percent complete, in less than 1 ft of contact. The concept has been employed for residual devolatilization in refineries.

**Spray Towers as Direct Contact Condensers** Similarly, spray contactors can be highly effective for direct contact condensers, which are also liquid-limited. The high transfer rate in the initial formation of sprays is key. Kunesh [*Ind. Engr. Chem. Res.* **32:** 2387–2389 (1993)] reported a 97 percent approach to equilibrium in a hydrocarbon system in the 6-in space below the discharge of a row of hollow-cone spray nozzles.

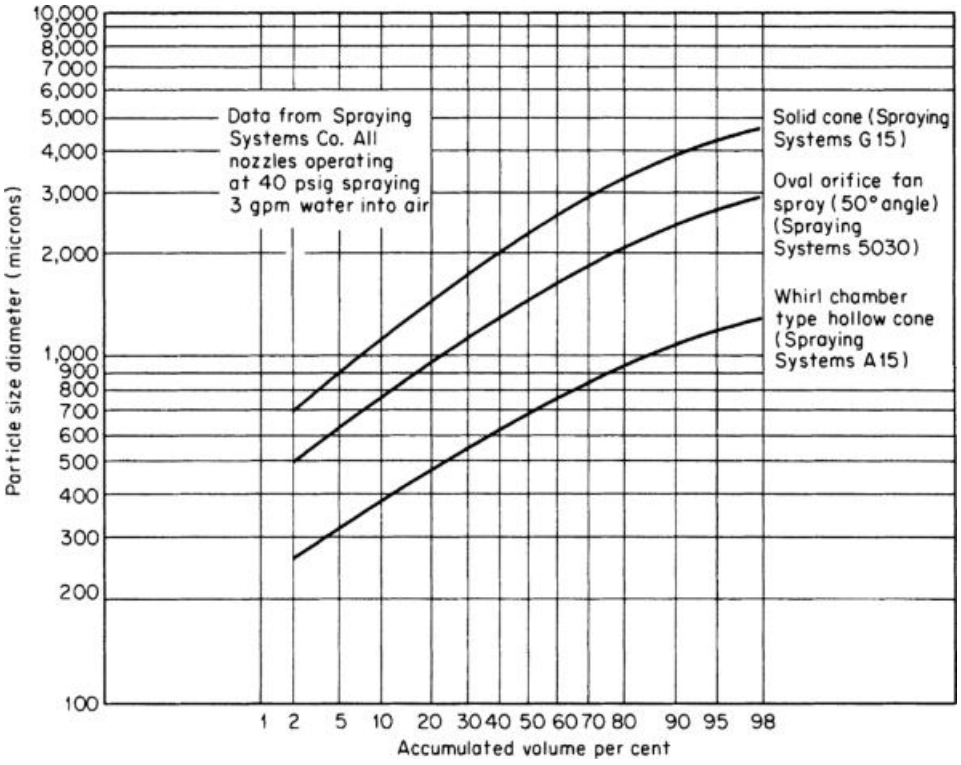

**FIG. 14-83** Droplet-size distribution for three different types of nozzles. To convert pounds per square inch gauge to kilopascals, multiply by 6.89; to convert gallons per minute to cubic meters per hour, multiply by 0.227. (*Spraying Systems Inc.*)

Other results on heat transfer in a large spray condenser are given by Waintraub et al. ("Removing Packings from Heat Transfer Sections of Vacuum Towers," AIChE 2005 Spring National Meeting, *Proceedings of Topical Conference*, Apr. 10, 2005, Atlanta, Ga., p. 79). The paper highlights the importance of good gas and liquid distribution.

**Converting Liquid Mass-Transfer Data to Direct Contact Heat Transfer** Liquid-limited performance measures are much more commonly given for mass transfer than for heat transfer. Often mass-transfer data are reported as $k_La$ with units of $h^{-1}$. This can be converted to $h_La$ with units of Btu/(h · °F · ft³) by Eq. (14-183).

$$h_La = 187(k_La)\,(c_L)\,(\rho_L)\,(\mu_L/T)^{0.5} \tag{14-183}$$

where $\mu_L$ = liquid, cP
$T$ = temperature, °R
$\rho_L$ = liquid density, lb/ft³
$c_L$ = liquid specific heat, Btu/(lb · °F)

The calculation of transfer units for heat transfer is relatively simple. For a liquid,

$$N_L = \frac{(\text{liquid contact time})(h_La)}{\rho_L c_L} \tag{14-184}$$

where $\rho_L$ = liquid density and $c_L$ = liquid specific heat. [See parallel gas expression, Eq. (14-176).]

Unlike gases, the liquid properties that control mass and heat transfer differ greatly. The key term is *diffusivity*, which for liquids drops with viscosity.

The resulting values for $h_La$ and $N_L$ can be surprisingly large when a pure vapor such as steam is condensed. See Example 14-24.

***Example 14-24 Estimating Direct Contact Condensing Performance Based on $k_La$ Mass-Transfer Data*** If an aqueous system at 560°R gives a $k_La$ of 60 $h^{-1}$, what does Eq. (14-183) predict for $h_La$ in a direct contact steam condenser?

For an aqueous system

$$\mu_L = 1 \text{ cP}$$
$$\rho_L = 62 \text{ lb/ft}^3$$
$$c_L = 1 \text{ Btu/(lb} \cdot \text{°F)}$$

and Eq. (14-183) predicts

$$h_La = 187(60)(1)(62)(1/560)^{0.5} = 29{,}400 \text{ Btu/(h} \cdot \text{°F} \cdot \text{ft}^3\text{)}$$

When a pure gas such as HCl is absorbed by low-viscosity liquid such as water, simple spray systems can also be highly effective. See Example 14-25.

***Example 14-25 HCl Vent Absorber*** (Kister, *Distillation Troubleshooting*, Wiley, New York, 2006, p. 95) A 6-in-diameter, 8-ft-tall packed bed was giving major problems due to failure of the packing support. Water was the scrubbing fluid.

The liquid distributors were replaced with carefully positioned spray nozzles, and the packing was removed. HCl in the vent was removed to a level one-fortieth of the original design.

## LIQUID-IN-GAS DISPERSIONS

**Liquid Breakup into Droplets** There are four basic mechanisms for breakup of liquid into droplets:

- Droplets in a field of high turbulence (i.e., high power dissipation per unit mass)
- Simple jets at low velocity
- Expanding sheets of liquid at relatively low velocity
- Droplets in a steady field of high relative velocity

These mechanisms coexist, and the one that gives the smallest drop size will control. The four mechanisms follow distinctly different velocity dependencies:

1. *Breakup in a highly turbulent field* (1/velocity)$^{1.2}$. This appears to be the dominant breakup process in distillation trays in the spray regime, pneumatic atomizers, and high-velocity pipeline contactors.
2. *Breakup of a low-velocity liquid jet* (1/velocity)$^0$. This governs in special applications such as prilling towers and is often an intermediate step in liquid breakup processes.
3. *Breakup of a sheet of liquid* (1/velocity)$^{0.67}$. This governs drop size in most hydraulic spray nozzles.
4. *Single-droplet breakup at very high velocity* (1/velocity)$^2$. This governs drop size in free fall as well as breakup when droplets impinge on solid surfaces.

**Droplet Breakup—High Turbulence** This is the dominant breakup mechanism for many process applications. Breakup results from local variations in turbulent pressure that distort the droplet shape. Hinze [*Am. Inst. Chem. Eng. J.* **1:** 289–295 (1953)] applied turbulence theory to obtain the form of Eq. (14-185) and took liquid–liquid data to define the coefficient:

$$D_{max} = 0.725(\sigma/\rho_G)^{0.6}/E^{0.4} \tag{14-185}$$

where $E$ = (power dissipated)/mass — length²/time³
$\sigma$ = surface tension — mass/time²
$\rho_G$ = gas density — mass/length³

Note that $D_{max}$ comes out with units of length. Since $E$ typically varies with (gas velocity)³, this results in drop size dependence with (1/velocity)$^{1.2}$.

The theoretical requirement for the use of Eq. (14-185) is that the microscale of turbulence << $D_{max}$. This is satisfied in most gas systems. For example, in three cases,

| | (microscale of turbulence)/$D_{max}$ |
|---|---|
| Distillation tray in spray regime | 0.007 |
| Pipeline @ 40 m/s and atmospheric pressure | 0.012 |
| Two-fluid atomizer using 100 m/s air | 0.03 |

Many applications involve a three-step process with high velocity first tearing wave crests away from liquid sheets, followed by the breakup of ligaments into large droplets, followed by the breakup of the large droplets. The prediction of final droplet size based on power/mass works surprisingly well, as shown by Eqs. (14-193), (14-196), (14-197), and (14-198).

**Liquid-Column Breakup** Because of increased pressure at points of reduced diameter, the liquid column is inherently unstable. As a result, it breaks into small drops with no external energy input. Ideally, it forms a series of uniform drops with the size of the drops set by the fastest-growing wave. This yields a dominant droplet diameter about 1.9 times the initial diameter of the jet, as shown by Fig. 14-84. As shown, the actual breakup is quite close to prediction, although smaller satellite drops are also formed.

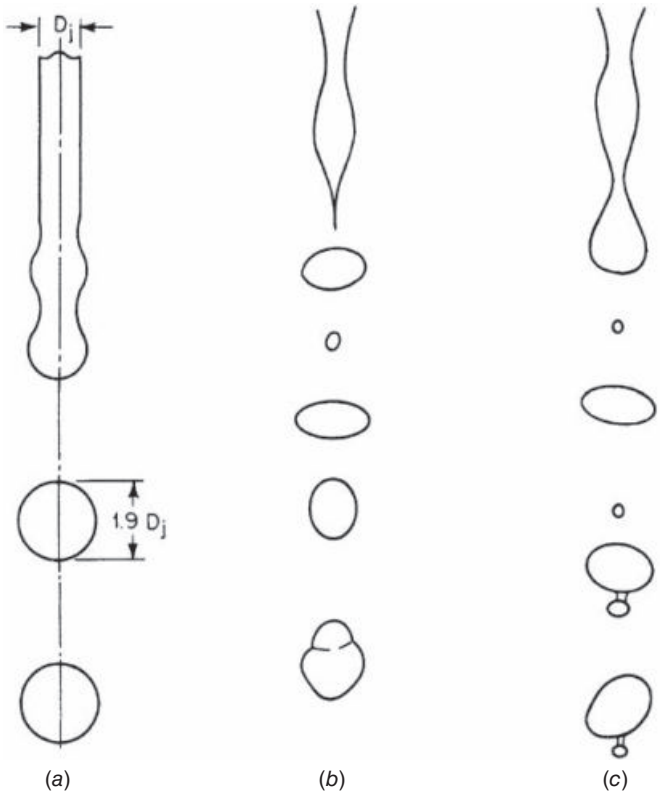

**FIG. 14-84** (*a*) Idealized jet breakup suggesting uniform drop diameter and no satellites. (*b*) and (*c*) Actual breakup of a water jet as shown by high-speed photographs. [*From W. R. Marshall,* "Atomization and Spray Drying," *Chem. Eng. Prog. Monogr. Ser., no. 2 (1954).*]

The prime advantage of this type of breakup is the greater uniformity of drop size.

For high-viscosity liquids, the drops are larger, as shown by Eq. (14-186):

$$D = 1.9 D_j \left[ 1 + \frac{3\mu_\ell}{(\sigma \rho_\ell D_j)^{1/2}} \right] \tag{14-186}$$

where $D$ = diameter of droplet
$D_j$ = diameter of jet
$\mu_\ell$ = viscosity of liquid
$\rho_\ell$ = density of liquid
$\sigma$ = surface tension of liquid

These units are dimensionally consistent; any set of consistent units can be used.

As the velocity of the jet is increased, the breakup process changes and ultimately becomes a mix of various competing effects, such as the capture of small drops by bigger ones in the slowing jet and the "turbulent breakup" of the bigger drops. The high-velocity jet is occasionally used in process applications because of the very narrow spray angle (5°–20°) and the high penetration into a gas it can give. The focused stream also aids erosion of a surface.

**Liquid-Sheet Breakup** The basic principle of most hydraulic atomizers is to form a thin sheet that breaks by a variety of mechanisms to form ligaments of liquid, which in turn yield chains of droplets. See Fig. 14-81.

For a typical nozzle, the drop size varies with 1/(pressure drop)$^{1/3}$. When (velocity)$^2$ is substituted for pressure drop, droplet size is seen to vary with (velocity)$^{-2/3}$.

**Isolated Droplet Breakup—in a Velocity Field** Much effort has focused on defining the conditions under which an isolated drop will break in a velocity field. The criterion for the largest stable drop size is the ratio of aerodynamic forces to surface-tension forces defined by the Weber number, $N_{We}$ (dimensionless):

$$N_{We\ crit} = \text{constant} = [\rho_G (\text{velocity})^2 (D_{max})/\sigma] \tag{14-187}$$

For low-viscosity fluids, $N_{We\ crit}$ commonly ranges from 10 to 20, with the larger value for a free-fall condition and the smaller for a sudden acceleration. High liquid viscosity also increases $N_{We\ crit}$.

Droplet breakup via impingement appears to follow a similar relationship, but many fewer data are available. This type of breakup can result from impingement on equipment walls or compressor blades. In general, there is less tendency to shatter on wetted surfaces.

**Droplet Size Distribution** Instead of the single droplet size implied by the preceding discussion, a spectrum of droplet sizes is produced. The most common ways to characterize this spectrum are as follows:

- *Volume median* (*mass median*) $D_{vm}$. This has no fundamental meaning but is easy to determine since it is at the midpoint of a cumulative-volume plot.
- *Sauter mean* $D_{32}$. This has the same ratio of surface to volume as the total drop population. It is typically 70 to 90 percent of $D_{vm}$. It is often used in transport processes and is used here to characterize drop size.
- *Maximum* $D_{max}$. This is the largest particle in the population. It is typically 3 to 4 times $D_{32}$ in turbulent breakup processes, per Walzel [*International Chemical Engineering* **33:** 46 (1993)]. It is the size directly calculated from the power/mass relationship. Thus $D_{32}$ is estimated from $D_{max}$ by

$$D_{32} = 0.3 D_{max} \tag{14-188}$$

and $D_{vm}$ is estimated from it by

$$D_{vm} = 0.4 D_{max} \tag{14-189}$$

However, any average drop size is fictitious, and none is completely satisfactory. For example, there is no way in which the high surface and transfer coefficients in small drops can be made available to the larger drops. Hence, a process calculation based on a given droplet size describes only what happens to that size and gives at best an approximation to the total mass.

There are a variety of ways to describe the droplet population. Figures 14-83 and 14-85 illustrate one of the most common methods, the plot of cumulative volume versus droplet size on log-normal graph paper. This satisfies the restraint of not extrapolating to a negative drop size. Its other advantages are that it is easy to plot, the results are easy to visualize, and it yields a nearly straight line at lower drop sizes.

Cumulative volume over the range of 1 to 50 percent can also be shown to vary approximately as $D^2$. This is equivalent to finding that the number

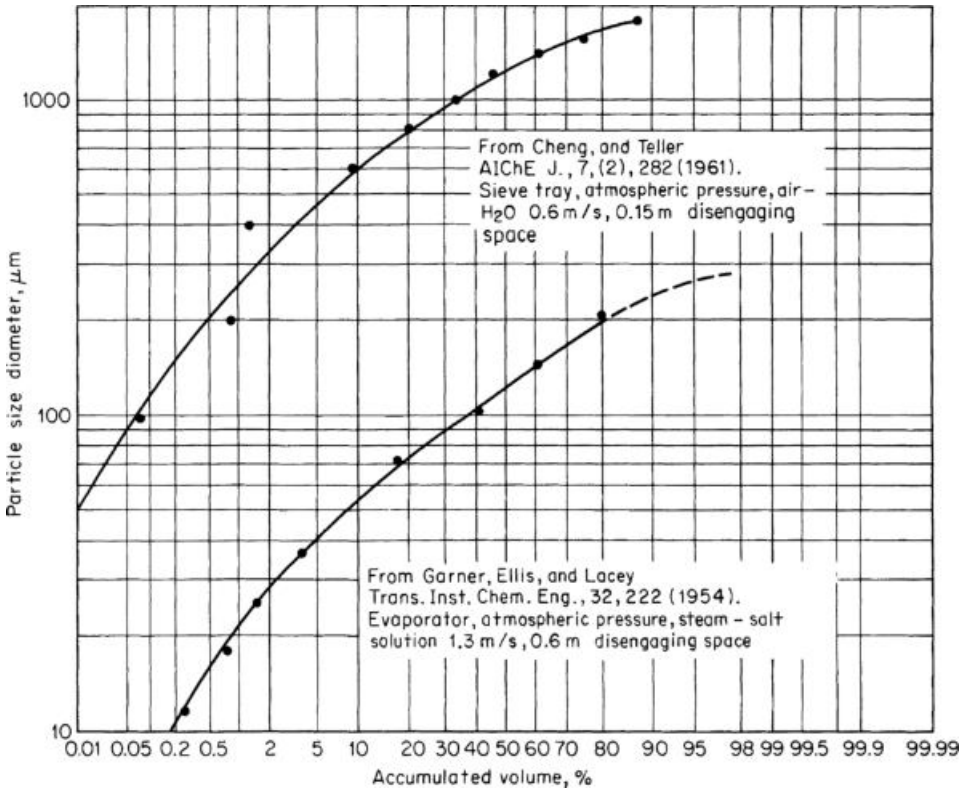

**FIG. 14-85** Entrainment droplet-size distribution. To convert meters per second to feet per second, multiply by 3.28; to convert meters to feet, multiply by 3.28.

of droplets of a given size is inversely proportional to the droplet area or the surface energy of the droplet.

**Atomizers** The common need to disperse a liquid into a gas has spawned a large variety of mechanical devices. The different designs emphasize different advantages, such as freedom from plugging, pattern of spray, small droplet size, uniformity of spray, high turndown ratio, and low power consumption.

As shown in Table 14-17, most atomizers fall into three categories:

1. Pressure nozzles (hydraulic)
2. Two-fluid nozzles (pneumatic)
3. Rotary devices (spinning cups, disks, or vaned wheels)

These share certain features, such as relatively low efficiency and low cost relative to most process equipment. The energy required to produce the increase in area is typically less than 0.1 percent of the total energy consumption. This is so because atomization is a secondary process resulting from high interfacial shear or turbulence. As droplet sizes decrease, this efficiency decreases.

Other types are available that use sonic energy ( from gas streams), ultrasonic energy (electronic), and electrostatic energy, but they are less commonly used in process industries. See Table 14-17 for a summary of the advantages and disadvantages of the different types of units. An expanded discussion is given by Lipp (*Practical Spray Technology*, Lake Innovation LLC, Lake Junaluska, N.C., 2012). Special requirements such as size uniformity in prilling towers can dictate still other approaches to dispersion. Here plates are drilled with many holes to develop nearly uniform columns.

Commonly, the most important feature of a nozzle is the size of droplet it produces. Since the heat or mass transfer that a given dispersion can produce is often proportional to $(1/D_d)^2$, fine drops are usually favored. At the other extreme, drops that are too fine will not settle, and a concern is the amount of liquid that will be entrained from a given spray operation. For example, if sprays are used to contact atmospheric air flowing at 1.5 m/s, then drops smaller than 350 mm [terminal velocity = 1.5 m/s (4.92 ft/s)] will be entrained. Even for the relative coarse spray of the hollow-cone nozzle shown in Fig. 14-83, 7.5 percent of the total liquid mass will be entrained.

**Hydraulic (Pressure) Nozzles** Manufacturers' data such as those shown by Fig. 14-83 are available for most nozzles for the air-water system. In Fig. 14-83, note the much coarser solid-cone spray. The coarseness results from the less uniform discharge.

**Effect of Physical Properties on Drop Size** Because of the extreme variety of available geometries, no attempt to encompass this variable is made here. The suggested predictive route starts with air-water droplet size data from the manufacturer at the chosen flow rate. This drop size is then corrected by Eq. (14-190) for different viscosity and surface tension:

$$\frac{D_{vm,\,\text{system}}}{D_{vm,\,\text{water}}} = \left(\frac{\sigma_{\text{system}}}{73}\right)^{0.25} \left(\frac{\mu_\ell}{1.0}\right)^{0.25} \tag{14-190}$$

where $D_{vm}$ = volume median droplet diameter
$\sigma$ = surface tension, mN/m (dyn/cm)
$\mu_\ell$ = liquid viscosity, mPa · s (cP)

The exponential dependencies in Eq. (14-190) represent averages of values reported by a number of studies, with particular weight given to Lefebvre

**TABLE 14-17 Atomizer Summary**

| Types of atomizer | Design features | Advantages | Disadvantages |
|---|---|---|---|
| Pressure. | Flow $\alpha(\Delta P/\rho_\ell)^{1/2}$. Only source of energy is from fluid being atomized. | Simplicity and low cost. | Limited tolerance for solids; uncertain spray with high-viscosity liquids; susceptible to erosion. Need for special designs (e.g., bypass) to achieve turndown. |
| 1. Hollow cone. | Liquid leaves as conical sheet as a result of centrifugal motion of liquid. Air core extends into nozzle. | High atomization efficiency. | Concentrated spray pattern at cone boundaries. |
| *a.* Whirl chamber (see Fig. 14-86*a*). | Centrifugal motion developed by tangential inlet in chamber upstream of orifice. | Minimum opportunity for plugging. | |
| b. Grooved core. | Centrifugal motion developed by inserts in chamber. | Smaller spray angle than 1*a* and ability to handle flows smaller than 1*a*. | |
| 2. Solid cone (see Fig. 14-86*b*). | Similar to hollow cone but with insert to provide even distribution. | More uniform spatial pattern than hollow cone. | Coarser drops for comparable flows and pressure drops. Failure to yield same pattern with different fluids. |
| 3. Fan ( flat) spray. | Liquid leaves as a flat sheet or flattened ellipse. | Flat pattern is useful for coating surfaces and for injection into streams. | Small clearances. |
| *a.* Oval or rectangular orifice (see Fig. 14-86*c*). Numerous variants on cavity and groove exist. | Combination of cavity and orifice produces two streams that impinge within the nozzle. | | |
| *b.* Deflector (see Fig. 14-86*d*). | Liquid from plain circular orifice impinges on curved deflector. | Minimal plugging. | Coarser drops. |
| *c.* Impinging jets (see Fig. 14-86*e*). | Two jets collide outside nozzle and produce a sheet perpendicular to their plane. | Different liquids are isolated until they mix outside of orifice. Can produce a flat circular sheet when jets impinge at 180°. | Extreme care needed to align jets. |
| 4. Nozzles with wider range of turndown. | | | |
| *a.* Spill (bypass) (see Fig. 14-86*f*). | A portion of the liquid is recirculated after going through the swirl chamber. | Achieves uniform hollow cone atomization pattern with very high turndown (50:1). | Waste of energy in bypass stream. Added piping for spill flow. |
| *b.* Poppet (see Fig. 14-86*g*). | Conical sheet is developed by flow between orifice and poppet. Increased pressure causes poppet to move out and increase flow area. | Simplest control over broad range. | Difficult to maintain proper clearances. |
| Two-fluid (see Fig. 14-86*h*). | Gas impinges coaxially and supplies energy for breakup. | High velocities can be achieved at lower pressures because the gas is the high-velocity stream. Liquid-flow passages can be large, and hence plugging can be minimized. | Because gas is also accelerated, efficiency is inherently lower than pressure nozzles. |
| Sonic. | Gas generates an intense sound field into which liquid is directed. | Similar to two-fluid but with greater tolerance for solids. | Similar to two-fluid. |
| Rotary wheels (see Fig. 14-86*i*) disks, and cups. | Liquid is fed to a rotating surface and spreads in a uniform film. Flat disks, disks with vanes, and bowl-shaped cups are used. Liquid is thrown out at 90° to the axis. | The velocity that determines drop size is independent of flow. Hence these can handle a wide range of rates. They can also tolerate very viscous materials as well as slurries. Can achieve very high capacity in a single unit; does not require a high-pressure pump. | Mechanical complexity of rotating equipment. Radial discharge. |
| Ultrasound. | Liquid is fed over a surface vibrating at a frequency > 20 kHz. | Fine atomization, small size, and low injection velocity. | Low flow rate and need for ultrasound generator. |

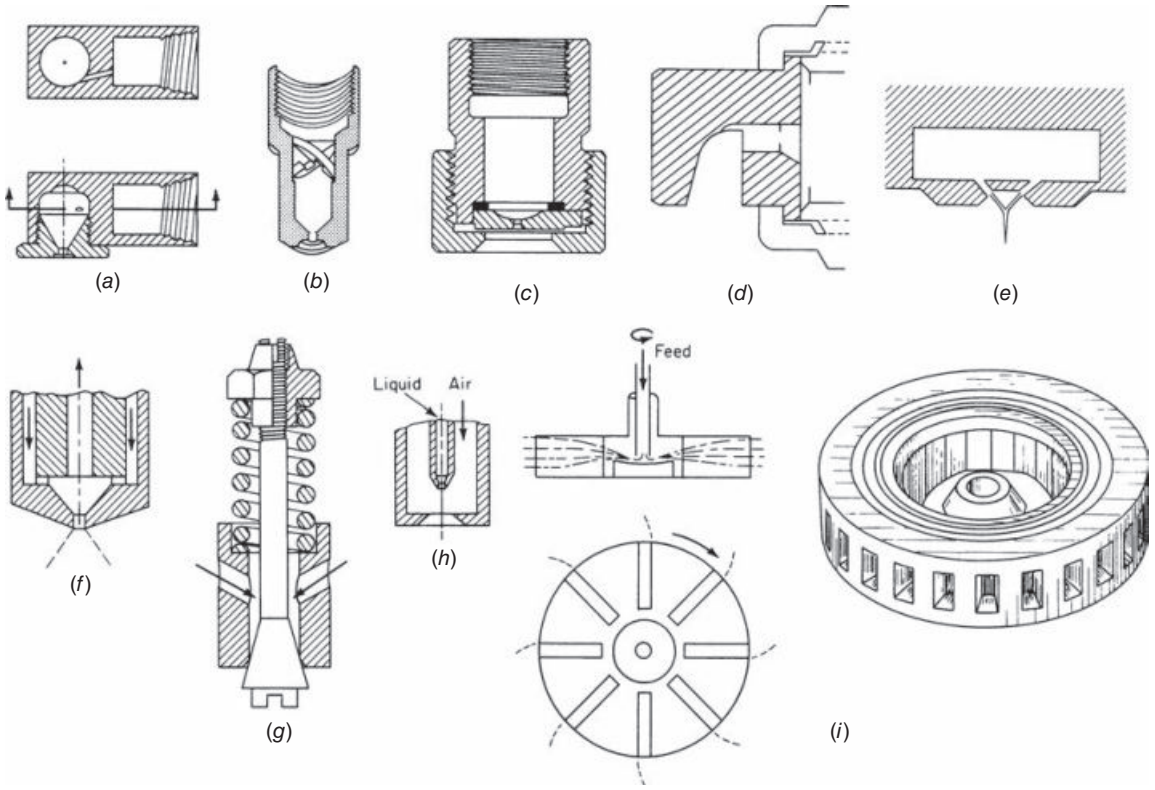

**FIG. 14-86** Characteristic spray nozzles. (*a*) Whirl-chamber hollow cone. (*b*) Solid cone. (*c*) Oval-orifice fan. (*d*) Deflector jet. (*e*) Impinging jet. (*f*) Bypass. (*g*) Poppet. (*h*) Two-fluid. (*i*) Vaned rotating wheel.

(*Atomization and Sprays,* Hemisphere, New York, 1989). Since viscosity can vary over a much broader range than surface tension can, viscosity has much greater leverage over drop size. For example, it is common to find an oil with 1000 times the viscosity of water, while most liquids fall within a factor of 3 of their surface tension. Liquid density is generally even closer to that of water, and since the data are not clear that a liquid density correction is needed, none is shown in Eq. (14-190). Vapor density also has an impact on drop size, but the impact is complex, involving conflicts of a number of effects, and vapor density is commonly omitted in atomizer drop size correlations.

**Effect of Pressure Drop and Nozzle Size** For a nozzle with a developed pattern, the average drop size can be estimated to fall with rising $\Delta P$ (pressure drop) by Eq. (14-191):

$$\frac{D_1}{D_2}=\left(\frac{\Delta P_2}{\Delta P_1}\right)^{1/3} \tag{14-191}$$

For similar nozzles and constant $\Delta P$, the drop size will increase with nozzle size as indicated by Eq. (14-192):

$$\frac{D_1}{D_2}=\left(\frac{\text{orifice diameter}_1}{\text{orifice diameter}_2}\right)^{1/2} \tag{14-192}$$

Once again, these relationships are averages of a number of reported values and are intended as rough guides.

The normal operating regime is well below the turbulent breakup velocity. However, the data of Kennedy [*J. of Engineering for Gas Turbines and Power* **108:** 191 (1986)] at very high pressure drop in large nozzles shows a shift to a higher dependence on pressure drop. These data suggest that turbulent droplet breakup can also be governing with hydraulic spray nozzles, although this is unusual.

**Spray Angle** A shift to a smaller-angle nozzle gives slightly larger drops for a given type of nozzle because of the reduced tendency of the sheet to thin. Dietrich [*Proc. 1st Int. Conf. Liq. Atomization Spray Systems,* Tokyo, 1978] shows the following:

| Angle | 25° | 50° | 65° | 80° | 95° |
|---|---|---|---|---|---|
| $D_{vm}$, μm | 1459 | 1226 | 988 | 808 | 771 |

In calculating the impact point of spray, one should recognize that the spray angle closes in as the spray moves away from the nozzle. This is caused by a loss of momentum of the spray to the gas.

At some low flow, pressure nozzles do not develop their normal pattern but tend to approach solid streams. The required flow to achieve the normal pattern increases with viscosity.

**Two-Fluid (Pneumatic) Atomizers** This general category includes such diverse applications as venturi atomizers and reactor-effluent quench systems, in addition to two-fluid spray nozzles. Depending on the manner in which the two fluids meet, several of the breakup mechanisms may be applicable, but the final one is high-level turbulent rupture.

As shown by Table 14-18, empirical correlations for two-fluid atomization show a dependence on high gas velocity to supply atomizing energy, usually to a power dependence close to that for turbulent breakup. In addition, the correlations show a dependence on the ratio of gas to liquid and system dimension.

Further differences from hydraulic nozzles (controlled by sheet and ligament breakup) are the stronger increase in drop size with increasing surface tension and decreasing gas density.

**TABLE 14-18 Exponential Dependence of Drop Size on Different Parameters in Two-Fluid Atomization**

| | Relative velocity | Surface tension | Gas density | $1+L/G$ | Atomizer dimension |
|---|---|---|---|---|---|
| Jasuja (empirical for small nozzle) | −0.9 | 0.45 | −0.45 | 0.5 | 0.55 |
| El-Shanawany and Lefebvre (empirical for small nozzle) | −1.2 | 0.6 | −0.7 | 1 | 0.40 |
| Tatterson, Dallman, and Hanratty (pipe flow) | −1 | 0.5 | −0.5 | | 0.5 |
| Power/mass | −1.2 | 0.6 | −0.6 | 0.4 | 0.4 |

The similarity of these dependencies to Eq. (14-185) led to a reformulation with two added terms that arise naturally from the theory of power dissipation per unit mass. The result is Eq. (14-193), which is labeled power/mass in Table 14-18.

$$D_{32} = 0.29\left(\frac{\sigma}{\rho_G}\right)^{0.6} (1/\text{velocity})^{1.2}\left(1+\frac{L}{G}\right)^{0.4} (D_{\text{nozzle}})^{0.4} \qquad (14\text{-}193)$$

where $\sigma$ = surface tension
$\rho_G$ = gas density
$L/G$ = mass ratio of liquid flow to gas flow
$D_{\text{nozzle}}$ = diameter of the air discharge

This is remarkably similar to the empirical two-fluid atomizer relationships of El-Shanawany and Lefebvre [*J. Energy* **4:** 184 (1980)] and Jasuja [*Trans. Am. Soc. Mech. Engr.* **103:** 514 (1981)]. For example, El-Shanawany and Lefebvre give a relationship for a prefilming atomizer:

$$D_{32} = 0.0711(\sigma/\rho_G)^{0.6}(1/\text{velocity})^{1.2}(1+L/G)(D_{\text{nozzle}})^{0.4}(\rho_L/\rho_G)^{0.1} + 0.015[(\mu_L)^2/(\sigma\times\rho_L)]^{0.5}(D_{\text{nozzle}})^{0.5}(1+L/G) \qquad (14\text{-}194)$$

where $\mu_L$ is liquid viscosity.

According to Jasuja,

$$D_{32} = 0.17(\sigma/\rho_G)^{0.45}(1/\text{velocity})^{0.9}(1+L/G)^{0.5}(D_{\text{nozzle}})^{0.55} + \text{viscosity term} \qquad (14\text{-}195)$$

[Equations (14-193), (14-194), and (14-195) are dimensionally consistent; any set of consistent units on the right-hand side yields the droplet size in units of length on the left-hand side.]

The second, additive term carrying the viscosity impact in Eq. (14-194) is small at viscosities around 1 cP but can become controlling as viscosity increases. For example, for air at atmospheric pressure atomizing water, with nozzle conditions

$$D_{\text{nozzle}} = 0.076 \text{ m (3 in)}$$
$$\text{Velocity} = 100 \text{ m/s (328 ft/s)}$$
$$L/G = 1$$

El-Shanaway measured 70 μm, and his Eq. (14-194) predicted 76 μm. The power/mass correlation [Eq. (14-193)] predicts 102 μm. The agreement between both correlations and the measurement is much better than is normally achieved.

**Rotary Atomizers** For rotating wheels, vaneless disks, and cups, there are three regimes of operation. At low rates, the liquid is shed directly as drops from the rim. At intermediate rates, the liquid leaves the rim as threads, and at the highest rate, the liquid extends from the edge as a thin sheet that breaks down in a manner similar to a fan or hollow-cone spray nozzle. As noted in Table 14-17, rotary devices have many unique advantages, such as the ability to handle high viscosity and slurries and to produce small droplets without high pressures. The prime applications are in spray drying. See Masters (*Spray Drying Handbook,* Wiley, New York, 1991) for more details.

**Pipeline Contactors** The correlation for droplet diameter based on power/mass is similar to that for two-fluid nozzles. The dimensionless correlation is

$$D_{32} = 0.8(\sigma/\rho_G)^{0.6}(1/\text{velocity})^{1.2}(D_{\text{pipe}})^{0.4} \qquad (14\text{-}196)$$

(The relation is dimensionally consistent; any set of consistent units on the right-hand side yields the droplet size in units of length on the left-hand side.)

The relationship is similar to the empirical correlation of Tatterson, Dallman, and Hanratty [*Am. Inst. Chem. Eng. J.* **23**(1): 68 (1977)]

$$D_{32} \sim \left(\frac{\sigma}{\rho_G}\right)^{0.5} (1/\text{velocity})^1 (D_{\text{pipe}})^{0.5}$$

Predictions from Eq. (14-196) align well with the Tatterson data. For example, for a velocity of 43 m/s (140 ft/s) in a 0.05-m (1.8-in) equivalent diameter channel, Eq. (14-196) predicts $D_{32}$ of 490 μm, compared to the measured 460 to 480 μm.

**Entrainment Due to Gas Bubbling/Jetting Through a Liquid** Entrainment generally limits the capacity of distillation trays and is commonly a concern in vaporizers and evaporators. Fortunately, it is readily controllable by simple inertial entrainment capture devices such as wire-mesh pads in gravity separators.

In distillation towers, entrainment lowers the tray efficiency, and 1 lb of entrainment per 10 lb of liquid is sometimes taken as the limit for acceptable performance. However, the impact of entrainment on distillation efficiency depends on the relative volatility of the component being considered. Entrainment has a minor impact on close separations when the difference between vapor and liquid concentrations is small, but this factor can be dominant for systems where the liquid concentration is much higher than the vapor in equilibrium with it (i.e., when a component of the liquid has a very low volatility, as in an absorber).

As shown by Fig. 14-85, entrainment droplet sizes span a broad range. The reason for the much larger drop sizes of the upper curve is the short disengaging space. For this curve, over 99 percent of the entrainment has a terminal velocity greater than the vapor velocity. For contrast, in the lower curve the terminal velocity of the largest particle reported is the same as the vapor velocity. For the settling velocity to limit the maximum drop size entrained, at least 0.8 m (30 in) of disengaging space is usually required. Note that even for the lower curve, less than 10 percent of the entrainment is in drops of less than 50 μm. The coarseness results from the relatively low power dissipation per mass on distillation trays. This means that it is relatively easy to remove by a device such as a wire-mesh pad. Over 50 percent is typically captured by the underside of the next-higher tray or by a turn in the piping leaving an evaporator. Conversely, though small on a mass basis, the smaller drops are extremely numerous. On a number basis, more than one-half of the drops in the lower curve are under 5 μm. These can serve as nuclei for fog condensation in downstream equipment.

Entrainment $E$ is inherent in the bubbling process and can stem from a variety of sources, as shown by Fig. 14-87. However, the biggest practical problem is entrainment generated by the kinetic energy of the flowing vapor rather than the bubbling process. As the vapor velocity approaches the flooding limit [Eq. (14-197)], the entrainment rises approximately with $(\text{velocity})^8$.

Pinczewski and Fell [*Trans. Inst. Chem Eng.* **55:** 46 (1977)] show that the velocity at which vapor jets onto the tray sets the droplet size, rather than the superficial tray velocity. The power/mass correlation predicts an average drop size close to that measured by Pinczewski and Fell. Combination of this prediction with the estimated fraction of the droplets entrained gave a relationship for entrainment, Eq. (14-197). The dependence of entrainment with the eighth power of velocity even approximates the observed velocity dependence, as flooding is approached.

$$E = \frac{\text{constant}\,(\text{velocity})^8(\rho_G)^4}{(A_f)^3(\rho_L-\rho_G)^{2.5}\sigma^{1.5}} \qquad (14\text{-}197)$$

(Here $E$ is the mass of entrainment per mass of vapor and $A_f$ is the fractional open area on the tray.)

When flooding is defined as the condition that gives $E$ of 1, the flood velocity is estimated by Eq. (14-198).

$$U_{\text{flood}} = \frac{1.25\,(A_f)^{3/8}[g(\rho_L-\rho_G)]^{0.3125}\sigma^{0.1875}}{\rho_G^{0.5}} \qquad (14\text{-}198)$$

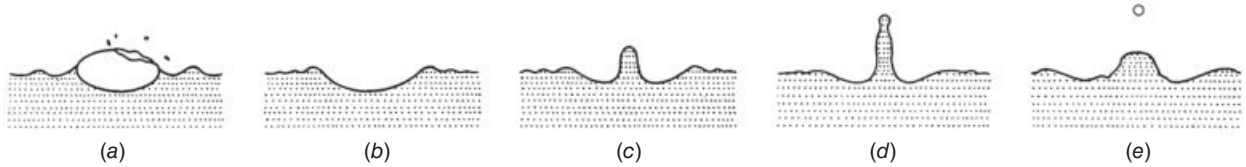

**FIG. 14-87** Mechanism of the burst of an air bubble on the surface of water. [*Newitt, Dombrowski, and Knellman,* Trans. Inst. Chem. Eng. ***32:*** *244 (1954).*]

The relationship is dimensionally consistent; any set of consistent units on the right-hand side yields velocity units on the left-hand side. It is similar in form to Eq. (14-168) and provides a conceptual framework for understanding the ultimate distillation column capacity concept.

**"Upper Limit" Flooding in Vertical Tubes** If, instead of a gas jet being injected into a liquid as in distillation, the liquid runs down the walls and the gas moves up the center of the tube, then higher velocities can be achieved than those shown by Eq. (14-198). This application is important in the design of vertical condensers.

Maharudrayya and Jayanti [*AIChE J.* **48**(2): 212–220 (2002)] show that peak pressure drop in a 25-mm vertical tube occurs at a value close to that predicted by Eq. (14-198). At this velocity, about 20 percent of the injected liquid is being entrained out of the top of the tube. However, the condition where essentially all liquid was entrained didn't occur until a velocity more than twice the value estimated from Eq. (14-198).

The higher velocities at modest entrainment observed by Maharudrayya and Jayanti were obtained with special smooth entry of gas (and exit of liquid) at the bottom of the tube. Hewitt (*Handbook of Heat Exchanger Design,* Begell House, 1992, pp. 2.3.2–2.3.23) suggests that these values should be derated by at least 35 percent for more typical sharp heat exchanger tube entry. Similar to the smooth entry effect, other data suggest that countercurrent capacity can be increased by providing an extension of the tube below the tube sheet, with the bottom of the extension cut on a steep angle (>60°) to the horizontal. The tapered extension facilitates the drainage of liquid.

An extensive data bank correlated by Diehl and Koppany [*Chem. Eng. Prog. Symp. Ser.* **65:** 77–83 (1965)] also gave higher allowable entry velocities than Eq. (14-198). Diehl and Koppany's correlation [Eq. (14-199)] is dimensional and appears to give a much higher dependence on σ than the more recent work. However, for many fluids, $\sigma^{0.5}$ is essentially the same as the combination $\sigma^{0.1875}(\rho_L - \rho_g)^{0.3125}$ that appears in Eq. (14-198). Hence Eq. (14-199) gives a similar physical property dependence.

$$U_f = F_1 F_2 (\sigma/\rho_g)^{0.5} \tag{14-199}$$

where $U_f$ = flooding gas velocity, m/s
$F_1 = 1.22$ when $3.2d_i/\sigma > 1.0$
$= 1.22\,(3.2\,d_i/\sigma)^{0.4}$ when $3.2d_i/\sigma < 1.0$
$F_2 = (G/L)^{0.25}$
$G/L$ = gas–liquid mass ratio
$d_i$ = inside diameter of column, mm
σ = surface tension, mN/m (dyn/cm)
$\rho_g$ = gas density, kg/m$^3$

The primary reason for citing Eq. (14-199) is the large successful experience base in practical applications. Note that the reduction in allowable gas velocity for small diameters given by the $F_1$ factor is conceptually the same as the effect of using smaller-diameter packing in distillation. Note also that over the range of $G/L$ between 1 and 0.1, the Maharudrayya and Jayanti data show a similar reduction in allowable gas rate to the $F_2$ factor in Eq. (14-199). The phenomenon behind this is that a thicker liquid film on the tube wall is more easily entrained.

While the limiting phenomenon of upper-limit flooding in a vertical pipe is similar to *ultimate capacity* in distillation, there is a distinct difference. *Upper limit* in a vertical pipe applies to a design where a conscious effort should be made to minimize gas–liquid contact. Carried to extremes, it would involve separate tubes for liquid flowing down and vapor going up. In contrast, *ultimate capacity* in a distillation column corresponds to the condition where effective mass transfer disappears due to high entrainment. One could force more vapor up through the contactor, but fractionation would be poor.

**Fog Condensation—The Other Way to Make Little Droplets** For a variety of reasons, a gas or vapor can become supersaturated with a condensible component. Surface tension and mass transfer impose barriers on immediate condensation, so the growth of fog particles lags behind what equilibrium predicts. Droplets formed by fog condensation are usually much finer (0.1 to 10 μm) than those formed by mechanical breakup and hence more difficult to collect. Sometimes fog can be a serious problem, as in the atmospheric discharge of a valuable or a hazardous material. More commonly, fog is a curiosity rather than a dominating element in chemical processing.

Fog particles grow because of excess saturation in the gas. Usually this means that the gas is supersaturated (i.e., it is below its dew point). Sometimes, fog can also grow on soluble foreign nuclei at partial pressures below saturation. Increased saturation can occur through a variety of routes:

1. Mixing of two saturated streams at different temperatures. This is commonly seen in the plume from a stack. Since vapor pressure is an exponential function of temperature, the resultant mixture of two saturated streams will be supersaturated at the mixed temperature. Uneven flow patterns and cooling in heat exchangers make this route to supersaturation difficult to prevent.
2. Increased partial pressure due to reaction. An example is the reaction of $SO_3$ and $H_2O$ to yield $H_2SO_4$, which has much lower vapor pressure than its components.
3. Isentropic expansion (cooling) of a gas, as in a steam nozzle.
4. Cooling of a gas containing a condensible vapor. Here the problem is that the gas cools faster than condensible vapor can be removed by mass transfer.

These mechanisms can be observed in many common situations. For example, fog via mixing can be seen in the discharge of breath on a cold day. Fog via adiabatic expansion can be seen in the low-pressure area over the wing of an airplane landing on a humid summer day. Fog via condensation can be seen in the exhaust from an automobile air conditioner (if you follow closely enough behind another car to pick up the ions or NO molecules needed for nucleation). All these occur at a very low supersaturation and appear to be keyed to an abundance of foreign nuclei. All these fogs also quickly dissipate as heat or unsaturated gas is added.

The supersaturation in condensers arises for two reasons. First, the condensible vapor is generally of higher molecular weight than the noncondensible gas. This means that the molecular diffusivity of the vapor will be much less than the thermal diffusivity of the gas. Restated, the ratio of $N_{Sc}/N_{Pr}$ is greater than 1. The result is that a condenser yields more heat-transfer units $dT_g/(T_g - T_i)$ than mass-transfer units $dY_g/(Y_g - Y_i)$. Second, both transfer processes derive their driving force from the temperature difference between the gas $T_g$ and the interface $T_i$. Each incremental decrease in interface temperature yields the same relative increase in temperature driving force. However, the interface vapor pressure can only approach the limit of 0. Because of this, for equal molecular and thermal diffusivities, a saturated mixture will supersaturate when cooled. The tendency to supersaturate generally increases with increased molecular weight of the condensible, increased temperature differences, and reduced initial superheating. To evaluate whether a given condensing step yields fog requires rigorous treatment of the coupled heat-transfer and mass-transfer processes through the entire condensation. Steinmeyer [*Chem. Eng. Prog.* **68**(7): 64 (1972)] illustrates this, showing the impact of foreign-nuclei concentration on calculated fog formation. See Table 14-19. Note the relatively large particles generated for cases 1 and 2 for 10,000 foreign nuclei per cubic centimeter. These are large enough to be fairly easily collected. There have been very few documented problems with industrial condensers despite the fact that most calculate to generate supersaturation along the condensing path. The explanation appears to be a limited supply of foreign nuclei.

Ryan et al. [*Chem. Eng. Progr.* **90**(8): 83 (1994)] show that separate mass- and heat-transfer rate modeling of an HCl absorber predicts 2 percent fog in the vapor. The impact is equivalent to lowering the stage efficiency to 20 percent.

**Spontaneous (Homogeneous) Nucleation** This process is quite difficult because of the energy barrier associated with creation of the interfacial area. It can be treated as a kinetic process with the rate a very steep function of the supersaturation ratio ($S$ = partial pressure of condensible per vapor pressure at gas temperature). For water, an increase in $S$ from 3.4 to

**TABLE 14-19 Simulation of Three Heat Exchangers with Varying Foreign Nuclei**

**TABLE 14-20 Experimental Critical Supersaturation Ratios**

| | Temperature, K | $S_{crit}$ |
|---|---|---|
| $H_2O$ | 264 | 4.91 |
| $C_2H_5OH$ | 275 | 2.13 |
| $CH_4OH$ | 264 | 3.55 |
| $C_6H_6$ | 253 | 5.32 |
| $CCl_4$ | 247 | 6.5 |
| $CHCl_3$ | 258 | 3.73 |
| $C_6H_5Cl$ | 250 | 9.5 |

3.9 causes a 10,000-fold increase in the nucleation rate. As a result, below a critical supersaturation ($S_{crit}$), homogeneous nucleation is slow enough to be ignored. Generally, $S_{crit}$ is defined as that which limits nucleation to one particle produced per cubic centimeter per second. It can be estimated roughly by traditional theory (*Theory of Fog Condensation,* Israel Program for Scientific Translations, Jerusalem, 1967) using the following equation:

$$S_{crit} = \exp\left[0.56\frac{M}{\rho_l}\left(\frac{\sigma}{T}\right)^{3/2}\right] \tag{14-200}$$

where $\sigma$ = surface tension, mN/m (dyn/cm)
$\rho_l$ = liquid density, g/cm$^3$
$T$ = temperature, K
$M$ = molecular weight of condensible

Table 14-20 shows typical experimental values of $S_{crit}$ taken from the work of Russel [*J. Chem. Phys.* **50:** 1809 (1969)]. Since the critical supersaturation ratio for homogeneous nucleation is typically greater than 3, it is not often reached in process equipment. However, fog formation is typically found in steam turbines. Gyarmathy [*Proc. Inst. Mech. E., Part A: J. Power and Energy* **219**(A6): 511–521 (2005)] reports fog in the range 3.5 to 5 percent of total steam flow, with average fog diameter in the range of 0.1 to 0.2 μm.

**Growth on Foreign Nuclei** As previously noted, foreign nuclei are often present in abundance and permit fog formation at much lower supersaturation. For example,

1. *Solids.* Surveys have shown that air contains thousands of particles per cubic centimeter in the 0.1-μm to 1-μm range suitable for nuclei. The sources range from ocean-generated salt spray to combustion processes. The concentration is highest in large cities and industrial regions. When the foreign nuclei are soluble in the fog, nucleation occurs at $S$ values very close to 1.0. This is the mechanism controlling atmospheric water condensation. Even when not soluble, a foreign particle is an effective nucleus if wet by the liquid. Thus, a 1-μm insoluble particle with zero contact angle requires an $S$ of only 1.001 to serve as a condensation site for water.

2. *Ions.* Amelin (*Theory of Fog Condensation,* Israel Program for Scientific Translations, Jerusalem, 1967) reports that ordinary air contains even higher concentrations of ions. These ions also reduce the required critical supersaturation, but by only about 10 to 20 percent, unless multiple charges are present.

3. *Entrained liquids.* The production of small droplets is inherent in the bubbling process, as shown by Fig. 14-86. Values range from near zero to 10,000/cm$^3$ of vapor, depending on how the vapor breaks through the liquid and on the opportunity for evaporation of the small drops after entrainment.

As a result of these mechanisms, most process streams contain enough foreign nuclei to cause some fogging. While fogging has been reported in only a relatively low percentage of process partial condensers, it is rarely looked for and volunteers its presence only when yield losses or pollution is intolerable.

**Drop Size Distribution** Monodisperse (nearly uniform droplet size) fogs can be grown by providing a long retention time for growth. However, industrial fogs usually show a broad distribution, as in Fig. 14-88. Note also that for this set of data, the sizes are several orders of magnitude smaller than those shown earlier for entrainment and atomizers.

The result, as discussed in a later subsection, is a demand for different removal devices for the small particles.

While generally fog formation is a nuisance, it can occasionally be useful because of the high surface area generated by the fine drops. An example is insecticide application.

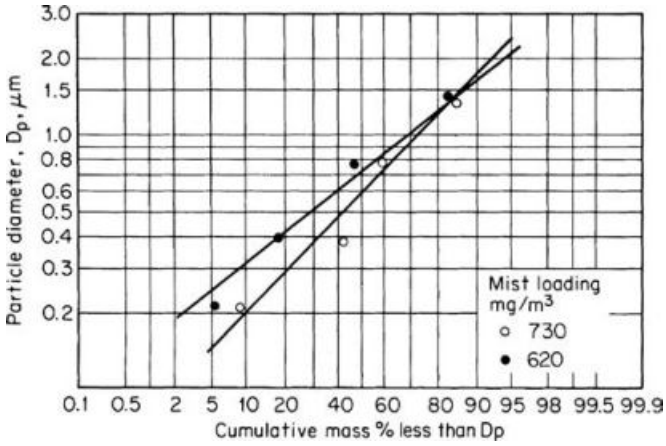

**FIG 14-88** Particle-size distribution and mist loading from absorption tower in an $H_2SO_4$ plant [*Gillispie and Johnstone,* Chem. Eng. Prog. ***51****(2): 74 (1955).*]

## GAS-IN-LIQUID DISPERSIONS

**General References:** Design methods for agitated vessels are presented by Penney in Couper et al., *Chemical Process Equipment, Selection and Design*, 3d ed., chap. 10, Elsevier, New York, 2005. A comprehensive review of all industrial fluid mixing technology is given by Paul et al., *Handbook of Industrial Mixing,* Wiley, Hoboken, N.J., 2004 and by Kresta et al., *Advances in Industrial Mixing: A Companion to the Handbook of Industrial Mixing,* Wiley, Hoboken, N.J., 2015. Comprehensive treatments of bubbles or foams are given by Akers, *Foams: Symposium 1975,* Academic Press, New York, 1973; and Exerowa and Kruglyakov, *Foam and Foam Films,* Elsevier, New York, 1998. The formation of bubbles is comprehensively treated by Clift et al., *Bubbles, Drops and Particles,* Academic Press, New York, 1978, and the literature is reviewed by Kulkarni and Joshi [*Ind. Eng. Chem. Res.* **44:** 5873 (2005)]. Design methods for unit operation in bubble columns and stirred vessels are covered by Lemoine and Morsi [*Chem. Eng. J.* **114:** 9 (2005)].

A review of foam rheology is given by Herzhaft [*Oil & Gas Sci. & Technol.* **54:** 587 (1999)] and Heller and Kuntamukkula [*Ind. Eng. Chem. Res.* **26:** 318 (1987)]. The influence of surface-active agents on bubbles and foams is summarized in selected passages from Schwartz and Perry, *Surface Active Agents,* vol. 1, Interscience, New York, 1949; and from Schwartz, Perry, and Berch, *Surface Active Agents and Detergents,* vol. 2, Interscience, New York, 1958.

A review of foam stability also is given by de Vries and Meded [*Rubber Sticht. Delft.* No. 328, 1957]. Foam-separation methodology is discussed by Aguoyo and Lemlich [*Ind. Eng. Chem. Process Des. Dev.* **13:** 153 (1974)] and Lemlich [*Ind. Eng Chem.* **60:** 16 (1968)].

Prior references, which can be useful, are given in previous editions of this handbook; the most helpful is the eighth edition, Sec. 14, McGraw-Hill, New York, 2008.

**Objectives of Gas Dispersion** The dispersion of gas as bubbles in a liquid or in a plastic mass is effected for one of the following purposes: (1) gas–liquid contacting (to promote absorption or stripping, with or without chemical reaction), (2) agitation of the liquid phase, or (3) foam or froth production. Gas-in-liquid dispersions also may be produced or encountered inadvertently, sometimes undesirably.

***Gas–Liquid Contacting*** Usually this is accomplished with conventional columns or with spray absorbers (see preceding subsection, Liquid-in-Gas Dispersions). For systems containing solids or tar likely to plug columns, absorptions accomplished by strongly exothermic reactions, or treatments involving a readily soluble gas or a condensable vapor, however, bubble columns or agitated vessels may be used to advantage.

***Agitation*** Agitation by a stream of gas bubbles (often air) rising through a liquid is often employed when the extra expense of mechanical agitation is not justified. Gas spargers may be used for simple blending operations involving a liquid of low volatility or for applications where agitator shaft sealing is difficult.

***Foam Production*** This is important in froth-flotation separations; in the manufacture of cellular elastomers, plastics, and glass; and in certain special applications (e.g., food products, fire extinguishers). Unwanted foam can occur in process columns, in agitated vessels, and in reactors in which a gaseous product is formed; it must be avoided, destroyed, or controlled. Berkman and Egloff (*Emulsions and Foams,* Reinhold, New York, 1941, pp. 112–152) have mentioned that foam is produced only in systems that have the proper combination of interfacial tension, viscosity, volatility, and concentration of solute or suspended solids. From the standpoint of gas comminution, foam production requires the creation of small bubbles in a liquid capable of sustaining foam.

**Theory of Bubble and Foam Formation** Foam is a group of bubbles separated from one another by thin films, the aggregation having a finite static life. Although nontechnical dictionaries do not distinguish between foam and froth, a technical distinction is often made. A highly concentrated dispersion of bubbles in a liquid is considered a froth even if its static life is

substantially nil (i.e., it must be dynamically maintained). Thus, all foams are also froths, whereas the reverse is not true. The thin walls of bubbles comprising a foam are called *laminae* or *lamellae.*

Bubbles in a liquid originate from one of three general sources: (1) They may be formed by de-supersaturation of a solution of the gas or by the decomposition of a component in the liquid, (2) they may be introduced directly into the liquid by a bubbler or sparger or by mechanical entrainment, and (3) they may result from the disintegration of larger bubbles already in the liquid.

***Generation*** Spontaneous generation of gas bubbles within a homogeneous liquid is theoretically impossible (Bikerman, *Foams: Theory and Industrial Applications,* Reinhold, New York, 1953, p. 10). The appearance of a bubble requires a gas nucleus as a void in the liquid. The nucleus may be in the form of a small bubble or of a solid carrying adsorbed gas, examples of the latter being dust particles, boiling chips, and a solid wall. A void can result from cavitation, mechanically or acoustically induced. Basu, Warrier, and Dhir [*J. Heat Transfer* **124:** 717 (2002)] have reviewed boiling nucleation, and Blander and Katz [*AIChE J.* **21:** 833 (1975)] have thoroughly reviewed bubble nucleation in liquids.

In a 58-page paper, with 271 references cited, Kulkarni and Joshi [*Ind. Eng. Chem. Res.* **44:** 5873 (2005)] have reviewed bubble formation and rise.

**Bubble Formation, Bubble Diameter, and Bubble Rise Velocity**

***Formation at a Single Orifice*** The formation of bubbles at an orifice or capillary immersed in a liquid has been the subject of much study. The paper by Wilkinson and Van Dierendonck [*Chem. Eng. Sci.* **49:** 1429 (1994)] is an excellent starting point to review pertinent literature.

There are three regimes of bubble production (Silberman in *Proceedings of the Fifth Midwestern Conference on Fluid Mechanics,* Univ. of Michigan Press, Ann Arbor, 1957, pp. 263–284): (1) single-bubble, (2) intermediate, and (3) jet.

***Single-Bubble Regime*** ( for $\mathrm{Re}_g = V_g d_o \rho_g/\mu_l < 100$, where $V_g$ = gas velocity m/s, $d_o$ = orifice diameter, m, $\mu_l$ = liquid viscosity, kg/m · s, and $\rho_g$ = gas density, kg/m$^3$) Bubbles are produced one at a time, their size being influenced primarily by orifice diameter, $d_o$, interfacial tension, $\sigma$, and the liquid density, $\rho_l$.

***Intermediate Regime*** ($100 < \mathrm{Re}_g < 2000$) As the gas flow through a submerged orifice increases beyond the limit of the single-bubble regime, the frequency of bubble formation increases more slowly, and the bubbles begin to grow in size. Between the two regimes there may indeed be a range of gas rates over which the bubble size decreases with increasing rate, owing to the establishment of liquid currents that nip the bubbles off prematurely. The net result can be the occurrence of a minimum bubble diameter at some particular gas rate [Mater, *U.S. Bur. Mines Bull.* 260 (1927) and Bikerman, *Foams: Theory and Industrial Applications,* Reinhold, New York, 1953, p. 4]. At the upper portion of this region, the frequency becomes very nearly constant with respect to gas rate, and the bubble size correspondingly increases with gas rate. Bubble size is affected primarily by $d_o$, $\mu_b$, $\rho_b$, and $Q$ (the gas flow rate, m$^3$/s).

Kulkarni and Joshi (2005, pp. 5878–5880) have listed 17 references that contain predictive correlations for bubble size from a single submerged orifice in a liquid and 22 references (pp. 5886–5888) for correlations of a more general nature. One of those correlations, by Gaddis and Vogelpohl [*Chem. Eng. Sci.* **41:** 97 (1986)], "shows a very good match with experimental data," according to Kulkarni and Joshi (p. 5891).

$$d_b/d_o = [(6\sigma/\rho_l g d_o^2)^{4/3} + (81\mu_l Q/\pi g d_o^4) + (135Q^2/4\pi^2 g d_o^5)^{4/5}]^{1/4} \qquad (14\text{-}201)$$

where $d_b$ = bubble diameter, $d_o$ = orifice diameter, and $g$ = local gravity, m/s$^2$

For conditions approaching constant pressure at the orifice entrance, which probably simulates most industrial applications, there is no independently verified predictive method. For air at near atmospheric pressure sparged into relatively inviscid liquids (11 ~ 100 cP), the correlation of Kumar et al. [*Can. J. Chem. Eng.* **54:** 503 (1976)] fits experimental data well. Their correlation is presented here as Fig. 14-89.

***Jet Regime*** With further rate increases, turbulence occurs at the orifice, and the gas stream approaches the appearance of a continuous jet that breaks up 8 to 10 cm above the orifice. Actually, the stream consists of large, closely spaced, irregular bubbles with a rapid swirling motion. These bubbles disintegrate into a cloud of smaller ones of random size distribution between 0.025 cm or smaller and about 1.25 cm, with a mean size for air and water of about 0.4 cm (Leibson et al., *AIChE J.* **2:** 300–308 [1956]). According to Kulkarni and Joshi (2005, p. 5890), jetting begins when the Weber number exceeds 4

$$\mathrm{We} = \rho_g d_o V_g^2/\sigma > 4 \qquad (14\text{-}202)$$

There are many contradictory reports about the jet regime, and theory, although helpful (see, for example, Silberman 1957), is as yet unable to describe the phenomena observed. The correlation of Kumar et al. (Fig. 14-89) is recommended.

***Formation at Multiple Orifices*** The coverage in the eighth edition of this handbook could be helpful.

Jamialhanadi et al. [*Trans. IChemE* **79A:** 523 (2001)] have proposed a unified correlation for the estimation of average bubble size. Kulkarni and Joshi [*Chem. Eng. Res. Dev.* **89:** 1972 (2011)] have recommended this correlation for the prediction of bubble size from spargers in bubble columns.

$$d_b/d_o = [5/\mathrm{Bo}^{1.08} + 9.26\mathrm{Fr}^{0.36}/\mathrm{Ga}^{0.39} + 2.14\mathrm{Fr}^{0.51}]^{1/3} \qquad (14\text{-}203)$$

where Bo = Bond number = $\rho_l d_o^2 g/\sigma$; Fr = Froude number = $V_o^2/g d_o$; Ga = Galileo number = $\rho_l^2 d_o^3 g/\mu_l^2$, $V_o$ = orifice velocity, m/s. For most practical spargers, the gas velocity is high; thus, inertial forces will dominate, so the third term in Eq. (14-203) will dominate. Hence, the bubble diameter is proportional to $V_g^{0.34}$, which is counter to the decrease in bubble size with increasing $V_g$ predicted by Fig. 14-89 for $\mathrm{Re}_g > 2000$. The correlation of Jamialhanadi et al. is thus suspect for $\mathrm{Re}_g > 2000$. Use the result from Fig. 14-89 for Re > 2000.

***Critical Weep Point*** Spargers must to be designed to avoid weeping into the sparger header. Kulkarni and Joshi (2011) have addressed this issue, and they recommend the correlation of Thorat et al. [*Chem. Eng. Tech.* **24**(8): 815 (2001)] for sieve trays.

$$V_c^2[\rho_g/(\rho_l - \rho_g)]/(g d_o) = 0.37 + 140 H_l(\Delta X/d_o)^{-1.6}(t/d_o)^{0.75} \qquad (14\text{-}204)$$

where $V_c$ = critical gas velocity to avoid weeping, m/s; $\Delta X$ = distance between holes, m; $H_l$ = static liquid head above the sparger, m; $t$ = sparger plate thickness, m.

The correlation of Kulkarni et al. [*Chem. Eng. Res. Dev.* **87**(12): 1612 (2009)] is recommended for pipe spargers.

$$V_c^2 = [0.44(\rho_l - \rho_g) d_o g/\rho_g](L/d_o)^{-0.12}(\Delta X/d_o)^{-0.145}(H_l/d_o)^{0.67} \qquad (14\text{-}205)$$

where $L$ = length of the sparger pipe, m.

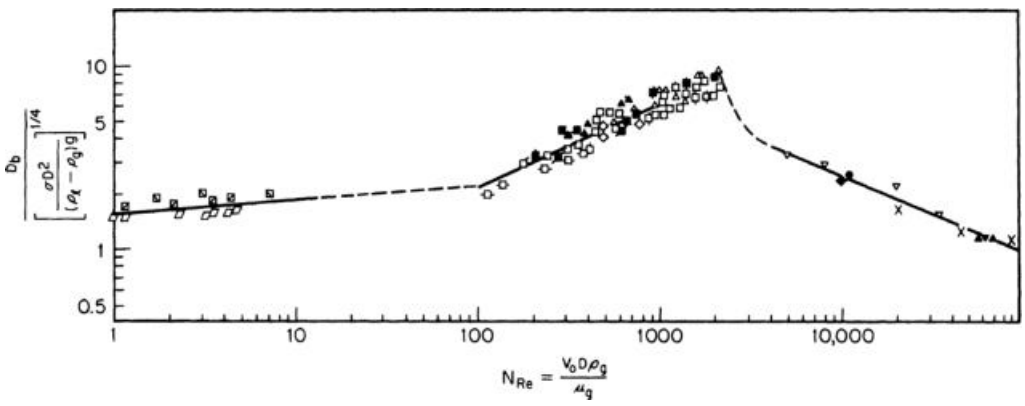

**FIG. 14-89** Bubble-diameter correlation for air sparged in relatively inviscid liquids. $D_b$ = bubble diameter, $D$ = orifice diameter, $V_o$ = gas velocity through the sparging orifice, $\rho_g$ = gas density, and $\mu_g$ = gas viscosity. [*From* Can. J. Chem. Eng. ***54:*** *503 (1976)*].

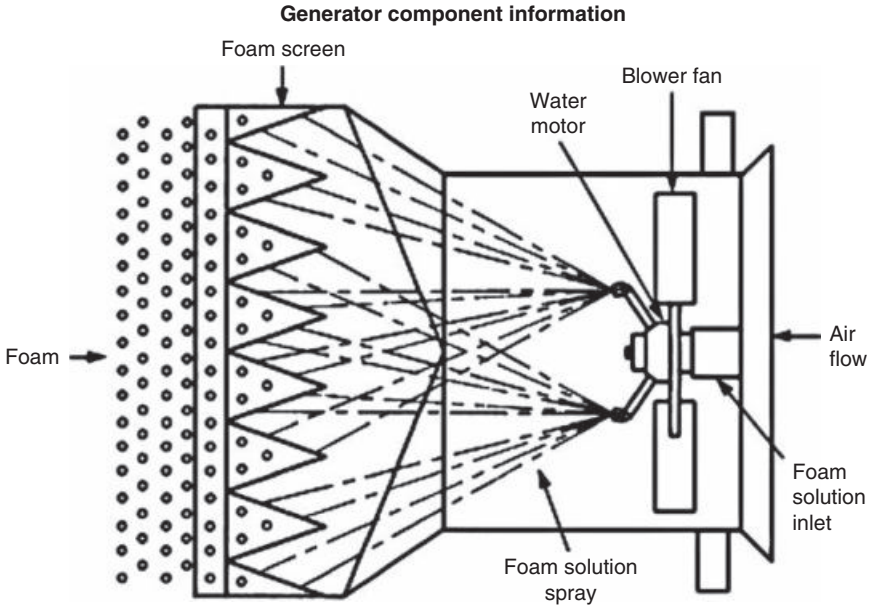

**FIG. 14-90** Details of the Ansul high-expansion foam generators. (https://www.ansul.com/en/us/DocMedia/F-93137.pdf.)

The prediction of bubble size and critical weeping velocity for a submerged sparger involves complex phenomena that cannot be modeled accurately; thus, a correlational approach using the appropriate dimensionless parameters must be taken. No correlation covers accurately the wide range of conditions for which spargers are used. The results obtained by using the recommended correlations must be used cautiously and, normally, with experimental verifications prior to scale-up from the laboratory or pilot plant to the full-scale plant.

**Entrainment and Mechanical Disintegration** Gas can be entrained into a liquid by a solid or a stream of liquid falling from the gas phase into the liquid, by surface ripples or waves, or by a vortex in a partially baffled mechanically agitated vessel. The disintegration of sparged gas is often accomplished by mechanical agitation. Quantitative correlations for gas entrainment by liquid jets and in agitated vessels will be given later.

**Foams** The excellent review by Exerowa and Kruglyakov (*Foam and Foam Films*, Elsevier, New York, 1998) covers the literature pertinent to foams. A foam is formed when bubbles rise to the surface of a liquid and persist for a while without coalescence with one another or without rupture into the vapor space. Gravitational force and interfacial tension forces favor the coalescence and ultimate disappearance of bubbles. The viscosity of the liquid in a film opposes the drainage of the film and its displacement by the approach of coalescing bubbles. The higher the viscosity, the slower will be the film-thinning process; furthermore, if viscosity increases as the film grows thinner, the process becomes self-retarding.

If the liquid laminae of a foam system can be converted to impermeable solid membranes, the film viscosity can be regarded as having become infinite, and the resulting solid foam will be permanent. Likewise, if the laminae are composed of a gingham plastic or a thixotrope, the foam will be permanently stable for bubbles whose buoyancy does not permit exceeding the yield stress. For other non-Newtonian fluids, however, and for all Newtonian ones, no matter how viscous, the viscosity can only delay but never prevent foam disappearance. Foam stability is keyed to the existence of a surface skin of low interfacial tension immediately overlying a solution bulk of higher tension, latent until it is exposed by rupture of the superficial layer [Maragoni, *Nuovo Cimento* **2**(5–6): 239 (1871)]. Such a phenomenon of surface elasticity, resulting from concentration differences between bulk and the surface of the liquid, accounts for the ability of bubbles to be penetrated by missiles without damage. It is conceivable that films below a certain thickness no longer carry any bulk of solution and hence have no capacity to close surface ruptures, thus becoming vulnerable to mechanical damage that will destroy them. The Maragoni phenomenon is consistent also with the observation that neither pure liquids nor saturated solutions will sustain a foam, since neither extreme will allow the necessary differences in concentration between surface and bulk of solution.

The specific ability of certain finely divided, insoluble solids to stabilize foam has long been known (Berkman and Egloff, *Emulsions and Foams,* Reinhold, New York, 1941, p. 133; and Bikerman, *Foams: Theory and Industrial Applications,* Reinhold, New York, 1953, chap. 11). Bartsch [*Kolloidchem. Beih* **20:** 1 (1925)] found that the presence of fine galena greatly extended the life of air foam in aqueous isoamyl alcohol, and the finer the solids, the greater the stability.

The production of foams is a well-established technology, covered extensively by YouTube videos and on the Web. An example of the technology available on the Web is the JET-X high-expansion foam generators (https://www.ansul.com/en/us/DocMedia/F-93137.pdf), for which the design details are included in Fig. 14-90.

**Characteristics of Dispersion**

***Dispersion Characteristics*** The chief characteristics of gas-in-liquid dispersions, like those of liquid-in-gas suspensions, are heterogeneity and instability.

The rate of rise of bubbles has been discussed by Clift, Grace, and Weber, *Bubbles, Drops and Particles,* Academic Press, New York, 1978; Benfratello, *Energ. Elettr.* **30:** 80 (1953); Haberman and Morton, *Report 802: David W. Taylor Model Basin,* Washington, September 1953; and Kulkarni and Joshi, *Ind. Eng. Chem. Res.* **44:** 5873–5931 (2005), in which reference they summarize 16 correlations for predicting the rise velocity of bubbles; however, none are accurate over the entire range of practical bubble sizes.

Figure 14-91 presents a graph of bubble rise velocities versus mean bubble size for a variety of pure liquids, liquid mixtures, and contaminated liquids. The shapes of these curves vary greatly depending on the purity and viscosity of the liquids.

Small bubbles (below 0.2 mm in diameter) are essentially rigid spheres and rise at terminal velocities that place them clearly in the laminar-flow region; hence their rising velocity may be calculated from Stokes' law [$V_b = 2g(\rho_l - \rho_g)D_b^2/18\mu_l$]. As bubble size increases to about 2 mm, the spherical shape is retained, and the Reynolds number is still so small (<10) that Stokes' law should be nearly obeyed. The Reynolds number Re is given by $\mathrm{Re} = V_b D_b/\mu_l$ where $V_b$ = bubble velocity, m/s; $D_b$ = bubble diameter, m; $\mu_l$ = liquid viscosity, kg/m · s.

As bubble size increases, two effects set in, however, that change the deviation from Stokes' law. At about Re = 100, a wobble begins that can develop into a helical path if the bubbles are not liberated too closely to one another [Houghton, McLean, and Ritchie, *Chem. Eng. Sci.* **7:** 40 (1957); and Houghton, Ritchie, and Thomson, *Chem. Eng. Sci.* **7:** 111 (1957)]. Furthermore, for bubbles in the range of 1 mm and larger (until distortion becomes serious), internal circulation can set in [Garner and Hammerton, *Chem. Eng. Sci.* **3**, (1954)], and, according to a theoretical analysis by Hadamard and Rybczynski (https://en.wikipedia.org/wiki/Hadamard%E2%80%93Rybczynski_equation), the rise velocity of a freely circulating bubble is 3/2 that of a rigid sphere for a low-viscosity gas and a much higher viscosity liquid. Redfield and Houghton [*Chem. Eng. Sci.* **20:** 131 (1965)] have found that $CO_2$ bubbles rising in pure water agree with the theoretical solution for a circulating drop below Re = 1. Extremely small quantities of impurities can retard or stop this

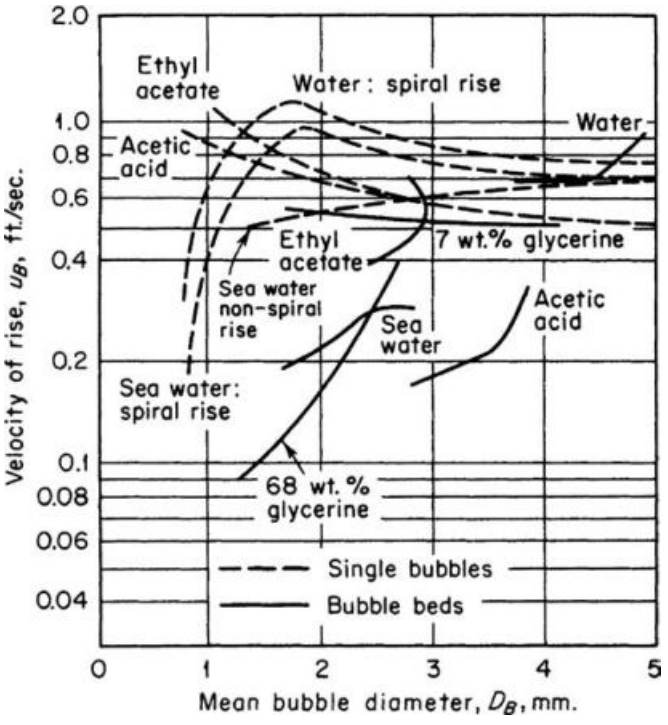

**FIG. 14-91** Velocity of rising bubbles, singly and in clouds. To convert feet per second to meters per second, multiply by 0.305. [*From* Chem. Eng. Sci. ***7:*** *48 (1957).*]

internal circulation as explained in *Bubble and Foam Chemistry*, Cambridge University Press, 2016, p. 114.

Above diameters of about 2 mm, bubbles begin to change to ellipsoids, and above 1 cm they become lens-shaped, according to Davies and Taylor [*Proc. Roy. Soc.* (London) **A200:** 379 (1950)] and Kulkarni and Joshi 2005, p. 5911. The rise velocity in thin liquids for the size range 1 mm $< D_B <$ 20 is 20 to 30 cm/s, as indicated by Fig. 14-89.

Above a Reynolds number of the order of magnitude of 1000, bubbles assume a helmet shape, with a flat bottom. After bubbles become large enough to depart from Stokes' law at their terminal velocity, behavior is generally complicated and erratic, and the reported data scatter considerably. The rise can be slowed, furthermore, by a wall effect if the diameter of the container is not greater than 10 times the diameter of the bubbles, as shown by Uno and Kintner [*AIChE J.* **2:** 420 (1956); and Collins, *J. Fluid Mech.* **28**(1): 97 (1967)]. Work has been done to predict the rise velocity of large bubbles [Rippin and Davidson, *Chem. Eng. Sci.* **22:** 217 (1967); Mendelson, *AIChE J.* **13:** 250 (1967); Lehrer, *J. Chem. Eng. Japan* **9:** 237 (1976); and Lehrer, *AIChE J.* **26:** 170 (1980)]. The works of Lehrer present correlations for rise velocities for a wide range of system properties for bubbles outside the Stokes' law regime.

Most practical applications occur where bubbles do not act as rigid spheres; instead, they oscillate and deform. Although the predictive methods for rise velocity are not very accurate outside the rigid sphere regime, that does not deter the use of bubble rise velocity for designing suitable processing equipment. The most widely used application of bubble rise velocity is to design bottom vessel outlets and horizontal vessels to separate gas from liquid when a gas dispersion exists within a system. From Fig. 14-89 we see that the maximum rise velocity, even for pure liquids, is about 30 cm/s.

When bubbles are produced in clouds, as by a porous disperser, their behavior during rising is further complicated by interaction among themselves. In addition to the tendency for small bubbles to coalesce and large ones to disintegrate, there are two opposing influences on the rate of rise of bubbles of any particular size: (1) A "chimney effect" can develop in which a massive current upward appears at the axis of the bubble stream, leading to increased net bubble velocity; and (2) the proximity of the bubbles to one another can result in a hindered-settling condition, leading to reduced average bubble velocity. Figure 14-91 shows the data for clouds of bubbles compared with their single-bubble data for pure water and seawater and of Peebles and Garber [*Chem. Eng. Progr.* **49:** 88 (1953)] for acetic acid and ethyl acetate. The bubble clouds were produced with a sintered-glass plate of mean pore size (inferred from air wet-permeability data) of 81 μm.

The difference between the curves for pure water and seawater again illustrates the significance of small concentrations of solute with respect

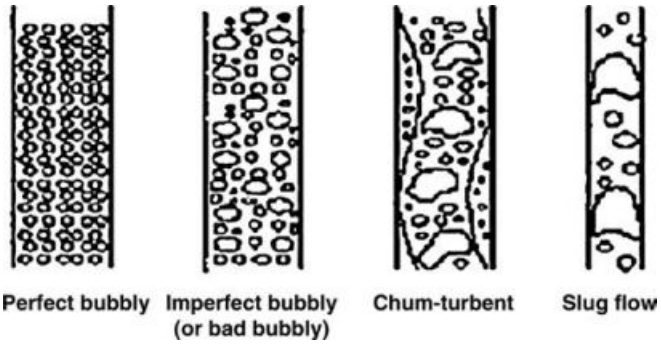

**FIG. 14-92** Visual representations of flow regimes in bubble columns. [*Kantarci et al.,* Process Biochemistry ***40****(7): (2005), p. 2269.*]

to bubble behavior. In commercial bubble columns and agitated vessels, coalescence and breakup are so rapid and violent that the rise velocity of a single bubble is meaningless. The average rise velocity can, however, be readily calculated from holdup correlations that will be given later.

**Methods of Gas Dispersion** The problem of dispersing a gas in a liquid may be attacked in several ways: (1) The gas bubbles of the desired size or which grow to the desired size may be introduced directly into the liquid; (2) a volatile liquid may be vaporized by either decreasing the system pressure or increasing its temperature; (3) a chemical reaction may produce a gas; or (4) a massive bubble or stream of gas is disintegrated by fluid shear, by, perhaps, mechanical agitation or turbulence in the liquid. Bubble columns and mechanically agitated columns are most commonly used for dispersing gas into liquid in commercial-scale equipment.

**Bubble Columns** The technical literature covering bubble column reactors was reviewed by Kantarci et al. [*Process Biochemistry* **40**(7): 2263 (2005)] and Chen [*Biotechnology and Genetic Engineering Reviews* **8:** 379–396 (November 1990)]; similarly, Middleton and Smith (*Handbook of Mixing Equipment*, Wiley, Hoboken, N.J., 2004, chap. 11, p. 585) have summarized the technical literature for gas–liquid mixing in mechanically agitated vessels. Gas/liquid processing vessels can be very large, as evidenced by the 265,000 L algae reactors at the Alltech Hendersonville, Ky., plant. [https://www.youtube.com/watch?v=a58JJH9pxOU]

**Flow Regimes in Bubble Columns** Assuming uniform dispersion at the tank bottom, the likely flow regimes and flow regime visualizations are presented in Figs. 14-92 and 14-93. In larger columns, bubbly flow exists up to a superficial gas velocity of 0.05 m/s; from 0.05 to 0.07 m/s the regime transitions from bubbly to churn-turbulent.

***Spargers: Simple Bubblers*** Gas dispersed in a liquid contained in a tank can be introduced through an open-end standpipe, horizontal perforated pipes, concentric ring pipes, or a perforated plate at the bottom of the tank.

Perforated-pipe or -plate spargers usually have orifices 1 to 10 mm in diameter [Kulkarni et al., *Chem. Eng. Res. & Des.* **87:** 1612 (2009); **89:** 1972 (2011)]. Effective design methods to minimize maldistribution are presented in the eighth edition of this handbook, p. 6-32, by Senecal [*Ind. Eng. Chem.*

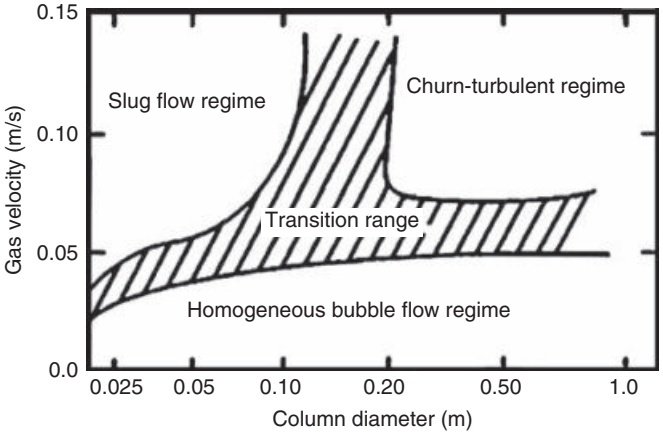

**FIG. 14-93** Flow regime map for bubble columns. [*Kantarci et al. (2005), p. 2269.*]

**49:** 993–997 (1957)] and Kulkarni et al. 2011. For turbulent flow conditions into the sparger, the following simpler relationship will allow conservative design of a perforated-pipe sparger for a given degree of maldistribution provided the number of holes exceeds about 5 and the length/diameter <300.

$$V_h/V_0 = [C_o V_h/(\Delta V_h/V_h)]^{(1/2)} \qquad (14\text{-}206)$$

where $V_h$ = hole velocity, m/s; $V_0$ = velocity entering the sparger pipe, m/s; $\Delta V_h$ = difference between maximum hole velocity and minimum hole velocity, m/s; $(\Delta V_h/V_h)$ = fractional maldistribution of flow along the sparger, and $C_o$ = the orifice coefficient for the holes. $C_o$ for holes in a pipe wall varies from 0.6 to 0.8, depending on the ratio of wall thickness to hole diameter $(t/D_h)$: $C_o = 0.6, 0.65, 0.7, 0.75, 0.8$ for $(t/D_h) = 0.1, 0.34, 0.45, 0.66, 2$; respectively. For example, for a thick wall pipe and small holes, $C = 0.8$; thus, for a fractional maldistribution of $0.05, V_h/V_0 = 4$.

Simple spargers are used as agitators for large tanks, principally in the cement and oil industries. Kauffman [*Chem. Metall. Eng.* **37:** 178–180 (1930)] reported the following air rates for various degrees of agitation in a tank containing 2.7 m (9 ft) of *liquid:*

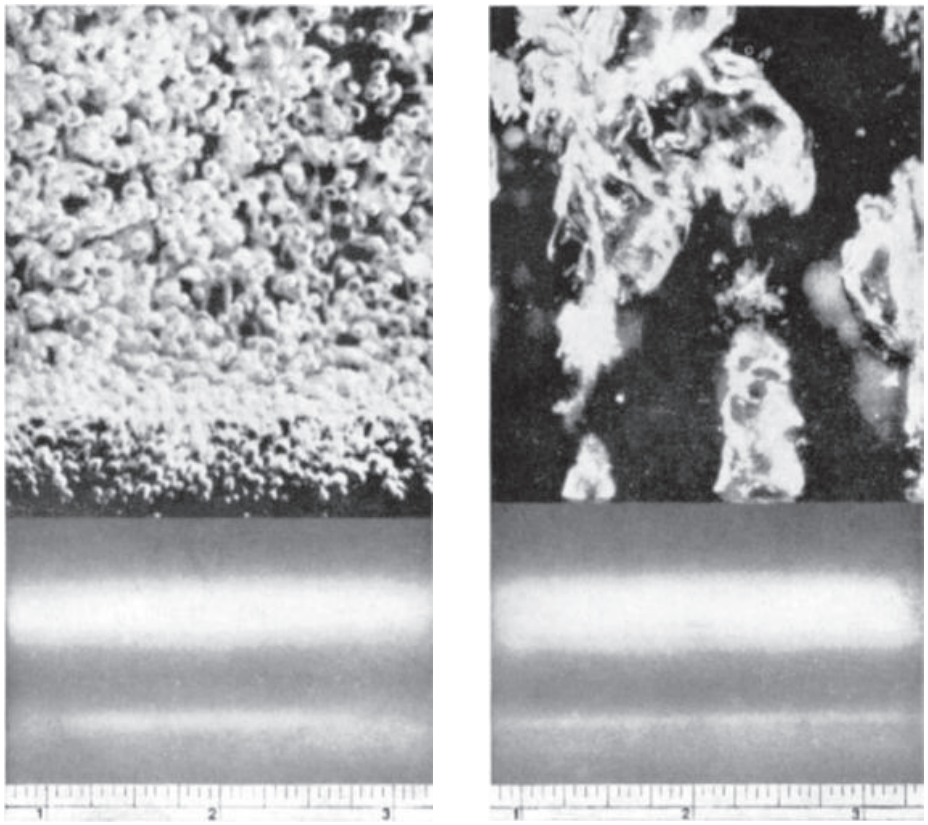
| Degree of agitation | Air rate (cfm/ft$^2$) | Air rate ([m$^3$/min]/m$^2$) |
|---|---|---|
| Moderate | 0.65 [0.011 ft/s] | 0.2 |
| Complete | 1.3 [0.022 ft/s] | 0.4 |
| Violent | 3.1 [0.05 ft/s] | 0.95 |

NOTE: For a liquid depth of 0.9 m (3 ft), Kauffman recommended that the listed rates be doubled.

**Tank Blending Using Gas Sparging** Lehrer [*Ind. Eng. Chem. Process Des. Dev.* 7: 226 (1968)] conducted liquid-blending tests with air sparging in a 0.61-m-diameter by 0.61-m-tall vessel and found that an air volume equal to about one-half of the vessel volume ( for vessel A6, Fig. 9 in Lehrer, at $t_b = 10$ s, $\nu_g = 0.1$ fts, $Q = 0.314$ cfs, $V_g = 3.14$ ft$^3$, and $V_g/V_t = 3.14/6.54 = 0.48$) gave thorough blending of inviscid liquids of equal viscosities. Using an analogy to mechanically agitated vessels in which equal tank turnovers give equal blend times, one would expect this criterion to be applicable to other vessel sizes. Liquids of unequal density and higher viscosities will require somewhat more air. This design criterion is substantiated by an analysis of the data presented by El Ezzi and Najmuldeen [*J. Eng. Res. & Application* **4**(4): 286 (2014)] for a gas lift vessel. Using a conservative design criterion of one tank volume of gas to blend a vessel is normally very practical; for example, for a 3-m-diameter × 6-m-tall vessel (42 m$^3$ = 11,000 gal), the total gas volume required for blending is 42 m$^3$. A gas flow of 4.2 m$^3$/min (150 cfm) will blend this vessel in 10 minutes.

Gas spargers are usually operated at orifice Reynolds numbers in excess of 6000 in order to obtain small bubbles, which increase the interfacial area and, consequently, mass transfer. In the "turbulent regime" (superficial gas velocity > about 5 cm/s), sparger design is not critical because a balance between coalescence and breakup is established very quickly according to Towell et al. [*AIChE Symp. Ser. No. 10*, 97 (1965)]. However, a reasonably uniform orifice distribution over the column cross section is desirable, and according to Fair [*Chem. Eng.* **74:** 67 (July 3, 1967); 207 (July 17, 1967)] the orifice velocity should be less than 75 to 90 m/s.

***Porous Septa*** In the quiescent regime, porous plates, tubes, disks, or other shapes that are made by bonding or sintering together carefully sized particles of carbon, ceramic, polymer, or metal are often used for gas dispersion, particularly in foam fractionators. Many companies supply such septa, including Mott (http://www.mottcorp.com/products) and GKN (http://www.gkn-filters.de/products_en/spargers/). The resulting septa may be used as spargers to produce much smaller bubbles than will result from a simple bubbler. Figure 14-94 shows a comparison of the bubbles emitted by a perforated-pipe sparger [0.16 cm orifices] and a porous carbon septum (120 μm pores). The air permability of porous spagers are given by the Mott Corp. in its *Porous Metal Design Guidebook*, p. 10 (https://mottcorp.com/sites/default/files/Porous%20Metal%20Design%20Guidebook%20Published%20by%20MPIF.pdf)



(*a*) (*b*)

**FIG. 14-94** Comparison of bubbles from a porous septum and from a perforated-pipe sparger. Air in water at 70°F. (*a*) Grade 25 porous-carbon diffuser operating under a pressure differential of 13.7 in of water. (*b*) Karbate pipe perforated with 1/16-in holes on 1-in centers. To convert inches to centimeters, multiply by 2.54; °C = 5/9 (°F − 32). (*National Carbon Co.*)

An Inyo website (http://www.inyoprocess.com/images/Porous_inj/porous_sparger_sizing.pdf) states, "When an injector is sized correctly, a bubble size of 200–6000 micron will be achieved in clear water. . . . If the velocity is too high, the smaller bubbles will tend to coalesce into larger bubbles." A working limit of 0.05 m/s (10 fpm) is recommended to avoid serious coalescence. Tubes and slabs of porous material are used as porous spargers. Roe [*Sewage Works J.* **18:** 878 (1945)] claimed that silicon carbide tubes are superior to horizontal plates, principally because of the wiping action of the liquid circulating past the tube; he reported respective maximum capacities of 0.015 to 0.025 m/s for a horizontal tube and a horizontal plate of the same material (unspecified grade).

Porous septa produce small bubbles that provide high mass transfer rates. The primary resistance to mass transfer is normally in the liquid phase, for which the limiting Sherwood number ($k_l D/d_b$) is 2 (https://en.wikipedia.org/wiki/Sherwood_number), where $k_l$ = liquid phase mass-transfer coefficient, m/s; $D$ = solute diffusivity, $m^2/s$, $d_b$ = bubble diameter, m.

***Precipitation and Generation Methods*** For a thorough understanding of the phenomena involved, bubble nucleation should be considered. A discussion of nucleation phenomena is beyond the scope of this handbook, but a starting point with recent references is Deng, Lee, and Cheng, *J. Micromech. Microeng.* **15:** 564 (2005), and Jones, Evans, and Galvin, *Adv. Colloid and Interface Sci.* **80:** 27 (1999).

***Agitated Vessels*** Agitated vessels are used extensively for gas–liquid dispersion, especially for the purposes of mass transfer. There are three modes of impellers commonly used for gas introduction. Those three arrangements are shown schematically in Fig. 14-95. The surface aeration impeller is often a four-blade pitched-blade impeller operating about one-half impeller diameter submerged below the free liquid surface. The gas-inducing impeller is a hollow-shaft design; these impellers are always of a special design, depending on the manufacturer; Ekato's gas-inducing impellers are shown and explained in http://www.ekato.com/fileadmin/user_upload/Documents/PresseCenter/Titel_Chemical_Engineering.pdf.

Chemineer (http://www.chemineer.com/products/chemineer/impellers.html) sells four impellers that are used for gas dispersion: a six-blade disk, CD-6, and the BT-6 for use as the bottom impeller just above the ring-type perforated pipe sparger, and normally a Maxiflow W for installation above the bottom impeller. Other manufacturers sell impellers that are competitive with those offered by Chemineer.

***Gas Dispersion—Vessel Headspace*** Boerma and Lankester [*Chem. Eng. Sci.* **23:** 799 (1968)] measured the surface aeration of a nine-bladed disk-type turbine (*Note*: A well-designed four-bladed pitched-blade turbine will give equal or better performance). In a fully baffled vessel, the optimum depth to obtain maximum gas dispersion was 15 to 50 percent of the impeller diameter. In a vessel with baffles extending only halfway to the liquid surface, the optimum impeller submergence increased with agitator speed because of the vortex formed. At optimum depth, the following correlation is recommended for larger vessels:

$$Q = 0.00015(N/10)^{2.5}(D/0.1)^{4.5} \qquad (14\text{-}207)$$

where $Q$ = rate of gas dispersed into the liquid, $m^3/s$, $N$ = impeller speed, rps, and $D$ = impeller diameter, m. Thus, a typical 3-m-diameter plant-size vessel, with four-blade pitched impeller ($D$ = 1 m) operating at 2 rps will give gas dispersion from the headspace into the batch of $Q = 0.00015(2/10)^{2.5}(2/0.1)^{4.5} = 1.9\ m^3/s$ (4000 cfm). There is another means of estimating the gas entraining capability of this impeller, and that is based on the pumping capability of the impeller in conjunction with a reasonable estimate of gas holdup. The impeller pumping number ($N_Q = Q/ND^3$) for a four-bladed pitched-blade impeller is 0.75 (Couper et al., *Chemical Process Equipment Selection and Design*, Elsevier, New York, 2010, p. 285); thus, the impeller pumping capability is $0.75(2)3^3 = 13.5\ m^3/s$. A reasonable estimate of the maximum gas fraction within the pumped liquid is 0.15; thus, the maximum expected gas entraining capability, at the optimum impeller depth, is $0.15(13.5) = 2\ m^3/s$, which agrees reasonably well with the $1.9\ m^3/s$ obtained by correlating the experimental results of Borema and Lankester ["The Occurrence of Minimum Stirring Rates in Gas-Liquid Reactors," *Chem. Eng. Sci.* **23:** 799–801 (1968)].

Borema and Lankester (1968) recommended headspace gas dispersion with partial baffling for fatty oils hydrogenation in stirred reactors: "The hydrogen in the head-space of the closed reactor can again be brought into contact with the liquid by a stirrer under the liquid level, . . ." and Chemineer (http://www.chemineer.com/hydrogenator.html) has this to say about using upper impellers in hydrogenation reactors, "It is important to re-incorporate the hydrogen into the batch to maintain the reaction and improve hydrogen utilization. This is very easily and efficiently accomplished by using a 4-bladed pitched impeller (P-4), or impellers, located above the BT-6 impeller. The P-4 impeller:

- Provides increased mixing intensity and draws a vortex for the reincorporation of the hydrogen gas from the vapor space,
- With proper design can handle varying liquid levels,
- Does not plug or foul as compared to self inducing impellers."

However, Middleton et al. in Paul et al. (*Handbook of Industrial Mixing*, Wiley, Hoboken, N.J., 2004) say, "The simplest self-inducer for an agitated vessel is an impeller located near the surface, sometimes with the upper part of the baffles removed so as to encourage the formation of a vortex. This is, however, a sensitive and unstable arrangement. It is better, although probably more expensive, to use a self-inducing impeller system in which gas is drawn down a hollow shaft to the low-pressure region behind the blades of a suitable, often shrouded impeller.... Various proprietary designs are available, such as the Ekato gasjet (http://www.ekato.com/products/product/show/Product/impellers/gasjet/); video included), Prasair AGR (http://citeseerx.ist.psu.edu/viewdoc/download?doi=10.1.1.624.6642&rep=rep1&type=pdf) and the Frings Friborator (http://www.frings.com/FRIBORATOR-Aerator.224+M52087573ab0.0.html)."

In many hydrogenation reactors, the impeller just underneath the free surface has, without any doubt, performed admirably; consequently, one must consider this fact very carefully when selecting a self-inducing impeller [e.g., inspired by the work of Borema and Lankester (op. cit.), in the early 1970s the capacity of a hydrogenation reactor in the Monsanto L-DOPA process (https://www.google.com/?gws_rd=ssl#q=l-dopa+monsanto+process) was more than doubled by adding a four-bladed pitched impeller just below the free liquid surface in a glass-lined reactor].

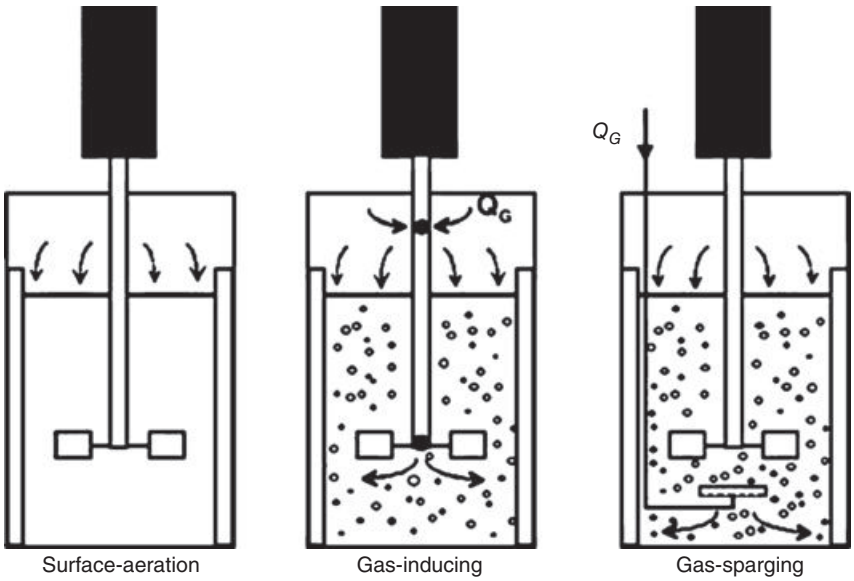


**FIG 14-95** Operating modes of gas–liquid reactors. [*Lemoine,* Chem. Eng. J. ***114:*** *9 (2005).*]

**FIG. 14-96** The Aqua-Jet surface aerator in operation. (http://www.aqua-aerobic.com/index.cfm/products-systems/aeration-mixing/aqua-jet/.)

**Critical Speed for Gas Entrainment** The critical speed for air entrainment to commence has been studied by Bhattacharya, Hebert, and Kresta [*IChemE* **85**(A5): 654 (2007)] and reviewed by Patwardhan and Joshi (*Can. J. Chem. Eng.* **76:** 339 (1998)]. This parameter is of marginal practical interest because practical operation (1–10 kW/kg) is far beyond the power input level where gas entrainment starts.

**Mass-Transfer Coefficient** The calculation of mass transfer rates is most important; correlations for $k_La$ have been developed by Leguay et al. (*10th European Conference on Mixing*, Elsevier, Amsterdam, 2000, p. 189) and Conway et al. "Gas-Liquid-Solid Operation of a Vortex-Ingesting Stirred Tank Reactor," available at (http://citeseerx.ist.psu.edu/viewdoc/download?doi=10.1.1.624.6642&rep=rep1&type=pdf), and the literature has been reviewed by Patwardhan and Joshi [*Ind. Eng. Chem. Res.* **38:** 49–80 (1999)] and Lemoine et al. [*Chem. Eng. and Processing* **42:** 621 (2003)].

***Surface Aerators*** Gas dispersion through the free surface by mechanical aerators is commonplace in aerobic waste-treatment lagoons. Surface aerators are generally of four types: (1) small-diameter high-speed (normally motor-speed) propellers operating in draft tubes (Fig. 14-96), (2) large-diameter slow-speed turbines operating just below the free surface of the liquid (Fig. 14-97), often pontoon-mounted, (3) aeration jets (http://www.wateronline.com/doc/kynar-pvdf-jet-aerator-for-improved-wear-resistance-0001), and (4) fine bubble spargers.

**FIG 14-97** The Voltas pontoon-mounted turbine-type surface aerator in operation. (http://www.voltas.com/voltas_water/images/pdf/aerator.pdf.)

**TABLE 14-21 Performance Parameters of the Voltas Pontoon-Mounted Turbine-Type Surface Aerator***

| Blade immersion (mm) | Power at aerator output shaft (kW) | Oxygenation capacity at 20°C (kg/h) | Oxygenation capacity efficiency (std.) (kg/kWh) |
|---|---|---|---|
| 216 | 5.7 | 15.60 | 2.76 |
| 241 | 6.6 | 19.50 | 2.96 |
| 267 | 7.7 | 20.00 | 2.60 |
| 292 | 9.5 | 26.80 | 2.83 |
| 318 | 10.6 | 29.30 | 2.75 |
| 345 | 13.7 | 39.60 | 2.90 |
| 368 | 15.7 | 44.00 | 2.81 |
| 381 | 16.8 | 52.20 | 3.10 |

*http://www.voltas.com/voltas_water/images/pdf/aerator.pdf.

The performance parameters of the Voltas pontoon-mounted turbine-type surface aerator are given in Table 14-21. Note that the oxygen transfer efficiency varies from about 2.75 to 3.1 (kg/hr)/kW. Stenstrom and Rosso ("Aeration," table, University of California–Los Angeles, 2010, p. 55) give lower transfer efficiencies than those given by Voltas; process guarantees must be used to ensure that the machinery will perform as the manufacturer specifies.

**Equipment Selection** Ideally, the selection of equipment to produce a gas-in-liquid dispersion should be made on the basis of a complete economic analysis. The design engineer and especially the pilot-plant engineer seldom have enough information or time to do a complete economic analysis. In the following discussion, some guidelines are given as to what equipment is feasible and what equipment might prove most economical.

For producing foam for foam-separation processes, perforated-plate or porous-plate spargers are normally used. Mechanical agitators are often not effective in the light foams needed in foam fractionation. Dissolved-air flotation, based on the release of a pressurized flow in which oxygen was dissolved, has been shown to be effective for particulate removal when sparged air failed because the bubbles formed upon precipitation are smaller—down to 80 μm—than bubbles possible with sparging, typically 1000 μm [Grieves and Ettelt, *AIChE J.* **13:** 1167 (1967)]. Mechanically agitated surface aerators such as the WEMCO-Fagergren flotation unit (http://www.flsmidth.com/en-US/Industries/Categories/Products/Flotation/WEMCOFlotation/WEMCOFlotation) are used extensively for ore flotation.

To produce foam in batch processes, mechanical agitators are used almost exclusively. The gas can either be introduced through the free surface by the entraining action of the impeller or alternatively sparged beneath the impeller. In such a batch operation, the liquid level gradually rises as the foam is generated; thus, squatty impellers such as turbines are rapidly covered with foam and must almost always be sparged from below. Tall impellers such as wire whips (https://www.google.com/search?q=wire+whip+agitators&biw=1920&bih=934&source=lnms&tbm=isch&sa=X&ved=0ahUKEwjWjJPbourRAhXJsFQKHQSZDXMQ_AUIBygC) are especially well suited to entrain gas from the vapor space. Intermeshing wire whips are standard kitchen utensils for producing foamed meringues, consisting of air, vegetable oil, and egg whites. For a new application, generally some experimentation with different impellers is necessary in order to get the desired fine final bubble size without frothing over initially. For producing foams continually, an aspirating venturi nozzle and restrictions in pipes such as baffles and metal gauzes are generally most economical.

For gas absorption, the equipment possibilities are generally packed columns; plate distillation towers, possibly with mechanical agitation on every plate; deep-bed contactors (bubble columns or sparged lagoons); and mechanically agitated vessels or lagoons. Packed towers and plate distillation columns are covered earlier in this section. Generally these devices are used when a relatively large number of stages (more than two or three) is required to achieve the desired result practically.

The volumetric mass-transfer coefficients and heights of transfer units for bubble columns and packed towers have been compared for absorption of $CO_2$ into water by Houghton et al. [*Chem. Eng. Sci.* **7:** 26 (1957)]. The bubble column will tolerate much higher vapor velocities, and in the overlapping region (superficial gas velocities of 0.009 to 0.018 m/s), the bubble column has about three times higher mass-transfer coefficient and about three times greater height of transfer unit. The liquid in a bubble column is, for practical purposes, quite well mixed; thus, chemical reactions and component separations requiring significant plug flow of the liquid cannot be effected with bubble columns. Bubble columns and agitated vessels are the ideal equipment for processes in which the fraction of gas absorbed need not be great, possibly the gas can be recycled, and the liquid can or should be well mixed. The gas phase in bubble columns is not nearly so well

back-mixed as the liquid, and often plug flow of the gas is a logical assumption, but in agitated vessels the gas phase is also well mixed.

The choice of a bubble column or an agitated vessel depends primarily on the solubility of the gas in the liquid, the corrosiveness of the liquid (often a gas compressor can be made of inexpensive material, whereas a mechanical agitator may have to be made of exotic, expensive materials), and the rate of chemical reaction as compared with the mass-transfer rate. Bubble columns and agitated vessels are seldom used for gas absorption except in chemical reactors. As a general rule, if the overall reaction rate is five times greater than the mass-transfer rate in a simple bubble column, a mechanical agitator will be most economical unless the mechanical agitator would have to be made from considerably more expensive material than the gas compressor.

In bubble columns and simply sparged lagoons, selecting the sparger is an important consideration. In the turbulent regime (superficial gas velocity greater than 0.046 to 0.06 m/s), inexpensive perforated-pipe spargers should be used. Often the holes must be placed on the pipe bottom in order to make the sparger free-draining. In the quiescent regime, porous septa will often give considerably higher overall mass-transfer coefficients than perforated plates or pipes because of the formation of small bubbles. Chain and coworkers (*First International Symposium on Chemical Microbiology,* World Health Organization, Monograph Ser. 10, Geneva, 1952) claimed that porous disks are about twice as effective as open-pipe and ring spargers for the air oxidation of sodium sulfite. Eckenfelder [*Chem. Eng. Progr.* **52**(7): 290 (1956)] has compared the oxygen-transfer capabilities of various devices on the basis of the operating power required to absorb a given quantity of $O_2$. The installed cost of the various pieces of equipment probably would not vary sufficiently to warrant being included in an economic analysis. Surface mechanical aerators are not included in this comparison. Of the units compared, it appears that porous tubes give the most efficient power usage. Kalinske (*Advances in Biological Waste Treatment,* Pergamon Press, New York, 1963, pp. 157–168) compared submerged sparged aerators with mechanical surface aerators. He summarized this comparison in *Water Sewage Works* **33** (January 1968). He indicated that surface aerators are significantly more efficient than subsurface aeration, both for oxygen absorption and for gas-stripping operations.

Zlokarnik and Mann (paper at Mixing Conference, Rindge, New Hampshire, August 1975) found the opposite of Kalinske, that is, subsurface diffusers, subsurface sparged turbines, and surface aerators compared approximately 4:2:1, respectively, in terms of their $O_2$ transfer efficiency. However, Zlokarnik [*Adv. Biochem. Eng.* **11:** 157 (1979)] later indicated that the scale-up correlation used earlier might be somewhat inaccurate. When all available information is considered, it appears that with near-optimum design, any of the aeration systems (diffusers, submerged turbines, or surface impellers) should give a transfer efficiency of at least 2.25 kg $O_2$/kWh. Thus, the final selection should probably be made primarily on the basis of operational reliability, maintenance, and capital costs.

**Mass Transfer** Mass transfer in plate and packed gas–liquid contactors has been covered previously in this section. Attention here will be limited to deep-bed contactors (bubble columns and agitated vessels). Theory underlying mass transfer between phases is discussed in Sec. 5 of this handbook.

To design deep-bed contactors for mass-transfer operations, one must have, in general, predictive methods for the following design parameters:

- Flooding ( for both columns and agitator impellers)
- Agitator power requirements
- Gas-phase and liquid-phase mass-transfer coefficients
- Interfacial area
- Interface resistance
- Mean concentration driving force for mass transfer

In most cases, available methods are incomplete or unreliable, and some supporting experimental work is necessary, followed by scale-up. The methods given here should allow theoretical feasibility studies, help minimize experimentation, and permit a measure of optimization in final design.

**Sparged Impellers** The most common method of introducing gas into an agitated vessel is through a ring-type perforated pipe sparger.

***Flooding of Agitator Impellers*** Impeller flooding correlations for six-blade disk (6BD) Rushton turbines and six-blade disk Smith turbines (Chemineer designation: CD-6) are presented by Bakker, Myers, and Smith [*Chem. Eng.* **101:** 98 (December 1994)]. The Bakker et al. correlation is

$$Q/ND^3 = C_{FL}N_{Fr}(D/T)^{3.5} \tag{14-208}$$

where $C_{FL}$ = 30 (experimentally determined dimensionless constant) for a 6BD impeller and $C_{FL}$ = 70 for a concave blade CD-6 impeller and $N_{Fr}$ = Froude number = $N^2D/g$; $Q$ = gas flow rate at flooding, $m^3/s$; $N$ = impeller speed, rps; $D$ = impeller diameter, m; and $T$ = tank diameter, m. Note that the CD-6 impeller will handle 70/30 = 2.33 times the gas a 6BD will handle, without flooding, at the same $N$ and $D$; this is the great advantage of the CD-6, along with lower power decrease as the gas flow rate increases.

**TABLE 14-22 Constants in Eq. (14-209) and Impeller Power Numbers**

| Impeller type | $a$ | $b$ | $c$ | $d$ | $N_p$ |
|---|---|---|---|---|---|
| 6BD | 0.72 | 0.72 | 24 | 0.25 | 3.2 |
| CD-6 | 0.12 | 0.44 | 12 | 0.37 | 5.5 |

***Gassed Impeller Power*** Bakker et al. 1994 have given a gassed power correlation for 6BD and CD-6 impellers, which can be seen at (http://www.chemineer.com/products/chemineer/impellers.html).

$$P_g / P_u = [1-(b-a\mu)]\, N_{Fr}^{d} \tanh\,(cN_A) \tag{14-209}$$

where $P_g$ = gassed power, W; $P_u$ = ungassed power, W; $N_A = Q/ND^3$; $\mu$ = batch viscosity, Pa-s (i.e., kg/m · s); and the constants of Eq. (14-209) are given in Table 14-22.

As mentioned previously, the CD-6 experiences much less power decrease with increased gassing compared to the 6BD. For example, at $N_A$ = 0.15, $P_g/P_u$ = 0.7 for the CD-6 and 0.5 for the CD-6.

The ungassed power is calculated by

$$P_u = N_p \rho_l / N^3 D^5 \tag{14-210}$$

where $\rho_l$ = liquid density, $kg/m^3$; $N$ = impeller speed, rps; $D$ = impeller diameter, m, and the impeller power numbers, $N_p$, are given in Table 14-22.

Bakker et al. 1994 have given correlations for gas holdup in agitated vessels. The Bakker et al. correlation is

$$\varepsilon = C_\varepsilon (P_g / V)^A \upsilon_{sg}^B \tag{14-211}$$

where $\varepsilon$ = fractional gas holdup, dimensionless; $C_\varepsilon$ = 0.16, experimentally determined parameter; $A$ = 0.33, $B$ = 0.67; $V$ = batch volume, $m^3$; $\upsilon_{sg}$ = superficial gas velocity = $Q/[(\pi/4)T^2]$, m/s; $Q$ = gas volumetric rate, $m^3/s$; $T$ = tank diameter, m. Equation (14-211) applies for both the 6BD and the CD-6.

***Interfacial Area*** This consideration in agitated vessels has been reviewed and summarized by Tatterson (*Fluid Mixing and Gas Dispersion in Agitated Tanks*, McGraw-Hill, 1991, pp. 477, 486). Predictive methods for interfacial area are not presented here because correlations are given for the overall volumetric mass-transfer coefficient, liquid phase controlling mass transfer.

***Overall Mass-Transfer Coefficient*** In systems with relatively sparing soluble gases, where the gas-phase resistance is negligible, the mass-transfer rate can be determined by using the concept of an overall volumetric mass-transfer coefficient $k_La$ as follows:

$$M_s = k_L a (C_s^* - C_{s,b}) V_l \tag{14-212}$$

where $M_s$ = solute molar mass-transfer rate, kg · mol/s; $k_La$ = overall mass-transfer coefficient, 1/s; $C_s^*$ = solute concentration in equilibrium with the liquid phase, $kg{\cdot}mol/m^3$; and $C_{s,b}$ = solute concentration in bulk of liquid, $kg{\cdot}mol/m^3$; $V_l$ = liquid volume, $m^3$.

Bakker et al. [*Chem. Eng.* **101:** 98 (December 1994)] have given a correlation for $k_La$ for aqueous systems in the absence of significant surface active agents.

$$k_L a = C_{kLa} (P_g / V)^a \upsilon_{sg}^b \tag{14-213}$$

where $C_{kLa}$ = 0.015, an experimentally determined parameter. Equation (14-213) applies for both the 6BD and the CD-6.

**Gas-Inducing and Gas-Sparging Impellers** The fundamentals of the operation and design of these impellers are presented by Bao, Ye and Jong (*Bioreactor Engineering Research and Industrial Application II*, Springer-Verlag, Berlin, 2016), Patwardhan and Joshi [*Ind. Eng. Chem. Res.* **38:** 49 (1999)], Lemoine et al. [*Chem. Eng. and Processing* **42:** 621 (2003)], Lemoine and Morsi [*Chem. Eng. J.* **114:** 9 (2005)], Patwardhan and Joshi [*Can. J. Chem. Eng.* **76:** 339 (1998)], and Saravanan et al. [*Ind. Eng. Chem. Res.* **33:** 2226 (1994)]. There are many different designs as evidenced by the six styles shown schematically on page 56 of Patwardhan and Joshi 1999. Only two styles will be covered here: (1) a six-blade disk impeller operating near the free surface in a baffled vessel and the WEMCO flotation machine. http://

**TABLE 14-23 Design Parameters for Four WEMCO Machines***

WEMCO flotation machine "Design Scale-Up"

| Design parameters | Cell size designation | | | |
|---|---|---|---|---|
| | #144 | #164 | #190 | #225 |
| Cell volume (cu. ft.) | 500 | 1000 | 1500 | 3000 |
| Fourth Area (sq. ft.) | 99 | 122 | 168 | 224 |
| Air/pump mixing volume (cu. ft.) | 15 | 31 | 51 | 105 |
| Impeller speed (RPM) | 192 | 185 | 164 | 140 |
| Air transfer* (ACFM) | 240 | 370 | 560 | 870 |
| Liquid circulation* (CFM) | 970 | 1620 | 1870 | 3370 |
| Mechanism power* (HP) | 26.7 | 48.3 | 82.7 | 160 |
| Air escape velocity* (Ft/min) | 2.42 | 3.03 | 3.33 | 3.88 |
| Specific circulation intensity (1/min.) | 1.94 | 1.62 | 1.25 | 1.12 |
| Air/pulp mixing residence time (sec.) | 0.72 | 0.92 | 1.26 | 1.49 |
| Mechanism power number ($P/pn^3D^5$) | 0.019 | 0.019 | 0.022 | 0.024 |
| Pulp circulation velocity (Ft/min) | 263 | 330 | 280 | 334 |
| Air capacity number ($Q_a/ND^3$) | 0.123 | 0.128 | 0.138 | 0.135 |
| Froude Number ($N^2D/g$) | 27.2 | 29.1 | 26.7 | 23.9 |

*http://www.flsmidth.com/en-US/Industries/Categories/Products/Flotation/WEMCOFlotation/WEMCOFlotation.

www.flsmidth.com/~/media/PDF%20Files/Liquid-Solid%20Separation/Flotation/Wemco11brochure.ashx

**Six-Blade Disk Impeller** At the optimum depth of submergence, the gas induction rate is estimated on the basis of a gas holdup of 15 percent going through the impeller region. The pumping number for a 6BD impeller is 0.72 (http://www.postmixing.com/mixing%20forum/impellers/impellers.htm); thus, the gas pumping number is $(0.15)0.72 = 0.11 = Q_g/ND^3$. The ratio of gassed power to ungassed power ($P_g/P_{ug}$) is assumed to be the same as that for a 6BD impeller operating above a ring-type sparger.

The mass transfer correlation of Wu [*Chem. Eng. Sci.* **50:** 2801–2811 (1995)] is recommended

$$k_La = 0.0634(P/V_l)^{0.65} \tag{14-214}$$

where $P$ = impeller power, W; $V$ = batch volume, $m^3$; and $k_La$ = volumetric mass-transfer coefficient, 1/s.

The gas holdup within the batch is calculated by Eq. (14-211).

**WEMCO Machine** The design method is developed from the information presented in Table 14-23 from the WEMCO Flotation Technology Brochure (http://www.flsmidth.com/en-US/Industries/Categories/Products/Flotation/WEMCOFlotation/WEMCOFlotation).

Consider the #164 machine, which has cell volume of 1000 $ft^3$ (6500 gal; 28.4 $m^3$) (Fig. 14-98). The air capacity number ($Q_a/ND^3$) is given as 0.128; the liquid circulation is given as 1620 cfm, so the liquid capacity number is $[1620/\{185(3.33)^3\}] = 0.017$. The power number is given as 0.019, and $Fr = N^2D/g = 3.08^2(3.33/3.28)/9.81 = 0.98$; thus, the 29.1 in the table is incorrect. The air capacity number is 0.128; thus, the air induced is $Q_a = 0.128(185)3.33^3 = 874$ cfm, which is higher than the value of 370 in Table 14-23.

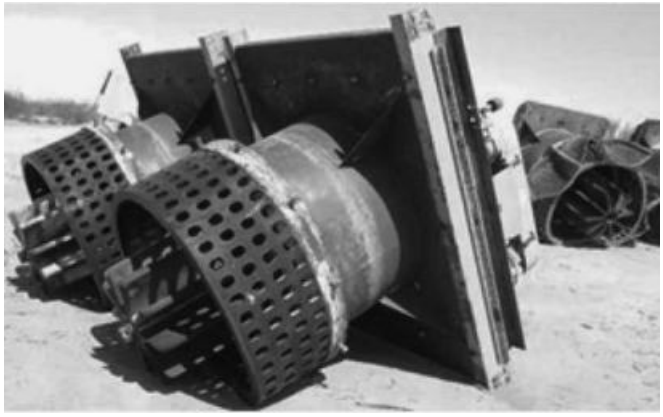

**FIG 14-98** A photograph of a Model 164 WEMCO flotation machine. (*Note*: from the photo and the brochure, the impeller diameter is about 40 in.) (http://www.flsmidth.com/en-US/Industries/Categories/Products/Flotation/WEMCOFlotation/WEMCOFlotation.)

***Interfacial Phenomena*** These can significantly affect overall mass transfer. Deckwer (*Bubble Column Reactors*, Wiley, Hoboken, N.J., 1992) has covered the effect of surfactants on mass transfer in bubble columns. In fermentation reactors, small quantities of surface-active agents (especially antifoaming agents) can drastically reduce overall oxygen transfer, and in aerobic mechanically aerated waste-treatment lagoons, overall oxygen transfer has been found to be from 0.5 to 3 times that for pure water from tests with typical sewage streams.

One cannot quantitatively predict the effect of the various interfacial phenomena; thus, these phenomena will not be covered in detail here. The following literature gives a good general review of the effects of interfacial phenomena on mass transfer: Goodridge and Robb, *Ind. Eng. Chem. Fund.* **4:** 49 (1965); Calderbank, *Chem. Eng. (London)* CE 205 (1967); Gal-Or et al., *Ind. Eng. Chem.* **61**(2): 22 (1969); Kintner, *Adv. Chem. Eng.* **4** (1963); Resnick and Gal-Or, *Adv. Chem. Eng.* **7** (1968), p. 295; Valentin, *Absorption in Gas-Liquid Dispersions*, E. & F. N. Spon, London, 1967; Elenkov, *Theor. Found Chem. Eng.* **1**(1): 117 (1967); and *Ind. Eng. Chem. Ann. Rev. Mass Transfer* **60**(1): 67 (1968); **60**(12): 53 (1968); **62**(2): 41 (1970). In the following outline, the effects of the various interfacial phenomena on the factors that influence overall mass transfer are given. Possible effects of interfacial phenomena are as follows:

1. Effect on continuous-phase mass-transfer coefficient
   *a.* Impurities concentrate at interface. Bubble motion produces circumferential surface-tension gradients that retard circulation and vibration, thereby decreasing the mass-transfer coefficient.
   *b.* Large concentration gradients and large heat effects (very soluble gases) can cause interfacial turbulence (the Marangoni effect), which increases the mass-transfer coefficient.
2. Effect on interfacial area
   *a.* Impurities will lower static surface tension and give smaller bubbles.
   *b.* Surfactants can electrically charge the bubble surface (produce ionic bubbles) and retard coalescence (soap stabilization of an oil/water emulsion is an excellent example of this phenomenon), thereby increasing the interfacial area.
   *c.* Large concentration gradients and large heat effects can cause bubble breakup.
3. Effect on mean mass-transfer driving force
   *a.* Relatively insoluble impurities concentrate at the interface, giving an interfacial resistance. This phenomenon has been used in retarding evaporation from water reservoirs.
   *b.* The axial concentration variation can be changed by changes in coalescence. The mean driving force for mass transfer is therefore changed.

***Gas Holdup (ε) in Bubble Columns*** Bubble column gas holdup literature has been reviewed by Kantarci, Borak, and Ulgen [*Process Biochemistry* **40**(7): 2263 (2005)], Tsuchiya and Nakanishi [*Chem. Eng. Sci.* **47**(13/14): 3347 (1992)], and Sotelo et al. [*Int. Chem. Eng.* **34**(1): 82–90 (1994)].

With coalescing systems, holdup may be estimated from Hughmark's work [*Ind. Eng Chem. Process Des. Dev.* **6:** 218–220 (1967)] (see Fig. 14-82). For noncoalescing systems, with considerably smaller bubbles, ε can be as great as 0.6 at $U_{sg} = 0.05$ m/s, according to Mersmann [*Ger. Chem. Eng.* **1:** 1 (1978)].

A simple application of the continuity relationship determines that the gas holdup is given by the following equation, given by Joshi and Sharma [*Trans. IChemE* **57:** 244 (1979), eq. 30]:

$$\varepsilon = U_{sg}/U_b \tag{14-215}$$

where $U_{sg}$ = superficial gas velocity, m/s, and $U_b$ = volume average vertical bubble rise velocity, m/s. This relationship cannot be used directly with the bubble rise velocities previously discussed because of liquid circulation within the column, which increases the effective bubble rise velocity and lowers the gas holdup; Joshi and Sharma (1979) have addressed the consequences of liquid circulation on gas holdup. An empirical equation suggested by Mashelkar [*Br. Chem. Eng.* **15:** 1297 (1970)] fits Hughmark's data [*Ind. Eng Chem. Process Des. Dev.* **6:** 218–220 (1967)] very well for column diameters >4 in (0.1 m).

$$\varepsilon = U_{sg}/(0.3 + 2U_{sg}) \tag{14-216}$$

Kantarci [*Process Biochemistry* **40**(7): 2263 (2005)] lists 20 correlations for gas holdup in bubble columns; a thorough study would include an evaluation of each correlation; however, due to (1) sparger variations and (2) the effect of surfactants on holdup, an initial evaluation need go no further than the use of the works mentioned previously. Only an experimental study will determine accurately the holdup in real systems with varying sparger and varying interfacial effects.

Liquid-phase mass-transfer coefficients in bubble columns have been reviewed by Kantarci et al. (2005). Data by Ozturk, Schumpe, and Deckwer [*AIChE J.* **33:** 1473–1480 (1987)] are presented in Figs. 14-99 and 14-100; these

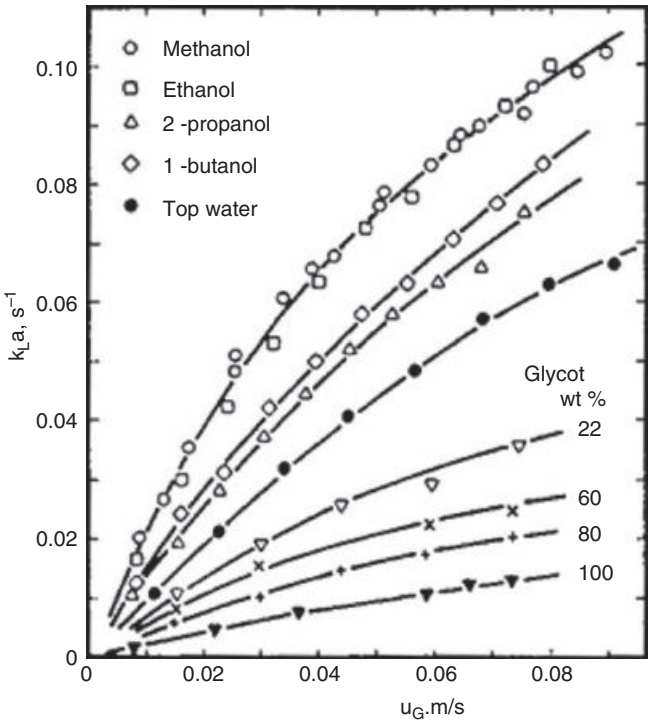

**FIG 14-99** Volumetric mass-transfer coefficients in alchols and glycol solutions. [*Ozturk, Schumpe, and Deckwer,* AIChE J. ***33:*** *1477 (1987).*]

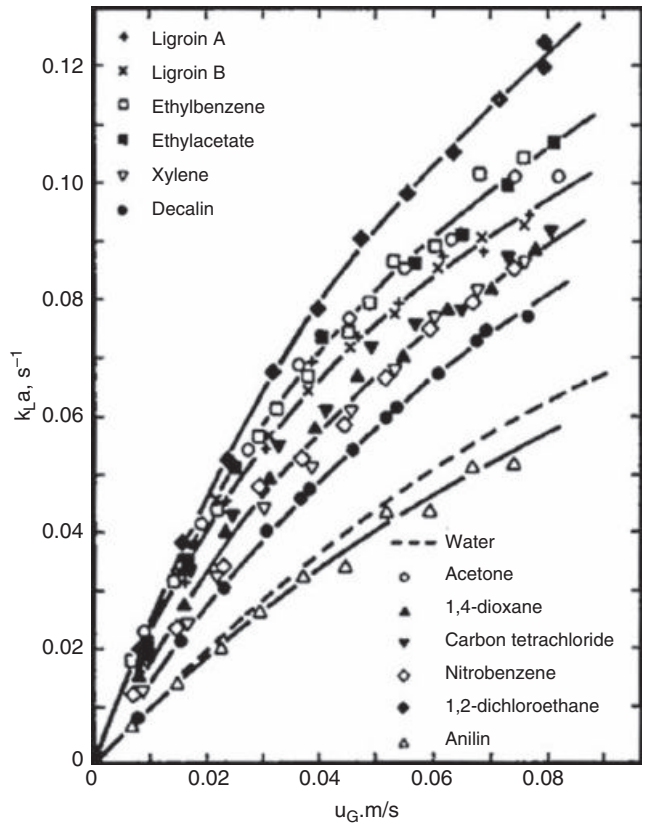

**FIG 14-100** Volumetric-mass transfer coefficients in various organic liquids. [*Ozturk, Schumpe, and Deckwer,* AIChE J. ***33:*** *1477 (1987).*]

data can be used directly to estimate the $k_La$ for various systems. These data were used to develop a correlation for the volumetric mass-transfer coefficient

$$\mathrm{Sh}_b = 0.62\mathrm{Sc}^{0.3}\mathrm{Bo}^{0.33}\mathrm{Ga}^{0.29}\mathrm{Fr}^{0.68}(\rho_g/\rho_l)^{0.04} \tag{14-217}$$

$\mathrm{Sh}_b$ = Sherwood number $(k_La)d_b^2/D_l$; Sc = Schmidt number $(\mu_l/\rho_lD_l)$; Bo = Bond number $(g\rho_l d_b^{\,2}/\sigma)$; Ga = Galileo number = $(g\rho_l d_b^{\,3}/\mu_l^2)$; Fr = Froude number = $U_g/(gd_b)^{1/2}$ and $k_La$ = volumetric mass-transfer coefficient, $s^{-1}$; $d_b$ = bubble diameter = 0.003 m; $D_l$ = diffusivity of the solute in the solvent, $m^2/s$; $U_g$ = mean superficial gas velocity; $\mu_l$ = liquid viscosity, kg/m · s; $g$ = local gravity, $m/s^2$; $\sigma$ = interfacial tension, N/m. Based on the study of Qucker and Deckwar [*Ger. Chem. Eng.* **4:** 363 (1981)], the bubble diameter was assumed to have a constant value of 3 mm.

The following dependencies are implied:

$$k_La \propto D_l^{0.5}\rho_l^{0.37}\mu_l^{-0.08}\sigma^{-0.33}\rho_g^{0.04}d_b^{-0.81}U_g^{0.68} \tag{14-218}$$

As mentioned earlier, surfactants and ionic solutions significantly affect mass transfer. Normally, surface effects retard coalescence and thus increase the mass transfer. For example, Hikata et al. [*Chem. Eng. J.* **22:** 61–69 (1981)] have studied the effect of KCl on mass transfer in water. As KCl concentration increased, the mass transfer increased up to about 35 percent at an ionic strength of 6 gm/L. Other investigators have found similar increases for liquid mixtures.

**Axial Dispersion** Backmixing in bubble columns has been extensively studied. Wiemann and Mewes [*Ind. Eng. Chem. Res.* **44:** 4959 (2005)] and Wild et al. [*Int. J. Chemical Reactor Eng.* 1: R7 (2003)] give a long list of references pertaining to backmixing in bubble columns. An excellent review article by Shah et al. [*AIChE J.* **24:** 369 (1978)] has summarized the literature prior to 1978. Works by Konig et al. [*Ger. Chem. Eng.* **1:** 199 (1978)], Lucke et al. [*Trans. Inst. Chem. Eng.* **58:** 228 (1980)], Riquarts [*Ger. Chem. Eng.* **4:** 18 (1981)], Mersmann [*Ger. Chem. Eng.* **1:** 1 (1978)], Deckwer (*Bubble Column Reactors*, Wiley, Hoboken, N.J., 1992), Yang et al. [*Chem. Eng. Sci.* **47**(9–11): 2859 (1992)], and Garcia-Calvo and Leton [*Chem. Eng. Sci.* **49**(21): 3643 (1994)] are particularly useful references.

Axial dispersion occurs in both the liquid and the gas phases. The degree of axial dispersion is affected by vessel diameter, vessel internals, gas superficial velocity, and surface-active agents that retard coalescence. For systems with coalescence-retarding surfactants, the initial bubble size produced by the gas sparger is also significant. The gas and liquid physical properties have only a slight effect on the degree of axial dispersion, except that liquid viscosity becomes important as the flow regime becomes laminar. With pure liquids, in the absence of coalescence-inhibiting, surface-active agents, the nature of the sparger has little effect on the axial dispersion, and experimental results are reasonably well correlated by the dispersion model. For the liquid phase, the correlation recommended by Deckwer et al. [*Can. J. Chem. Eng.* **58:** 190 (1980)], after the original work by Baird and Rice [*Chem. Eng. J.* **9:** 171(1975)] is as follows:

$$\frac{E_L}{(DU_G)} = 0.35\left(\frac{gD}{U_G^2}\right)^{1/3} \tag{14-219}$$

where $E_L$ = liquid-phase axial dispersion coefficient, $m^2/s$; $U_G$ = superficial velocity of the gas phase, m/s, $D$ = vessel diameter, m; and $g$ = local gravity, $m/s^2$.

The recommended correlation for the gas-phase axial-dispersion coefficient is given by Field and Davidson ["Axial Dispersion in Bubble Columns," *Trans. Inst. Chem. Eng.* **58:** 228–236 (1980)]:

$$E_G = 56.4\,D^{1.33}\left(\frac{U_G}{\varepsilon}\right)^{3.56} \tag{14-220}$$

where $E_G$ = gas-phase axial-dispersion coefficient, $m^2/s$; $D$ = vessel diameter, m; $U_G$ = superficial gas velocity, m/s; and $\varepsilon$ = fractional gas holdup, volume fraction.

The correlations given in the preceding paragraphs are applicable to vertical cylindrical vessels with pure liquids without coalescence inhibitors. For other vessel geometries such as columns of rectangular cross section, packed columns, and coiled tubes, the work of Shah et al. [*AIChE J.* **24:** 369 (1978)] should be consulted. For systems containing coalescence-inhibiting surfactants, axial dispersion can be vastly different from that in systems in which coalescence is negligible. Konig et al. [*Ger. Chem. Eng.* **1:** 199 (1978)] have well demonstrated the effects of surfactants and sparger type by conducting tests with weak alcohol solutions using three different porous spargers. With pure water, the sparger—and, consequently, initial bubble size—had little effect on backmixing because coalescence produced a dynamic-equilibrium bubble

**TABLE 14-24 Comparison of Gas–Liquid Processing Options for Mass Transfer**

[1]Data taken from http://www.flsmidth.com/~/media/PDF%20Files/Liquid-Solid%20Separation/Flotation/Wemco11brochure.ashx
[2]The impeller diameter is about 40" to require 35 hp (at the impeller) at 185 rpm.
[3]$k_La = 0.0159(P_g/V)^{0.86} = 0.0159(1.34)^{0.86} = 0.023$ [Sawant et al. (op. cit.)].
[4]$k_La = 0.0634(P_g/V)^{0.65} = 0.0634(1.8)^{0.65} = 0.086$ [*Wu* {CES, **50: 2801** (1995)}].
[5]With $D = 40$" (1.02 m) $N = 185$ rpm (3.08 rps), Fr ≠ 29.1 as the WEB table shows.
[6]The WEB given induced gas is 370 cfm; however an air capacity number of 0.128 gives $Q_g = 0.128(3.08)(1.02)^3 = 0.418$ cms = 826 cfm; something is not consistent.

size not far above the sparger. With surfactants, the average bubble size was smaller than the dynamic-equilibrium bubble size. Small bubbles produced minimal backmixing up to ε ≈ 0.40; however, above ε ≈ 0.40, backmixing increased very rapidly as $U_G$ increased. The rapid increase in backmixing as ε exceeds 0.40 was postulated to occur indirectly because a bubble carries upward with it a volume of liquid equal to about 70 percent of the bubble volume, and, for ε ≈ 0.40, the bubbles carry so much liquid upward that steady, uniform bubble rise can no longer be maintained and an oscillating, slugging flow develops, which produces fluctuating pressure at the gas distributor and the formation of large eddies. The large eddies greatly increase backmixing. For the air-alcohol-water system, the minimum bubble size to prevent unsteady conditions was about 1, 1.5, and 2 mm for $U_G = 1$, 3, and 5 cm/s, respectively. Any smaller bubble size produced increased backmixing. The results of Konig et al. (1978) clearly indicate that the interaction of surfactants and sparger can be very complex; thus, one should proceed very cautiously in designing systems for which surfactants significantly retard coalescence. Caution is particularly important because surfactants can produce either much more or much less backmixing than surfactant-free systems, depending on the bubble size, which, in turn, depends on the sparger used.

Table 14-24 summarizes pertinent parameters for two bubble columns—one in the single-bubble regime with $v_s = 0.01$ m/s and the second in the churn-turbulent regime with $v_s = 0.08$ m/s—and three mechanically agitated designs, a 6BD operating near the free liquid surface, a commercial surface aerator (WEMCO), and a concave blade impeller operating above a ring-style perforated pipe gas sparger. In terms of mass transfer capability, the churn-turbulent bubble column, the 6BD surface aerator, and the sparged CD-6 were about equal. The WEMCO machine lagged behind these three by a factor of 4, and the single-bubble regime and the single-bubble regime bubble column was a distant fifth. The surface aeration using a 6BD was selected because Wu [*Chem. Eng. Sci.* **50:** 2801–2811 (1995)] investigated that device. As the literature indicates, a four-blade pitched impeller is probably a more efficient machine for this application. As is evident from this evaluation of the various mass-transfer devices, there are many choices for a given process application. Reliable data and reliable design correlations are only available for a few of the possibilities. However, vendors have a storehouse of knowledge that has not been and never will be published. The truly effective process engineer uses vendor resources effectively. For example, Chemineer and other agitator manufacturers can provide design and scale-up help for a four-blade pitched impeller operating just beneath the free surface; Ekato can provide excellent help for hollow shaft and hollow impeller designs, and the FLSmidth and Co. A/S can provide assistance to define, design, and implement a WEMCO machine.

# PHASE SEPARATION

Gases and liquids may be intentionally contacted as in absorption and distillation, or a mixture of phases may occur unintentionally as in vapor condensation from inadvertent cooling or liquid entrainment from a film. Regardless of the origin, it is usually desirable or necessary to separate gas–liquid dispersions. Natural separation of the liquid and gas phases occurs due to density differences; however, natural separation is generally inadequate because the process is slow and the location of the separation is uncontrolled. Separation processes are used to accelerate the natural phase separation and to control the location of the phases. Technology for phase separation has changed little in recent years; the challenge remains the correct selection and application of the existing technology to meet the needs for a particular service. Failures in phase separation can cause severe problems in plant performance from direct damage to hardware if excessive liquid reaches a turbine, to corrosion resulting from liquids in unexpected locations, to failure to meet air emission requirements.

## GAS-PHASE CONTINUOUS SYSTEMS

Practical separation techniques for liquid particles in gases are discussed. Since gas-borne particulates include both liquid and solid particles, many devices used for dry-dust collection (discussed in Sec. 17 under Gas–Solids Separations) can be adapted to liquid-particle separation. Separation of liquid particulates is often desirable in chemical processes such as in countercurrent-stage contacting because liquid entrainment with the gas partially reduces efficiency. Separation before entering another process step may be needed to prevent corrosion, yield loss, or equipment damage or malfunction. Separation before the atmospheric release of gases may be necessary to prevent environmental problems and for regulatory compliance.

**Definitions: Mist, Fog, and Spray** Little standardization has been adopted in defining gas-borne liquid particles, and this often leads to confusion in the selection, design, and operation of collection equipment. *Aerosol* applies to suspended particulate, either solid or liquid, that is slow to settle by gravity and to particles from the submicrometer range up to 10 to 20 μm. Fogs and mists are fine suspended liquid dispersions that usually result from condensation, as discussed in the subsection Liquid-in-Gas Dispersions, and they range upward in particle size from around 0.1 μm. The distinction between fogs and mists is the density of the liquid dispersed in the gas, with fog referring to a denser dispersion. Spray refers to entrained liquid droplets, as described under Liquid-in-Gas Dispersions. In such instances, size will range from the finest particles produced up to a particle whose terminal settling velocity is equal to the entraining gas velocity if some settling volume is provided. Process spray is often created unintentionally, such as by the condensation of vapors on cold duct walls and its subsequent reentrainment, or from two-phase flow in pipes, gas bubbling through liquids, and entrainment from boiling liquids. Table 14-25 lists typical ranges of particle size created by different mechanisms. Figure 14-101 compares the approximate size range of liquid particles with other particulate material and the approximate applicable size range of collection devices.

**Background** Much of the development of phase separation technology has been driven by air pollution and the evolving environmental regulations. Phase separation requirements are often defined by the need to meet air emissions limits; inadequate phase separation reduces the efficiency of emissions control devices. Much development was funded by the EPA and other government agencies; many of these studies were led by Calvert [Calvert and Englund, eds., *Handbook of Air Pollution Technology,* Wiley, New York, 1984; Yung, Barbarika, and Calvert, *J. Air Pollut. Control Assoc.* 27: 348 (1977)]. Several websites provide access to this information. EPA's Air Pollution Training Institute at www.apti-learn.net provides training courses on wet scrubbers, electrostatic precipitators, and other issues related to air compliance. Another useful resource is www.ntis.gov, which provides access to the National Technical Reports Library and NTIS publications, including relevant technical reports (Calvert, Goldchmid, Leith, and Mehta, NTIS Publ. PB-213016, 213017, 1972; Calvert, Yung, and Leung, NTIS Publ. PB-248050, 1975).

**Gas Sampling** The sampling of gases containing mists and sprays may be necessary to obtain data for collection-device design, in which case particle-size distribution, total mass loading, and gas volume, temperature, pressure, and composition may all be needed. Other reasons for sampling may be to determine equipment performance, measure yield loss, or determine compliance with regulations. Sampling of two-phase systems must consider both the distribution of the phases in the system and the potential for introduction of errors through the sampling technique.

Location of a sample probe in the process stream is critical, especially when larger particles must be sampled. Mass loading in one portion of a duct may be several times greater than in another portion as affected by flow patterns. Horizontal ducts will tend to concentrate particles toward the bottom of the duct, while vertical ducts will tend to show a higher particle concentration than the true concentration in upflow and a lower concentration in downflow. Therefore, the stream should be sampled at a number of points. The U.S. Environmental Protection Agency [*Code of Federal Regulations,* 40 (CFR 40), subchapter C—Air Programs, parts 50–99, Office of the Federal Register, Washington] has specified 8 points for ducts between 0.3 and 0.6 m (12 and 24 in) and 12 points for larger ducts, provided there are no flow disturbances for eight pipe diameters upstream and two downstream from the sampling point. When only particles smaller than 3 μm are to be sampled, the location and number of sample points are less critical since such particles remain reasonably well dispersed by Brownian motion.

**TABLE 14-25 Particle Sizes Produced by Various Mechanisms**

| Mechanism or process | Particle-size range, μm |
|---|---|
| Liquid pressure spray nozzle | 100–5000 |
| Gas-atomizing spray nozzle | 1–100 |
| Gas bubbling through liquid or boiling liquid | 20–1000 |
| Condensation processes with fogging | 0.1–30 |
| Annular two-phase flow in pipe or duct | 10–2000 |

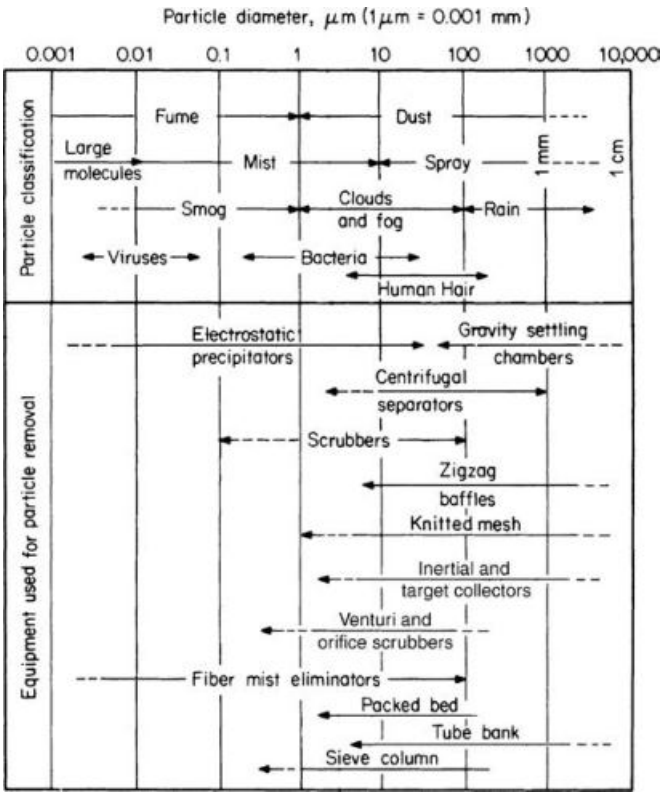

**FIG. 14-101** Particle classification and useful collection equipment versus particle size.

Isokinetic sampling (velocity at the probe inlet is equal to local duct velocity) is required to get a representative sample of particles larger than 3 μm (error is small for 4- to 5-μm particles). Lower sample velocities will result in a measured concentration lower than the true concentration, while higher sample velocities will overpredict the true concentration. Sampling methods and procedures for mass loading have been developed [Calvert and Englund, eds., *Handbook of Air Pollution Technology,* Wiley, New York, 1984; Stern, *Air Pollution,* 3d ed., vols. 3–5, Academic Press, Orlando, Fla., 1976–77; *Code of Federal Regulations,* 40 (CFR 40), subchapter C—Air Programs, parts 50–99, Office of the Federal Register, Washington].

**Particle Size Analysis** Many particle-size-analysis methods suitable for dry-dust measurement are unsuitable for liquids because of coalescence and drainage after collection. Measurement of particle sizes in the flowing stream by using a cascade impactor is one of the better means. The impacting principle was described by Ranz and Wong [*Ind. Eng. Chem.* **44:** 1371 (1952)] and Gillespie and Johnstone [*Chem. Eng. Prog.* **51:** 75F (1955)]. An impactor designed specifically for collecting liquids was described by Brink, Kennedy, and Yu [*Am. Inst. Chem. Eng. Symp. Ser.* **70**(137): 333 (1974)].

In most cases, the design for a phase separator will be based on similar successful applications and an estimate of the range of liquid particle sizes based on the mechanism for the formation of the dispersion rather than on sample results. For new systems, predictions based on similar applications must be used.

**Collection Mechanisms** Mechanisms that may be used for separating liquid particles from gases are (1) gravity settling, (2) inertial (including centrifugal) impaction, (3) flow-line interception, (4) diffusional (Brownian)

deposition, (5) electrostatic attraction, (6) thermal precipitation, (7) flux forces (thermophoresis, diffusiophoresis, Stefan flow), and (8) particle agglomeration (nucleation) techniques. These techniques are similar to techniques for gas–solid separations; equations and parameters for these mechanisms are given in Table 17-2. Most collection devices rarely operate with only a single mechanism, although one mechanism may so predominate that it may be referred to, for instance, as an inertial-impaction device.

Unlike solids, after collection, liquid particles coalesce and must be drained from the unit, minimizing reentrainment. Liquid coalescence allows the use of some devices like wire mesh pads, which would plug in gas–solid separations. Calvert (Calvert, Yung, and Leung, NTIS Publ. PB-248050, 1975) studied the mechanism of reentrainment in a number of liquid-particle collectors. Four types of reentrainment were typically observed: (1) transition from separated flow of gas and liquid to a two-phase region of separated-entrained flow, (2) rupture of bubbles, (3) liquid creep on the separator surface, and (4) shattering of liquid droplets and splashing. Generally, reentrainment increased with increasing gas velocity. Unfortunately, in devices collecting primarily by centrifugal and inertial impaction, primary collection efficiency increases with gas velocity; thus overall efficiency may go through a maximum as reentrainment overtakes the incremental increase in efficiency.

**Design and Selection of Collection Devices** The selection of phase separation equipment depends on the relative quantities of vapor and liquid, the size of the liquid particles to be removed, the separation efficiency required, the allowable pressure drop, and whether solids are also present in the system. The efficiency required may be determined by regulatory needs if a stream is being cleaned for atmospheric discharge. The particle diameter range of the dispersion combined with the efficiency will determine what the minimum particle size requiring high-efficiency removal will be. Gravity separators are the least efficient on smaller particle sizes, with centrifugal separators, impingement separators (chevrons, mesh pads, baffle separators, etc.), venturi and other scrubbers improving separation at the cost of increased pressure drop and investment. Electrostatic precipitators or fiber mist eliminators are required when the very finest particles must be removed. Because of the difficulty in predicting precisely the particle-size distribution of the liquid, experience with successful designs in similar systems should be considered, as should the experience of the equipment manufacturer. For meaningful design discussions, all of the following must be considered: operating temperature and pressure, gas flow rate and composition for normal and surge conditions, estimated liquid volume, composition, and particle-size distribution based on the process creating the dispersion, liquid and gas physical properties, available pressure drop, required efficiency, and approximate concentration, size distribution, and properties of any solids present.

Calvert and coworkers (Calvert and Englund 1984; Calvert et al. 1972; Calvert 1974; Calvert 1977; and Calvert, Yung, and Leung 1975 in General References) have suggested useful design and selection procedures for particulate-collection devices in which direct impingement and inertial impaction are the most significant mechanisms. The concept is based on the premises that the mass median aerodynamic particle diameter $d_{p50}$ is a significant measure of the difficulty of collection of the liquid particles and that the collection device cut size $d_{pc}$ (defined as the aerodynamic particle diameter collected with 50 percent efficiency) is a significant measure of the capability of the collection device. The aerodynamic diameter for a particle is the diameter of a spherical particle (with an arbitrarily assigned density of 1 g/cm$^3$) that behaves in an air stream in the same fashion as the actual particle. For airborne liquid particles, the assumption of spherical shape is reasonably accurate. For dilute aqueous particles at ambient temperatures, the actual liquid particle diameter is approximately the equivalent aerodynamic diameter. When a distribution of particle sizes that must be collected is present, the actual size distribution must be converted to a mass distribution by aerodynamic size. Often the distribution can be represented or approximated by a log-normal distribution (a straight line on a log-log plot of cumulative mass percent of particles versus diameter), which can be characterized by the mass median particle diameter $d_{p50}$ and the standard statistical deviation of particles from the median $\sigma_g$. $\sigma_g$ can be obtained from the log-log plot by $\sigma_g = D_{pa50}/D_{pe}$ at 15.87 percent $= D_{pe}$ at 84.13 percent$/D_{pa50}$.

The grade efficiency $\eta$ of most collectors can be expressed as a function of the aerodynamic particle size in the form of an exponential equation. It is simpler to write the equation in terms of the particle penetration $P_t$ (those particles not collected), where the fractional penetration $P_t = 1 - \eta$, when $\eta$ is the fractional efficiency. The typical collection equation is

$$P_t = e^{(-A^a D_{pa}{}^B)} \tag{14-221}$$

where $A_a$ and $B$ are functions of the collection device. Calvert et al. (1975) determined that for many devices in which the primary collection mechanism is direct interception and inertial impaction—such as packed beds, knitted-mesh collectors, zigzag baffles, and target collectors such as tube banks, sieve-plate columns, and venturi scrubbers—the value of $B$ is approximately 2.0. For cyclonic collectors, the value of $B$ is approximately 0.67. The overall integrated penetration $\overline{P}_t$ for a device handling a distribution of particle sizes can be obtained by

$$\overline{P}_t = \int_0^W \left(\frac{dW}{W}\right) P_t \tag{14-222}$$

where $(dW/W)$ is the mass of particles in a given narrow size distribution and $P_t$ is the average penetration for that size range. When the particles to be collected are log-normally distributed and the collection device efficiency can be expressed by Eq. (14-221), the required overall integrated collection efficiency $\overline{P}_t$ can be related to the ratio of the device aerodynamic cut size $D_{pc}$ to the mass median aerodynamic particle size $D_{pa50}$. This required ratio for a given distribution and collection is designated $R_{rL}$, and these relationships are illustrated graphically in Fig. 14-102. For the many devices for which $B$ is approximately 2.0, a simplified plot (Fig. 14-103) is obtained. From these figures, by knowing the desired overall collection efficiency and particle distribution, the value of $R_{rL}$ can be read. Substituting the mass median particle diameter gives the aerodynamic cut size required from the collection device being considered. Therefore, an experimental plot of aerodynamic cut size for each collection device versus operating parameters can be used to determine the device suitability.

**Collection Equipment**

***Gravity Settlers*** Gravity can remove larger droplets. Settling or disengaging space above aerated or boiling liquids in a tank or spray zone in a tower can be very useful. If gas velocity is kept low, all particles with terminal settling velocities (see Sec. 6) above the gas velocity will eventually settle. Increasing vessel cross section in the settling zone is helpful. Terminal velocities for particles smaller than 50 μm are very low and generally not attractive for particle removal. Laminar flow of gas in long horizontal paths between trays or shelves on which the droplets settle is another effective means of using gravity. Design equations are given in Sec. 17 under the subsection Gas–Solids Separations. Settler pressure drop is very low, usually being limited to entrance and exit losses. Gravity settling in knockout pots is often used to remove bulk liquid ahead of another device such as an impingement separator, or when a gross separation is all that is needed.

***Centrifugal Separation*** Centrifugal force can be used to enhance particle collection to several hundred times the force of gravity. The design of cyclone separators for dust removal is treated in detail in Sec. 17 under the subsection Gas–Solids Separations, and typical cyclone designs are shown in Fig. 17-55. Cyclones, if carefully designed, can be more efficient on liquids than on solids because liquids coalesce on capture and are easy to drain from the unit. However, some precautions not needed for solid cyclones are necessary to prevent reentrainment.

(*Stern et al.,* Cyclone Dust Collectors, *American Petroleum Institute, New York, 1955.*)

Cyclone separators can be used for cases of high liquid loading or in demisting applications. Kouba and Shoham ["A Review of Gas–Liquid Cylindrical Cyclone (GLCC) Technology," Production Separation Systems International Conference, Aberdeen, UK, April 23–24, 1996] describe applications of gas–liquid cylindrical cyclones (GLCCs) in oil and gas applications, including metering, preseparation, and internal applications. Hoffman and Stein (*Gas Cyclones and Swirl Tubes: Principles, Design, and Operation*, 2d ed., Springer, New York, 2008) present a detailed analysis of demisting cyclones. Cyclone separators are more efficient than spray towers, smaller and more efficient than gravity separators, and less prone to fouling than impingement separators. Internal cyclone separators have also been used effectively in retrofit situations where existing equipment is not providing adequate phase separation.

Tests by Calvert et al. (1975) showed high primary collection efficiency on droplets down to 10 μm and in accordance with the efficiency equations of Leith and Licht [*Am. Inst. Chem. Eng. Symp. Ser.* **68**(126): 196–206 (1972)] for the specific cyclone geometry tested if entrainment is avoided. Typical entrainment points are (1) creep along the gas outlet pipe, (2) entrainment by shearing of the liquid film from the walls, and (3) vortex pickup from accumulated liquid in the bottom (Fig. 14-104*a*). Reentrainment from creep of liquid along the top of the cyclone and down the outlet pipe can be prevented by providing the outlet pipe with a flared conical skirt (Fig. 14-104*b*), which provides a point from which the liquid can drip without being caught in the outlet gas. The skirt should be slightly shorter than the gas outlet pipe but should extend below the bottom of the gas inlet. The cyclone inlet gas should not impinge on this skirt. Often the bottom edge of the skirt is V-notched or serrated. Roof skimmers or inlet raceways can also be provided to reduce liquid creep.

Reentrainment is generally reduced by lower inlet gas velocities. Calvert et al. (1975) reviewed the literature on predicting the onset of entrainment and found that of Chien and Ibele (ASME Pap. 62-WA170) to be the most reliable. Calvert applied their correlation to a liquid Reynolds number on the wall of the cyclone, $N_{Re,L} = 4Q_L/h_i\upsilon_L$, where $Q_L$ is the volumetric liquid flow rate, $cm^3/s$; $h_i$ is the cyclone inlet height, cm; and $\upsilon_L$ is the kinematic liquid viscosity, $cm^2/s$. He found that the onset of entrainment occurs at a cyclone inlet gas velocity $V_{ci}$, m/s, in accordance with the relationship in $V_{ci} = 6.516 - 0.2865 \ln N_{Re,L}$.

Reentrainment from the bottom of the cyclone can be prevented in several ways. If a typical long-cone dry cyclone is used and liquid is kept continually drained, vortex entrainment is unlikely. However, a vortex breaker baffle in the outlet is desirable, and perhaps a flat disk on top extending to within 2 to 5 cm (0.8 to 2 in) of the walls may be beneficial. Often liquid cyclones are built without cones and have dished bottoms. These designs require both an isolation plate to prevent the vortex from contacting the liquid level and a vortex breaker on the liquid outlet. Perforated, vertical wall baffles can also be considered to reduce bulk rotation of the liquid pool. Research continues on the optimum designs to prevent liquid reentrainment; for example, Moen et al. (U.S. Patent 9233320 B2, Jan. 12, 2016) present configurations for roof skimmers, isolation plates, and vortex breakers to improve efficiency.

As with dust cyclones, no reliable pressure-drop equations exist (see Sec. 17), although many have been published. A part of the problem is that there is no standard cyclone geometry. Calvert et al. (1975) experimentally obtained $\Delta P = 0.000513\ \rho_g(Q_g/h_i w_i)^2(2.8h_i w_i/d_o^2)$, where $\Delta P$ is in cm of water; $\rho_g$ is the gas density, $g/cm^3$; $Q_g$ is the gas volumetric flow rate, $cm^3/s$; $h_i$ and $w_i$ are cyclone inlet height and width, respectively, cm; and $d_o$ is the gas outlet diameter, cm. This equation is in the same form as that proposed by Shepherd and Lapple [*Ind. Eng. Chem.* **31:** 1246 (1940)] but gives only 37 percent as much pressure drop.

Liquid cyclone efficiency can be improved somewhat by introducing a coarse spray of liquid in the cyclone inlet. Large droplets that are easily collected collide with finer particles as they sweep the gas stream in their travel to the wall. (See the subsection Wet Scrubbers regarding optimum spray size.) The most effective operation is obtained by spraying countercurrently to the gas flow in the cyclone inlet duct at liquid rates of 0.7 to 2.0 $L/m^3$ of gas. There are also many proprietary designs of liquid separators using centrifugal force, some of which are illustrated in Fig. 14-105. Many of these were originally developed as steam separators to remove entrained condensate. In some designs, impingement on swirl baffles aids separation.

***Impingement Separation*** Impingement separation employs direct impact and inertial forces between particles, the gas streamlines, and target bodies to provide capture. The mechanism is discussed in Sec. 17 under the subsection Gas–Solids Separations. With liquids, droplet coalescence occurs on the target surface, and provision must be made for drainage without reentrainment. Calvert et al. (1975) studied droplet collection by impingement on targets consisting of banks of tubes, zigzag baffles, and packed and mesh beds. Figure 14-106 illustrates several types of impingement-separator designs. Methods for efficiency calculations are discussed; in practice, the equipment manufacturers' experience will most likely guide the design.

In its simplest form, an impingement separator may be nothing more than a target placed in front of a flow channel such as a disk at the end of a tube. To improve collection efficiency, the gas velocity may be increased by forming the end into a nozzle (Fig. 14-106*a*). Particle collection as a function of size may be estimated by using the target-efficiency correlation in Fig. 17-52. Since target efficiency will be low for systems with separation numbers below 5 to 10 (small particles, low gas velocities), the mist will often be subjected to a number of targets in series as in Fig. 14-106*c*, *d*, and *g*.

The overall droplet penetration is the product of penetration for each set of targets in series. For a distribution of particle sizes, an integration procedure is required to give overall collection efficiency. This target-efficiency method is suitable for predicting efficiency when the design effectively prevents the bypassing or short-circuiting of targets by the gas stream and provides adequate time to accelerate the liquid droplets to gas velocity. Katz (M.S. thesis, Pennsylvania State University, 1958) investigated a jet and

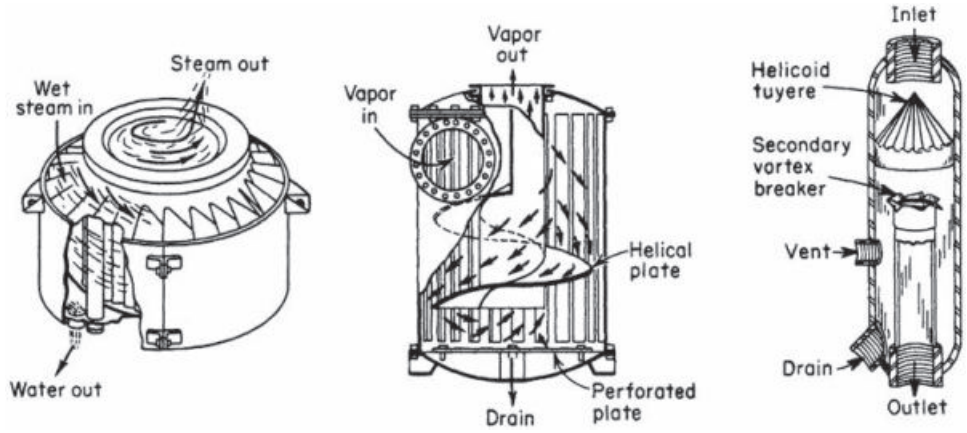

**FIG. 14-105** Typical separators using impingement in addition to centrifugal force. (*a*) Hi-eF purifier. (*V. D. Anderson Co.*) (*b*) Flick separator. (*Wurster & Sanger, Inc.*) (*c*) Type RA line separator. (*Centrifix Corp., Bull. 220.*)

target-plate entrainment separator design and found the pressure drop less than would be expected to supply the kinetic energy both for droplet acceleration and gas friction. An estimate based on his results indicates that the liquid particles on the average were being accelerated to only about 60 percent of the gas velocity. The largest droplets, which are the easiest to collect, will be accelerated less than the smaller particles. This factor has a leveling effect on collection efficiency as a function of particle size, so experimental results on such devices may not show as sharp a decrease in efficiency with particle size as predicted by calculation. Katz (1958) also studied *wave-plate impingement separators* (Fig. 14-106*b*) made up of 90° formed arcs with an 11.1-mm (0.44-in) radius and a 3.8-mm (0.15-in) clearance between sheets. The pressure drop is a function of system geometry. The pressure drop for

Katz's system and collection efficiency for a separator with seven waves are shown in Fig. 14-107. Katz used the Souders-Brown expression to define a design velocity $U$ for the gas between the waves:

$$U = K\sqrt{(\rho_l - \rho_g)/\rho_g} \tag{14-223}$$

$K$ is 0.12 to give $U$ in ms$^{-1}$ (0.4 for ft/s), and $\rho_l$ and $\rho_g$ are liquid and gas densities in any consistent set of units. Katz found no change in efficiency at gas velocities from one-half to three times that given by the equation.

Calvert et al. (1975) investigated *zigzag baffles* of a design more like Fig. 14-106*e*. The baffles may have spaces between the changes in direction or be connected as shown. He found close to 100 percent collection for water droplets of 10 μm and larger. Some designs had high efficiencies down to 5 or 8 μm. Desirable gas velocities were 2 to 3.5 m/s (6.6 to 11.5 ft/s), with a pressure drop for a six-pass baffle of 2 to 2.5 cm (0.8 to 1.0 in) of water. On the basis of turbulent mixing, an equation was developed for predicting primary collection efficiency as a function of particle size and collector geometry:

$$\eta = 1 - \exp\left[-\frac{u_{te} n W \theta}{57.3 U_g b \tan\theta}\right] \tag{14-224}$$

where $\eta$ is the fractional primary collection efficiency; $u_{te}$ is the drop terminal centrifugal velocity in the normal direction, cm/s; $U_g$ is the superficial gas velocity, cm/s; $n$ is the number of rows of baffles or bends; $\theta$ is the angle of inclination of the baffle to the flow path, °; $W$ is the width of the baffle, cm; and $b$ is the spacing between baffles in the same row, cm. For conditions of low Reynolds number ($N_{Re,D} < 0.1$) where Stokes' law applies, Calvert obtained the value for drop terminal centrifugal velocity of $u_{te} = d_p^2 \rho_p a / 18\mu_g$, where $d_p$ and $\rho_p$ are the drop particle diameter, cm, and particle density, g/cm$^3$, respectively; $\mu_g$ is the gas viscosity, P; and $a$ is the acceleration due to centrifugal force. It is defined by the equation $a = 2U_g^2 \sin\theta / W \cos^3\theta$. For situations in which Stokes' law does not apply, Calvert recommended $u_{te} = 4 d_p \rho_p a / 3 C_D \rho_g$, where $\rho_g$ is the gas density, g/cm$^2$; and $C_D$ is the drag coefficient from Foust et al. (*Principles of Unit Operations,* Toppan Co., Tokyo, 1959).

Calvert found that reentrainment from the baffles was affected by the gas velocity, the liquid-to-gas ratio, and the orientation of the baffles. Horizontal gas flow past vertical baffles provided the best drainage and lowest reentrainment. Safe operating regions with vertical baffles are shown in Fig. 14-108. Horizontal baffles gave the poorest drainage and the highest reentrainment, with inclined baffles intermediate in performance. Equation (14-225), developed by Calvert, predicts pressure drop across zigzag baffles. The indicated summation must be made over the number of rows of baffles present.

$$\Delta P = \sum_{i=1}^{i=n} 1.02 \times 10^{-3} f_D \rho_g \frac{U_g' A_p}{2 A_t} \tag{14-225}$$

$\Delta P$ is the pressure drop, cm of water; $\rho_g$ is the gas density, g/cm$^3$; $A_p$ is the total projected area of an entire row of baffles in the direction of inlet gas flow, cm$^2$; and $A_t$ is the duct cross-sectional area, cm$^2$. The value $f_D$ is a drag coefficient for gas flow past inclined flat plates taken from Fig. 14-109, while $U_g'$ is the actual gas velocity, cm/s, which is related to the superficial gas velocity $U_g$ by $U_g' = U_g/\cos\theta$. It must be noted that the angle of incidence $\theta$ for the second and successive rows of baffles is twice the angle of incidence for the first row. Most of Calvert's work was with 30° baffles, but the method correlates well with other data on 45° baffles.

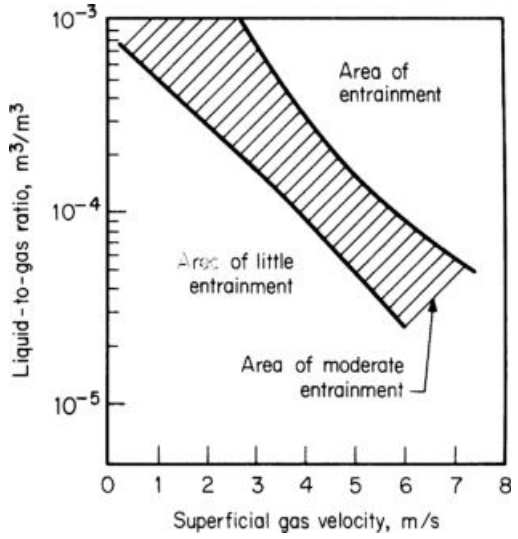

**FIG. 14-108** Safe operating region to prevent reentrainment from vertical zigzag baffles with horizontal gas flow. (*Calvert, Yung, and Leung, NTIS Publ. PB-248050, 1975.*)

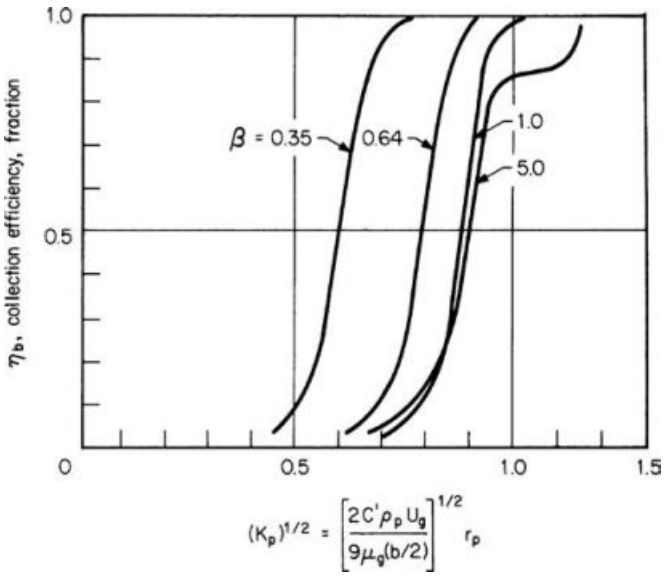

**FIG. 14-110** Experimental collection efficiencies of rectangular impactors. $C'$ is the Stokes-Cunningham correction factor; $\rho_p$, particle density, g/cm$^3$; $U_g$, superficial gas velocity, approaching the impactor openings, cm/s; and $\mu_g$, gas viscosity, P. [*Calvert, Yung, and Leung, NTIS Publ. PB-248050; based on Mercer and Chow,* J. Coll. Interface Sci. ***27:*** *75 (1968).*]

The use of multiple tube banks as a droplet collector was also studied by Calvert et al. (1975). He reported that collection efficiency for closely packed tubes follows equations for rectangular jet impaction, which can be obtained graphically from Fig. 14-110 by using a dimensionless parameter β that is based on the tube geometry; $\beta = 2l_i/b$, where $b$ is the open distance between adjacent tubes in the row (orifice width) and $l_i$ is the impaction length (distance between orifice and impingement plane), or approximately the distance between centerlines of successive tube rows. Note that the impaction parameter $K_p$ is plotted to the one-half power in Fig. 14-110 and that the radius of the droplet is used rather than the diameter. Collection efficiency overall for a given size of particle is predicted for the entire tube bank by

$$\eta = 1 - (1 - \eta_b)^N \tag{14-226}$$

where $\eta_b$ is the collection efficiency for a given size of particle in one stage of a rectangular jet impactor (Fig. 14-111) and $N$ is the number of stages in the tube bank (equal to one less than the number of rows). For widely spaced tubes, the target efficiency $\eta_g$ can be calculated from Fig. 17-52 or from the impaction data of Golovin and Putnam [*Ind. Eng. Chem. Fundam.* **1:** 264 (1962)]. The efficiency of the overall tube banks for a specific particle size can then be calculated from the equation $\eta = 1 - (1 - \eta_i a'/A)^n$, where $a'$ is the cross-sectional area of all tubes in one row, $A$ is the total flow area, and $n$ is the number of rows of tubes.

Calvert reported pressure drop through tube banks to be largely unaffected by liquid loading and indicated that Grimison's correlations in Sec. 6 (Tube Banks) for gas flow normal to tube banks or data for gas flow through heat-exchanger bundles can be used. However, the following equation is suggested:

$$\Delta P = 8.48 \times 10^{-3} n \rho_g U_g'^2 \tag{14-227}$$

where $\Delta P$ is cm of water; $n$ is the number of rows of tubes; $\rho_g$ is the gas density, g/cm$^3$; and $U_g'$ is the actual gas velocity between tubes in a row, cm/s. Calvert did find an increase in pressure drop of about 80 to 85 percent above that predicted by Eq. (14-227) in the vertical upflow of gas through tube banks due to liquid holdup at gas velocities above 4 m/s. The onset of liquid reentrainment from tube banks can be predicted from Fig. 14-111. Reentrainment occurred at much lower velocities in vertical upflow than in horizontal gas flow through vertical tube banks. While the top of the cross-hatched line of Fig. 14-111*a* predicts reentrainment above gas velocities of 3 m/s (9.8 ft/s) at high liquid loading, most of the entrainment settled to the bottom of the duct in 1 to 2 m (3.3 to 6.6 ft), and entrainment did not carry significant distances until the gas velocity exceeded 7 m/s (23 ft/s).

***Packed-Bed Collectors*** Many different materials, including coal, coke, and broken solids, as well as normal types of tower-packing rings, saddles, and special plastic shapes, have been used over the years in packed beds to remove entrained liquids through impaction and filtration. Separators using natural materials are not available as standard commercial units but

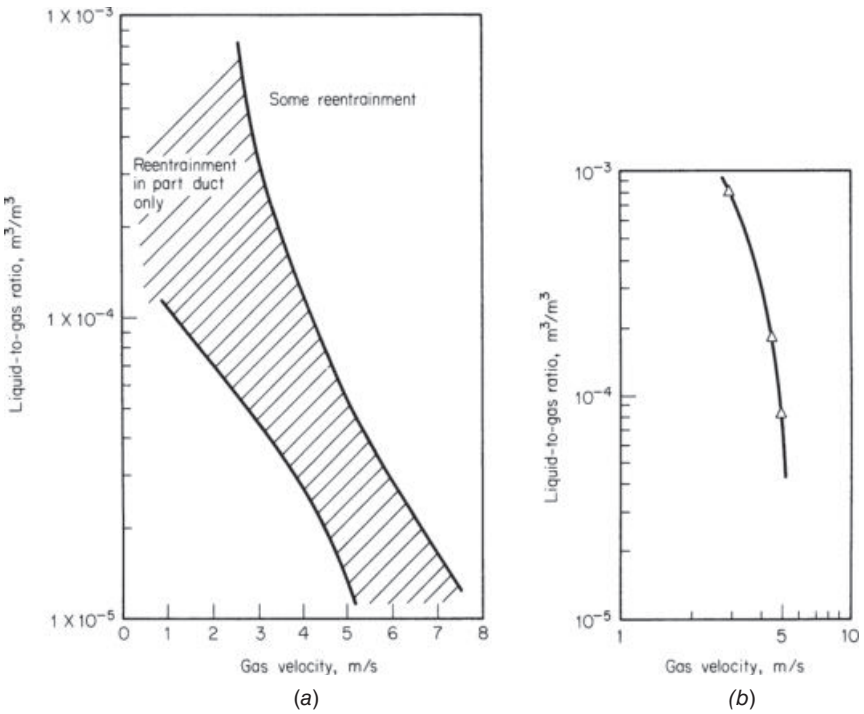

**FIG. 14-111** Experimental results showing effect of gas velocity and liquid load on entrainment from (*a*) vertical tube banks with horizontal gas flow and (*b*) horizontal tube banks with upflow. To convert meters per second to feet per second, multiply by 3.281. (*Calvert, Yung, and Leung, NTIS Publ. PB-248050.*)

are designed for specific applications and have now been largely superseded by more efficient devices.

Calvert et al. (1975) generalized several studies to predict the collection efficiencies of liquid particles in any packed bed. Assumptions in the theoretical development are that the drag force on the drop is given by Stokes' law and that the number of semicircular bends to which the gas is subjected, $\eta_1$, is related to the length of the bed, $Z$ (cm), in the direction of gas flow, the packing diameter, $d_c$ (cm), and the gas-flow channel width, $b$ (cm), such that $\eta_1 = Z/(d_c + b)$. The gas velocity through the channels, $U_{gb}$ (cm/s), is inversely proportional to the bed free volume for gas flow such that $U_{gb} = U_g[1/(\varepsilon - h_b)]$, where $U_g$ is the gas superficial velocity, cm/s, approaching the bed, $\varepsilon$ is the bed void fraction, and $h_b$ is the fraction of the total bed volume taken up with liquid, which can be obtained from data on liquid holdup in packed beds. The width of the semicircular channels $b$ can be expressed as a fraction $j$ of the diameter of the packing elements, such that $b = jd_c$. These assumptions (as modified by G. E. Goltz, personal communication) lead to an equation for predicting the penetration of a given size of liquid particle through a packed bed:

$$P_t = \exp\left[\frac{-\pi}{2(j+j^2)(\varepsilon - h_b)}\left(\frac{Z}{d_c}\right)K_p\right] \tag{14-228}$$

where

$$K_p = \frac{\rho_p d_p^2 U_g}{9\mu_g d_c} \tag{14-229}$$

Values of $\rho_p$ and $d_p$ are droplet density, g/cm$^3$, and droplet diameter, cm; $\mu_g$ is the gas viscosity, P. All other terms were defined previously. Table 14-26 gives values of $j$ calculated from experimental data of Jackson and Calvert. Values of $j$ for most manufactured packing appear to fall in the range from 0.16 to 0.19. The low value of 0.03 for coke may be due to the porosity of the coke itself.

Packed sections may be designed for vertical or horizontal gas flow with liquid flow either countercurrent, cocurrent, or cross-flow for horizontal gas flow. The cross-flow design can help prevent plugging in systems that contain solids. Calvert et al. (1975) tested the correlation in cross-flow packed beds, which tend to give better drainage than countercurrent beds, and has found the effect of gas-flow orientation insignificant. However, the onset of reentrainment was somewhat lower in a bed of 2.5-cm (1.0-in) Pall rings with gas upflow [6 m/s (20 ft/s)] than with horizontal cross-flow of gas. The onset of reentrainment was independent of liquid loading, and entrainment occurred at values somewhat above the flood point for packed beds as predicted by conventional correlations. In beds with more than 3 cm (1.2 in) of water pressure drop, the experimental drop with both vertical and horizontal gas flow was somewhat less than predicted by generalized packed-bed pressure-drop correlations. However, Calvert recommended these correlations for design as conservative.

Calvert's data indicate that packed beds irrigated only with the collected liquid can have collection efficiencies of 80 to 90 percent on mist particles down to 3 μm, but they have low efficiency on finer mist particles. Often, irrigated packed towers and towers with internals will be used with liquid having a wetting capability for the fine mist that must be collected. Calvert [Calvert et al. (1972); Calvert (1974)] reported on the efficiency of various gas-liquid-contacting devices for fine particles. Equation (14-228) can be used to calculate generalized design curves for collection in packed columns by finding parameters of packing size, bed length, and gas velocity that give collection efficiencies of 50 percent for various sizes of particles. Figure 14-112 illustrates such a plot for three gas velocities and two sizes of packing.

***Wire-Mesh Mist Collectors*** Knitted mesh of varying density and voidage is widely used for entrainment separators. Its advantage is close to 100 percent removal of drops larger than 5 μm at superficial gas velocities from about 0.2 ms/s (0.6 ft/s) to 5 m/s (16.4 ft/s), depending somewhat on the design of the mesh. Pressure drop is usually no more than 2.5 cm (1 in) of water. A major disadvantage is the ease with which tars and insoluble solids plug the mesh. The separator can be made to fit vessels of any shape and can be made of any material that can be drawn into a wire. Stainless steel and plastic fibers are most common, but other metals are sometimes used. Manufacturers typically consider the design details of these separators to be proprietary. While general correlations can be useful to understand likely performance, equipment manufacturers should be consulted for expected performance in a particular application. Generally three basic types of mesh are used: (1) layers with a crimp in the same direction (each layer is actually a nested double layer); (2) layers with a crimp in alternate directions, which increases voidage, reduces sheltering, and increases target efficiency per layer, and gives a lower pressure drop per unit length; and (3) spiral-wound layers that reduce pressure drop by one-third, but fluid creep may lead to higher entrainment. The filament size can vary from about 0.15 mm (0.006 in) for fine-wire pads to 3.8 mm (0.15 in) for some plastic fibers. Typical pad thickness varies from 100 to 150 mm (4 to 6 in), but occasionally pads up to 300 mm (12 in) thick are used.

Figure 14-113 presents an early calculated estimate of mesh efficiency as a fraction of mist-particle size. Experiments by Calvert et al. (1975) confirmed the accuracy of the equation of Bradie and Dickson (*Joint Symp. Proc. Inst. Mech. Eng./Yorkshire Br. Inst. Chem. Eng.,* 1969, pp. 24–25) for primary efficiency in mesh separators:

$$\eta = 1 - \exp(-2/3)\pi a l \eta_i) \tag{14-230}$$

**TABLE 14-26 Experimental Values for *j*, Channel Width in Packing as a Fraction of Packing Diameter**

| Packing size | | Type of packing | $j$ |
|---|---|---|---|
| cm | in | | |
| 1.27 | 0.5 | Berl and Intalox saddles, marbles, Raschig rings | 0.192 |
| 2.54 | 1.0 | Berl and Intalox saddles, pall rings | 0.190 |
| 3.8 | 1.5 | Berl and Intalox saddles, pall rings | 0.165 |
| 7.6–12.7 | 3–5 | Coke | 0.03 |

To convert meters to feet, multiply by 3.281; to convert centimeters to inches, multiply by 0.394. [*Calvert,* J. Air Pollut. Control Assoc. ***24:*** *929 (1974).*]

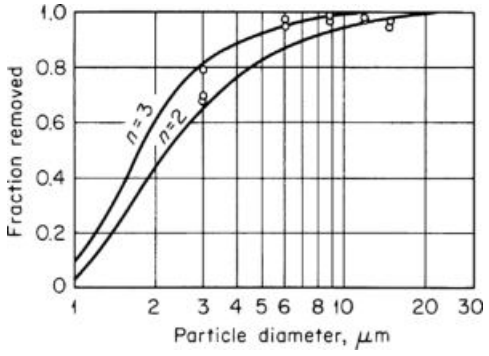

**FIG. 14-113** Collection efficiency of wire-mesh separator; 6-in thickness, 98.6 percent free space, 0.006-in-diameter wire used for experiment points. Curves calculated for target area equal to 2 and 3 times the solids volume of packing. To convert inches to millimeters, multiply by 25.4.

where $\eta$ is the overall collection efficiency for a given-size particle; $l$ is the thickness of the mesh, cm, in the direction of gas flow; $a$ is the surface area of the wires per unit volume of mesh pad, $cm^2/cm^3$; and $\eta_i$, the target collection efficiency for cylindrical wire, can be calculated from Fig. 17-52 or the impaction data of Golovin and Putnam [*Ind. Eng. Chem.* **1:** 264 (1962)]. The factor 2/3, introduced by Carpenter and Othmer [*Am. Inst. Chem. Eng. J.* **1:** 549 (1955)], corrects for the fact that not all the wires are perpendicular to the gas flow and gives the projected perpendicular area. If the specific mesh surface area $a$ is not available, it can be calculated from the mesh void area $\varepsilon$ and the mesh wire diameter $d_w$ in cm, $a = 4(1-\varepsilon)/d_w$.

York and Poppele [*Chem. Eng. Prog.* **59**(6): 45 (1963)] stated that factors governing maximum allowable gas velocity through the mesh are (1) gas and liquid density, (2) liquid surface tension, (3) liquid viscosity, (4) specific wire surface area, (5) entering-liquid loading, and (6) suspended-solids content. York [*Chem. Eng. Prog.* **50:** 421 (1954)] proposed the application of the Souders-Brown equation [Eq. (14-223)] for the correlation of maximum allowable gas velocity with values of $K$ for most cases of 0.1067 m/s to give $U$ in m/s (0.35 for ft/s). When liquid viscosity or inlet loading is high or the liquid is dirty, the value of $K$ must be reduced. Schroeder (M.S. thesis, Newark College of Engineering, 1962) found lower values for $K$ necessary when liquid surface tension is reduced, such as by the presence of surfactants in water. Ludwig (*Applied Process Design for Chemical and Petrochemical Plants,* 2d ed., vol. I, Gulf Publishing, Houston, 1977, p. 157) recommended reduced $K$ values of (0.061 m/s) under vacuum at an absolute pressure of 6.77 kPa (0.98 $lbf/in^2$) and $K = 0.082$ m/s at 54 kPa (7.83 $lbf/in^2$) absolute. Most manufacturers suggest setting the design velocity at three-fourths of the maximum velocity to allow for surges in gas flow.

York and Poppele [*Chem. Eng. Prog.* **59**(6): 45 (1963)] suggested that total pressure drop through the mesh is equal to the sum of the mesh dry pressure drop plus an increment due to the presence of liquid. They considered the mesh to be equivalent to many small circular channels and used the D'Arcy formula with a modified Reynolds number to correlate friction factor $f$ (see Fig. 14-114) for Eq. (14-231), giving dry pressure drop.

$$\Delta P_{\text{dry}} = fla\rho_g U_g^2 / 981\varepsilon^3 \qquad (14\text{-}231)$$

where $\Delta P$ is in cm of water; $f$ is from Fig. (14-114); $\rho_g$ is the gas density, $g/cm^3$; $U_g$ is the superficial gas velocity, cm/s; and $\varepsilon$ is the mesh porosity or void fraction; $l$ and $a$ are as defined in Eq. (14-230). Figure 14-114 gives data of York and Poppele for mesh crimped in the same and alternating directions and also includes the data of Satsangee, of Schurig, and of Bradie and Dickson.

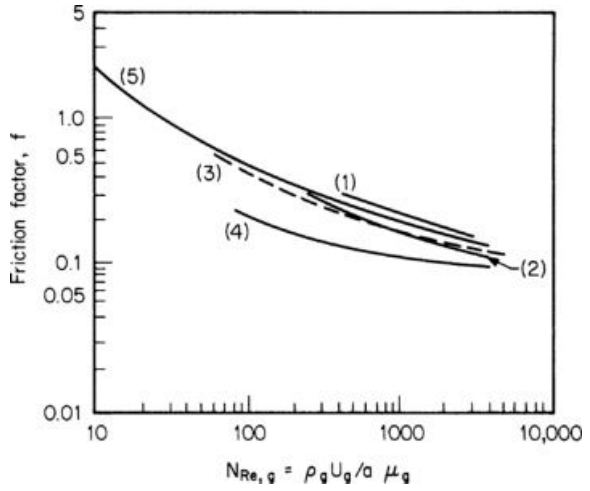

**FIG. 14-114** Value of friction factor $f$ for dry knitted mesh for Eq. (14-231). Values of York and Poppele [Chem. Eng. Prog. ***50:*** *421* (*1954*)] are given in curve 1 for mesh crimped in the alternating direction and curve 2 for mesh crimped in the same direction. Data of Bradie and Dickson (*Joint Symp. Proc. Inst. Mech. Eng./Yorkshire Br. Inst. Chem. Eng., 1969, pp. 24–25*) are given in curve 3 for layered mesh and curve 4 for spiral-wound mesh. Curve 5 is data of Satsangee (M.S. thesis, Brooklyn Polytechnic Institute, 1948) and Schurig (D.Ch.E. dissertation, Brooklyn Polytechnic Institute, 1946). (*From Calvert, Yung, and Leung, NTIS Publ. PB-248050, 1975.*)

The incremental pressure drop for wet mesh is not available for all operating conditions or for mesh of different styles. The data of York and Poppele for wet-mesh incremental pressure drop, $\Delta P_L$ in cm of water, are shown in Fig. 14-115 for parameters of liquid velocity $L/A$, defined as liquid volumetric flow rate, $cm^3/min$ per unit of mesh cross-sectional area in $cm^2$; liquid density $\rho_L$ is in $g/cm^3$.

York generally recommends the installation of the mesh horizontally with upflow of gas as in Fig. 14-106*f;* Calvert et al. (1975) tested the mesh horizontally with upflow and vertically with horizontal gas flow. He reported better drainage with the mesh vertical and somewhat higher permissible gas velocities without reentrainment, which is contrary to past practice. With horizontal flow through vertical mesh, he found collection efficiency to follow

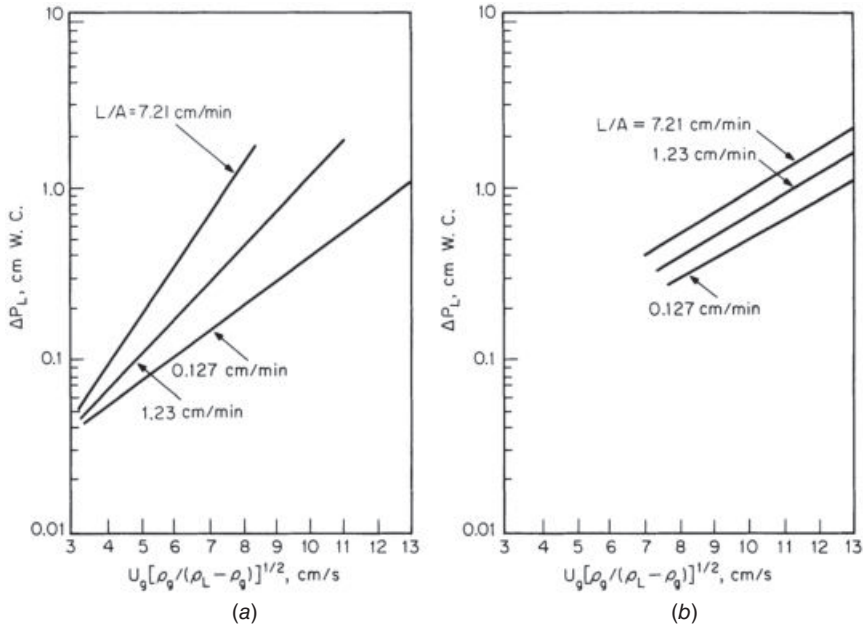

**FIG. 14-115** Incremental pressure drop in knitted mesh due to the presence of liquid (*a*) with the mesh crimps in the same direction and (*b*) with crimps in the alternating direction, based on the data of York and Poppele [*Chem. Eng. Prog.* **50:** 421 (*1954*)]. To convert centimeters per minute to feet per minute, multiply by 0.0328; to convert centimeters per second to feet per second, multiply by 0.0328. (*From Calvert, Yung, and Leung, NTIS Publ. PB-248050, 1975.*)

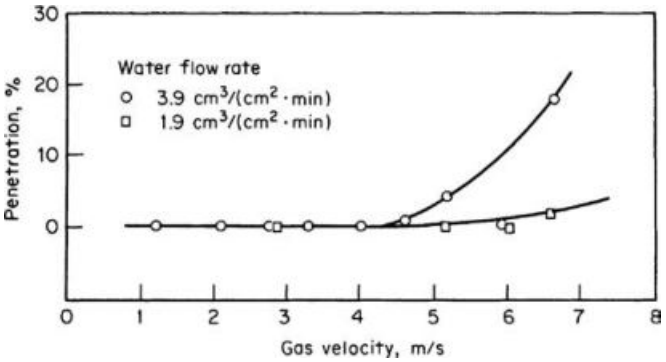

**FIG. 14-116** Experimental data of Calvert with air and water in mesh with vertical upflow, showing the effect of liquid loading on efficiency and reentrainment. To convert meters per second to feet per second, multiply by 3.281; to convert cubic centimeters per square centimeter-minute to cubic feet per square foot-minute, multiply by 0.0328. the predictions of Eq. (14-230) up to 4 m/s (13 ft/s) with air and water. Some reentrainment was encountered at higher velocities, but it did not appear serious until velocities exceeded 6.0 m/s (20 ft/s). With vertical upflow of gas, entrainment was encountered at velocities above and below 4.0 m/s (13 ft/s), depending on inlet liquid quantity (see Fig. 14-116). Figure 14-117 illustrates the onset of entrainment from mesh as a function of liquid loading and gas velocity and the safe operating area recommended by Calvert. Measurements of dry pressure drop by Calvert gave values only about one-third of those predicted from Eq. (14-231). He found the pressure drop to be highly affected by liquid load. The pressure drop of wet mesh could be correlated as a function of $U_g^{1.65}$ and parameters of liquid loading $L/A$, as shown in Fig. 14-118.

As indicated previously, mesh efficiency drops rapidly as particles decrease in size below 5 μm. An alternative is to use two mesh pads in series. The first mesh is made of fine wires and is operated beyond the flood point. It results in droplet coalescence, and the second mesh, using standard wire and operated below flooding, catches entrainment from the first mesh. Coalescence and flooding in the first mesh may be assisted with water sprays or irrigation. Massey [*Chem. Eng. Prog.* **53**(5): 114 (1959)] and Coykendall et al. [*J. Air Pollut. Control Assoc.* **18:** 315 (1968)] discussed

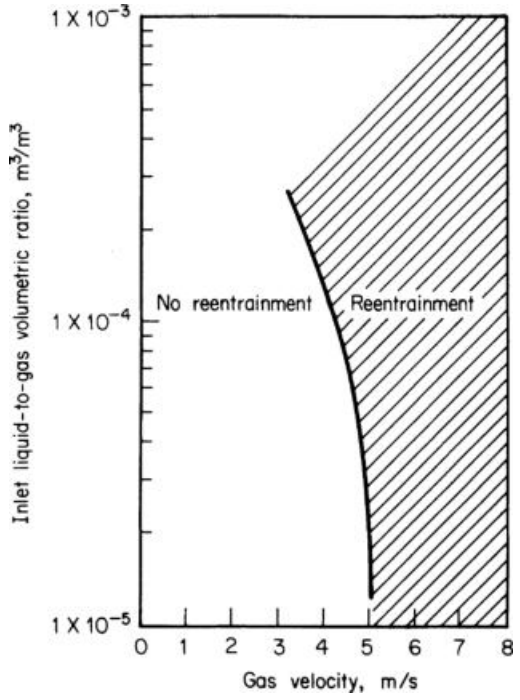

**FIG. 14-117** Effect of gas and liquid rates on onset of mesh reentrainment and safe operating regions. To convert meters per second to feet per second, multiply by 3.281. (*Calvert, Yung, and Leung, NTIS Publ. PB-248050, 1975.*)

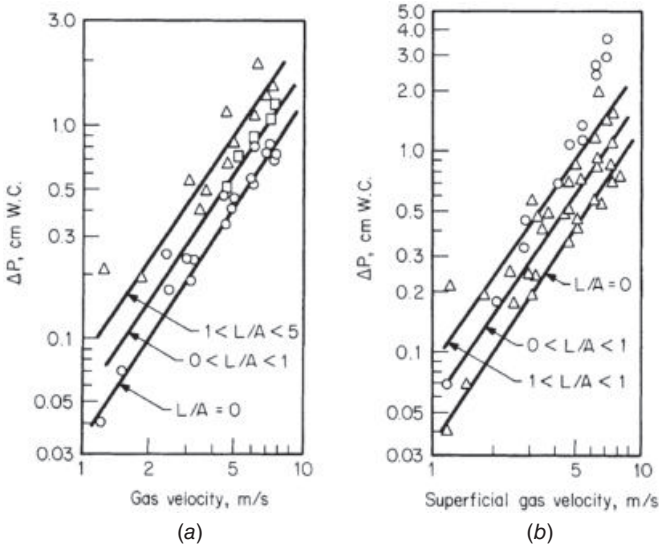

**FIG. 14-118** Experimental pressure measured by Calvert as a function of gas velocity and liquid loading for (*a*) horizontal gas flow through vertical mesh and (*b*) gas upflow through horizontal mesh. Mesh thickness was 10 cm with 2.8-mm wire and void fraction of 98.2 percent, crimped in alternating directions. To convert meters per second to feet per second, multiply by 3.281; to convert centimeters to inches, multiply by 0.394. (*Calvert, Yung, and Leung, NTIS Publ. PB-248050, 1975.*)

such applications. Calvert et al. (1975) presented data on the particle size of entrained drops from mesh as a function of gas velocity, which can be used for sizing the secondary collector. A major disadvantage of this approach is high pressure drop, which can be in the range from 25 cm (10 in) of water to as high as 85 cm (33 in) of water if the mist is mainly submicrometer.

***Wet Scrubbers*** Scrubbers have not been widely used for the collection of purely liquid particulate, probably because they are generally more complex and expensive than impaction devices of the types previously discussed. Further, scrubbers are no more efficient than the former devices for the same energy consumption. However, scrubbers of the types discussed in Sec. 17 and illustrated in Figs. 17-58 to 17-64 can be used to capture liquid particles efficiently. Their use is primarily indicated when we wish to accomplish another task at the same time, such as gas absorption or the collection of solid and liquid particulate mixtures.

Figure 14-119 gives calculated particle cut size as a function of tower height (or length) for vertical countercurrent spray towers and for horizontal-gas-flow, vertical-liquid-flow cross-current spray towers with parameters for liquid drop size. These curves are based on physical properties of standard air and water and should be used under conditions in which these are reasonable approximations. Lack of uniform liquid distribution or liquid flowing down the walls can affect the performance, requiring empirical correction factors. Many more complicated wet scrubbers use a combination of sprays or liquid atomization, cyclonic action, baffles, and targets. These combinations are not likely to be more efficient than similar devices previously discussed that operate at equivalent pressure drop. The vast majority of wet scrubbers operate at moderate pressure drop [8 to 15 cm (3 to 6 in) of water or 18 to 30 cm (7 to 12 in) of water] and cannot be expected to have high efficiency on particles smaller than 10 μm or 3 to 5 μm, respectively. Fine and submicrometer particles can be captured efficiently only in wet scrubbers that have high-energy input such as venturi scrubbers, two-phase eductor scrubbers, and flux-force-condensation scrubbers.

***Venturi Scrubbers*** One type of venturi scrubber is illustrated in Fig. 17-58. Venturi scrubbers have been used extensively for collecting fine and submicrometer solid particulate, condensing tars and mists, and mixtures of liquids and solids. To a lesser extent, they have also been used for simultaneous gas absorption, although Lundy [*Ind. Eng. Chem.* **50:** 293 (1958)] indicated that they are generally limited to three transfer units. Venturi scrubbers use pressure drop at the throat to generate many liquid droplets. The large number of liquid droplets reduces the distance a small particle must travel to collide with a larger droplet and be captured. The collection efficiency of a venturi scrubber is highly dependent on the throat velocity or pressure drop, the liquid-to-gas ratio, and the chemical nature of wettability of the particulate. Throat velocities may range from 60 to 150 m/s (200 to 500 ft/s). Liquid injection rates are typically 0.67 to 1.4 $m^3$/1000 $m^3$ of gas. A liquid rate of 1.0 $m^3$ per 1000 $m^3$ of gas is usually close to optimum, but liquid rates as high as 2.7 $m^3$ (95 $ft^3$) have been used. Efficiency improves

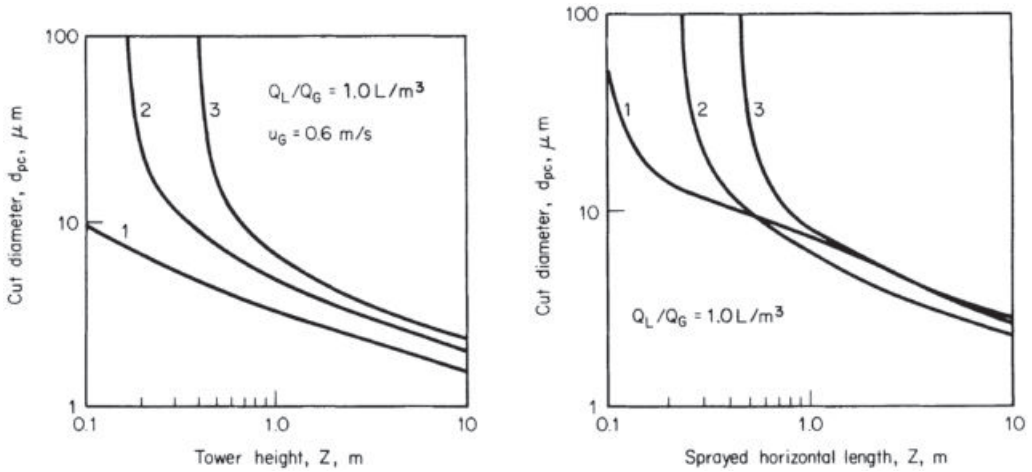

**FIG. 14-119** Predicted spray-tower cut diameter as a function of sprayed length and spray droplet size for (*a*) vertical-countercurrent towers and (*b*) horizontal-cross-flow towers per Calvert [J. Air Pollut. Control Assoc. ***24:*** 929 (*1974*)]. Curve 1 is for 200-μm spray droplets, curve 2 for 500-μm spray, and curve 3 for 1000-μm spray. $Q_L/Q_G$ is the volumetric liquid-to-gas ratio, $L$ liquid/m³ gas, and $u_G$ is the superficial gas velocity in the tower. To convert liters per cubic meter to cubic feet per cubic foot, multiply by $10^{-3}$.

with increased liquid rate but only at the expense of higher pressure drop and energy consumption. Pressure-drop predictions for a given efficiency are hazardous without determining the nature of the particulate and the liquid-to-gas ratio. In general, particles coarser than 1 μm can be collected efficiently with pressure drops of 25 to 50 cm of water. For appreciable collection of submicrometer particles, pressure drops of 75 to 100 cm (30 to 40 in) of water are usually required. When particles are much finer than 0.5 μm, pressure drops of 175 to 250 cm (70 to 100 in) of water have been used.

One of the problems in predicting the efficiency and required pressure drop of a venturi is the chemical nature or wettability of the particulate, which on 0.5-μm-size particles can make up to a threefold difference in the required pressure drop for its efficient collection. Calvert (Calvert et al. 1972; Calvert 1974) represented this effect with an empirical factor *f*, which is based on the hydrophobic ($f = 0.25$) or hydrophilic ($f = 0.50$) nature of the particles. Figure 14-120 gives the cut diameter of a venturi scrubber as a function of its operating parameters (throat velocity, pressure drop, and liquid-to-gas ratio) for hydrophobic particles. Figure 14-121 compares cut diameter as a function of pressure drop for an otherwise identically operating venturi on hydrophobic and hydrophilic particles. Calvert et al. (1972) give equations that can be used to construct cut-size curves similar to those of Fig. 14-121 for other values of the empirical factor *f*. Most real particles are neither completely hydrophobic nor completely hydrophilic but have *f* values lying between the two extremes. Unfortunately, no chemical-test methods have yet been devised for determining appropriate *f* values for a particulate in the laboratory, so design must be guided by experience in similar applications.

The pressure drop in a venturi scrubber is controlled by throat velocity. While some venturis have fixed throats, many are designed with variable louvers to change throat dimensions and control performance for changes in gas flow.

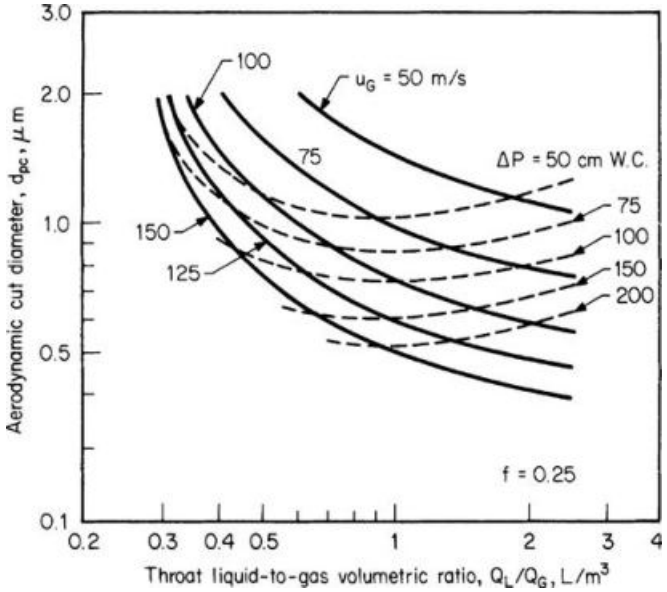

**FIG. 14-120** Prediction of venturi-scrubber cut diameter for hydrophobic particles as functions of operating parameters as measured by Calvert [*Calvert, Goldshmid, Leith, and Mehta, NTIS Publ. PB-213016, 213017, 1972; and Calvert*, J. Air Pollut. Control Assoc. ***24:*** *929 (1974)*]. $u_G$ is the superficial throat velocity, and $\Delta P$ is the pressure drop from converging to diverging section. To convert meters per second to feet per second, multiply by 3.281; to convert liters per cubic meter to cubic feet per cubic foot, multiply by $10^{-3}$; and to convert centimeters to inches, multiply by 0.394.

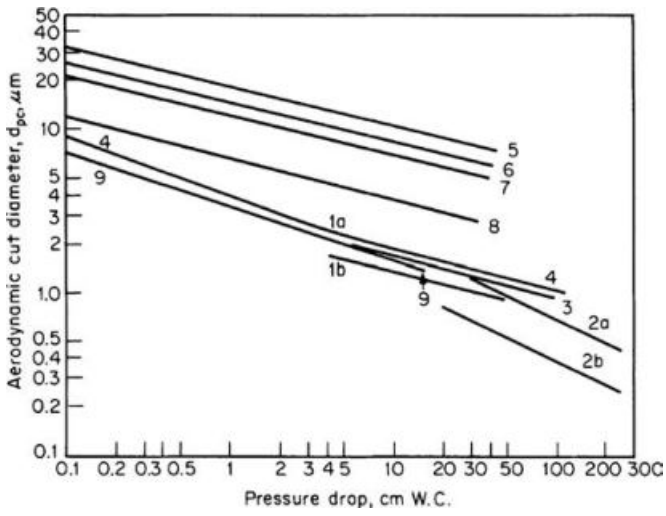

**FIG. 14-121** Typical cut diameter as a function of pressure drop for various liquid-particle collectors. Curves 1*a* and *b* are single-sieve plates with froth density of 0.4 g/cm³; 1*a* has sieve holes of 0.5 cm and 1*b* holes of 0.3 cm. Curves 2*a* and *b* are for a venturi scrubber with hydrophobic particles (2*a*) and hydrophilic particles (2*b*). Curve 3 is an impingement plate, and curve 4 is a packed column with 2.5-cm-diameter packing. Curve 5 is a zigzag baffle collector with six baffles at θ = 30°. Curve 7 is for six rows of staggered tubes with 1-cm spacing between adjacent tube walls in a row. Curve 8 is similar, except that tube-wall spacing in the row is 0.3 cm. Curve 9 is for wire-mesh pads. To convert grams per cubic centimeter to pounds per cubic foot, multiply by 62.43; to convert centimeters to inches, multiply by 0.394. [*Calvert*, J. Air Pollut. Control Assoc. ***24:*** *929 (1974); and Calvert, Yung, and Leung, NTIS Publ. PB-248050, 1975.*]

Calvert (Yung, Barbarika, and Calvert 1977) critiqued the many pressure-drop equations and suggested the following simplified equation as accurate to ±10 percent:

$$\Delta P = \frac{2\rho_\ell U_g^2}{981 g_c}\left(\frac{Q_\ell}{Q_g}\right)\left[1 - x^2 + \sqrt{(x^4 - x^2)^{0.5}}\right] \qquad (14\text{-}232)$$

where

$$x = (3 l_t C_{Di}\rho_g / 16 d_l \rho_l) + 1 \qquad (14\text{-}233)$$

$\Delta P$ is the pressure drop, cm of water; $\rho_\ell$ and $\rho_g$ are the density of the scrubbing liquid and gas respectively, g/cm$^3$; $U_g$ is the velocity of the gas at the throat inlet, cm/s; $Q_\ell/Q_g$ is the volumetric ratio of liquid to gas at the throat inlet, dimensionless; $l_t$ is the length of the throat, cm; $C_{Di}$ is the drag coefficient, dimensionless, for the mean liquid diameter, evaluated at the throat inlet; and $d_l$ is the Sauter mean diameter, cm, for the atomized liquid. The drag coefficient $C_{Di}$ should be evaluated by the Dickinson and Marshall [*Am. Inst. Chem. Eng. J.* **14:** 541 (1968)] correlation

$$C_{Di} = 0.22 + (24/N_{\mathrm{Re}i})(1 + 0.15\, N_{\mathrm{Re}i}^{0.6}) \qquad (14\text{-}234)$$

The Reynolds number, $N_{\mathrm{Re}i}$, is evaluated at the throat inlet conditions as $d_\ell G_g/\mu_g$.

All venturi scrubbers must be followed by an entrainment collector for the liquid spray. These collectors will have an additional pressure drop that must be added to that of the venturi itself.

***Other Scrubbers*** A liquid-ejector venturi (Fig. 17-59), in which high-pressure water from a jet induces the flow of gas, has been used to collect mist particles in the 1- to 2-μm range, but submicrometer particles will generally pass through an eductor. Power costs for liquid pumping are high if appreciable motive force must be imparted to the gas because jet-pump efficiency is usually less than 10 percent. Harris [*Chem. Eng. Prog.* **42**(4): 55 (1966)] described their application. Two-phase eductors have been considerably more successful on the capture of submicrometer mist particles and could be attractive in situations in which large quantities of waste thermal energy are available. However, the equivalent energy consumption is equal to that required for high-energy venturi scrubbers, and such devices are likely to be no more attractive than venturi scrubbers when the thermal energy is priced at its proper value. Sparks [*J. Air Pollut. Control Assoc.* **24:** 958 (1974)] discussed steam ejectors giving 99 percent collection of particles 0.3 to 10 μm. Energy requirements were 311,000 J/m$^3$ (8.25 Btu/scf). Gardenier [*J. Air Pollut. Control Assoc.* **24:** 954 (1974)] operated a liquid eductor with high-pressure (6900- to 27,600-kPa) (1000- to 4000-lbf/in$^2$) hot water heated to 200°C (392°F) that flashed into two phases as it issued from the jet. He obtained 95 to 99 percent collection of submicrometer particulate. Figure 14-122 shows the water-to-gas ratio required as a function of particle size to achieve 99 percent collection.

***Effect of Gas Saturation in Scrubbing*** If hot unsaturated gas is introduced into a wet scrubber, spray particles will evaporate to cool and saturate the gas. The evaporating liquid molecules moving away from the target droplets will repel particles that might collide with them. This results in the forces of diffusiophoresis opposing particle collection. Semrau and Witham (Air Pollut. Control Assoc. Prepr. 75-30.1) investigated temperature parameters in wet scrubbing and found a definite decrease in the efficiency of evaporative scrubbers and an enhancement of efficiency when a hot saturated gas was scrubbed with cold water rather than with recirculated hot water. Little improvement was experienced in cooling a hot saturated gas below a 50°C dew point.

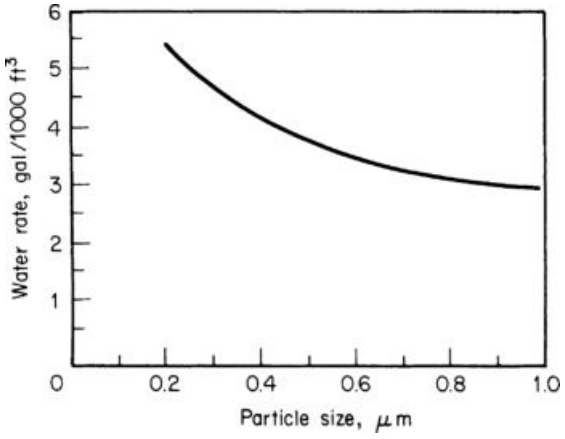

**FIG. 14-122** Superheated high-pressure hot-water requirements for 99 percent collection as a function of particle size in a two-phase eductor jet scrubber. To convert gallons per 1000 cubic feet to cubic meters per 1000 cubic meters, multiply by 0.134. [*Gardenier,* J. Air Pollut. Control Assoc. ***24:*** *954 (1974).*]

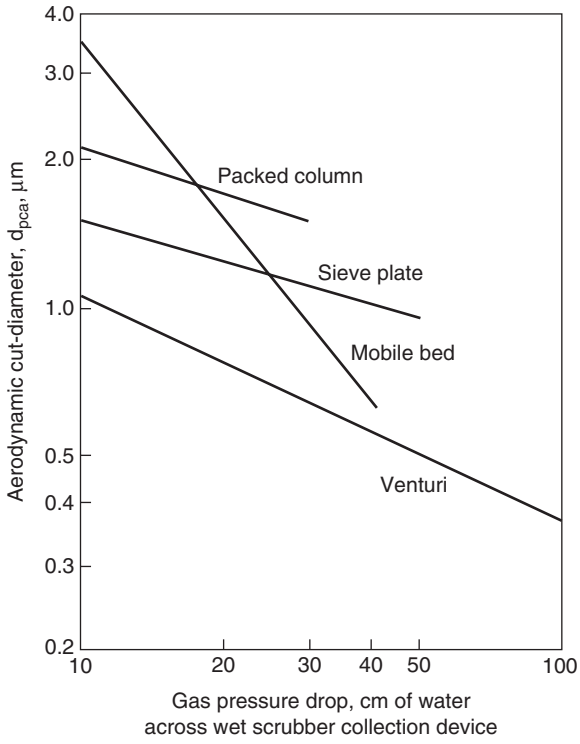

**FIG. 14-123** Calvert's refined particle cut-size/power relationship for particle inertial impaction wet collectors. (*Calvert and Englund, eds.,* Handbook of Air Pollution Technology, *Wiley, New York, 1984, chap. 10, pp. 215–248, by permission.*)

**Energy Requirements for Inertial-Impaction Efficiency** Calvert (Calvert and Englund 1984, p. 228) combined mathematical modeling with performance tests on a variety of industrial scrubbers and obtained a refinement of the power-input/cut-size relationship as shown in Fig. 14-123. He considered these relationships sufficiently reliable to use these data as a tool for the selection of scrubber type and performance prediction. The power input for this figure is based solely on gas pressure drop across the device.

**Collection of Fine Mists** Inertial-impaction devices previously discussed give high efficiency on particles above 5 μm in size and often reasonable efficiency on particles down to 3 μm in size at moderate pressure drops. However, this mechanism becomes ineffective for particles smaller than 3 μm because of the particles' gas-like mobility. Only impaction devices having extremely high energy input, such as venturi scrubbers and flooded mesh pads, can give high collection efficiency on fine particles, 3 μm and smaller, including the submicrometer range. Fine particles are subjected to Brownian motion in gases, and diffusional deposition can be used for their collection. Diffusional deposition becomes highly efficient as particles become smaller, especially below 0.2 to 0.3 μm. Table 14-27 shows the typical displacement velocity of particles. Randomly oriented fiber beds having tortuous and narrow gas passages are suitable devices for using this collection mechanism. (The diffusional collection mechanism is discussed in Sec. 17 under Mechanisms of Dust Collection.) Other collection mechanisms that are efficient for fine particles are electrostatic forces and flux forces, such as thermophoresis and diffusiophoresis. Particle growth and nucleation methods are also applicable. Efficient collection of fine particles is important because particles in the range of 2.0 to around 0.2 μm are the ones that penetrate and are deposited in the lung most efficiently. Hence, particles in this range constitute the largest health hazard.

**Fiber Mist Eliminators** These devices are produced in various configurations and are highly efficient for fine particles. Generally, randomly oriented glass or polypropylene fibers are densely packed between

**TABLE 14-27 Brownian Movement of Particles***

| Particle diameter, μm | Brownian displacement of particle, μm/s |
|---|---|
| 0.1 | 29.4 |
| 0.25 | 14.2 |
| 0.5 | 8.92 |
| 1.0 | 5.91 |
| 2.5 | 3.58 |

**TABLE 14-28 Operating Characteristics of Various Types of Fiber Mist Eliminators as Used on Sulfuric Acid Plants***

| | High efficiency | High velocity | Spray catcher |
|---|---|---|---|
| Controlling mechanism for mist collection | Brownian movement | Impaction | Impaction |
| Superficial velocity, m/s | 0.075–0.20 | 2.0–2.5 | 2.0–2.5 |
| Efficiency on particles greater than 3 μm, % | Essentially 100 | Essentially 100 | Essentially 100 |
| Efficiency on particles 3 μm and smaller, % | 95–99+ | 90–98 | 15–30 |
| Pressure drop, cm $H_2O$ | 12–38 | 15–20 | 1.0–2.5 |

*Brink, Burggrabe, and Greenwell, *Chem. Eng. Prog.,* **64**(11), 82 (1968). To convert centimeters to inches, multiply by 0.394.

reinforcing screens, producing fiber beds varying in thickness, usually from 25 to 75 mm (1 to 3 in), although thicker beds can be produced. Units with efficiencies as high as 99.9 percent on fine particles have been developed (see *Chemical Engineers' Handbook,* 5th ed., p. 18-88). A combination of mechanisms interacts to provide the high overall collection efficiency: particles larger than 2 to 3 μm are collected on the fibers by inertial impaction and direct interception, while small particles are collected by Brownian diffusion. When the device is designed to use this latter mechanism as the primary means, efficiency turndown problems are eliminated as collection efficiency by diffusion increases with residence time. Pressure drop through the beds increases with velocity to the first power since the gas flow is laminar.

Three series of fiber mist eliminators are typically available. A spray-catcher series uses inertial impacting as the controlling collection mechanism and is designed for essentially 100 percent capture of droplets larger than 3 μm. The high-velocity type also uses impaction and is designed to give moderately high efficiency on particles down to 1.0 μm. Both of these types are usually produced in the form of flat panels of 25- to 50-mm (1- to 2-in) thickness. The high-efficiency type uses Brownian motion to provide high efficiency on particles less than 3 μm and is illustrated in Fig. 14-124. As mist particles are collected, they coalesce into a liquid film that wets the fibers. Liquid is moved horizontally through the bed by the gas drag force and downward by gravity. It drains down the downstream retaining screen to the bottom of the element and is returned to the process through a liquid seal. Table 14-28 gives typical operating characteristics of the three types of collectors.

Solid particulates are captured as readily as liquids in fiber beds but can rapidly plug the bed if they are insoluble. Fiber beds have often been used for mixtures of liquids and soluble solids and with soluble solids in condensing situations. Enough solvent is atomized into the gas stream entering the collector to irrigate the fiber elements and dissolve the collected particulate. Such fiber beds have been used to collect fine fumes such as ammonium nitrate and ammonium chloride smokes, and oil mists from compressed air.

**Electrostatic Precipitators** The principles and operation of electrical precipitators are discussed in Sec. 17 under the subsection Gas–Solids Separations. Gas–liquid electrostatic precipitation has an advantage over gas–solid precipitation because the collected liquid can readily drain. Precipitators are admirably suited to the collection of fine mists and mixtures of mists and solid particulates. They have the advantage of low pressure drop compared to venturi scrubbers or fiber mist eliminators, but they require large areas. Electrostatic precipitators can be dry or wet types, with wet precipitators using water sprays or overflowing weirs. Such precipitators operate on the principle of making all particles conductive when possible, which increases the particle migration velocity and collection efficiency. Under these conditions, particle dielectric strength becomes a much more important variable, and particles with a low dielectric constant such as condensed hydrocarbon mists become much more difficult to collect than water-wettable particles. Bakke (U.S.–U.S.S.R. Joint Work. Group Symp.: Fine Particle Control, San Francisco, 1974) developed equations for particle charge and relative collection efficiency in wet precipitators that show the effect of dielectric constant. Wet precipitators can also be used to absorb soluble gases simultaneously by adjusting the pH or the chemical composition of the liquid spray. The presence of the electric field appears to enhance absorption. Wet precipitators have found their greatest usefulness to date in handling mixtures of gaseous pollutants and submicrometer particulate (either liquid or solid, or both) such as fumes from aluminum-pot lines, carbon anode baking, fiberglass-fume control, coke-oven and metallurgical operations, chemical incineration, and phosphate-fertilizer operations. Two-stage precipitators are used increasingly for moderate-volume gas streams containing nonconductive liquid mists that will drain from the collecting plates. Their application on hydrocarbon mists has been quite successful, but careful attention must be given to fire and explosion hazards.

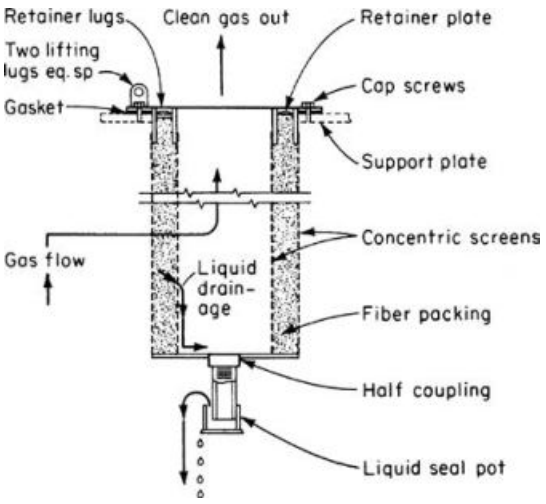

**FIG. 14-124** Monsanto high-efficiency fiber-mist-eliminator element. (*Monsanto Company.*)

**Electrically Augmented Collectors** Collection efficiency can be enhanced by the combining of electrostatic forces with devices using other collecting mechanisms, such as impaction and diffusion. Cooper (Air Pollut. Control Assoc. Prepr. 75-02.1) evaluated the magnitude of forces operating between charged and uncharged particles and concluded that electrostatic attraction is the strongest collecting force operating on particles finer than 2 μm. Nielsen and Hill [*Ind. Eng. Chem. Fundam.* **15:** 149 (1976)] quantified these relationships, and a number of practical devices have been demonstrated. Pilat and Meyer (NTIS Publ. PB-252653, 1976) demonstrated up to 99 percent collection of fine particles in a two-stage spray tower in which the inlet particles and water spray were charged with opposite polarity. The principle has been applied to retrofitting existing spray towers to enhance collection.

Klugman and Sheppard (Air Pollut. Control Assoc. Prepr. 75-30.3) developed an ionizing wet scrubber in which the charged mist particles were collected in a grounded, irrigated cross-flow bed of Tellerette packing. Particles smaller than 1 μm have been collected with 98 percent efficiency by using two units in series. Dembinsky and Vicard (Air Pollut. Control Assoc. Prepr. 78-17.6) used an electrically augmented low-pressure [5 to 10 cm (2 to 4 in) of water] venturi scrubber to give 95 to 98 percent collection efficiency on submicrometer particles.

**Particle Growth and Nucleation** Fine particles may be subjected to conditions that favor the growth of particles, either through condensation or through coalescence. Saturation of a hot gas stream with water, followed by condensation on the particles acting as nuclei when the gas is cooled, can increase particle size and ease of collection. The addition of steam can produce the same results. Scrubbing of the humid gas with a cold liquid can bring diffusiophoresis into play. The introduction of cold liquid drops causes a reduction in water-vapor pressure at the surface of the cold drop. The resulting vapor-pressure gradient causes a hydrodynamic flow toward the drop known as Stefan flow, which enhances the movement of mist particles toward the spray drop. If the molecular mass of the diffusing vapor is different from the carrier gas, this density difference also produces a driving force, and the sum of these forces is known as diffusiophoresis. A mathematical description of these forces was presented by Calvert et al. (1972)

and by Sparks and Pilat [*Atmos. Environ.* **4:** 651 (1970)]. Thermal differences between the carrier gas and the cold scrubbing droplets can further enhance collection through thermophoresis. Calvert and Jhaseri [*J. Air Pollut. Control Assoc.* **24:** 946 (1974); and NTIS Publ. PB-227307, 1973] investigated condensation scrubbing in multiple-sieve plate towers.

Submicrometer droplets can be coagulated through Brownian diffusion if given ample time. The introduction of particles 50 to 100 times larger in diameter can enhance coagulation, but the addition of a broad range of particle sizes is discouraged. Increasing turbulence will aid coagulation, so fans to stir the gas or narrow, tortuous passages such as those of a packed bed can be beneficial. Sonic energy can also produce coagulation, especially the production of standing waves in the confines of long, narrow tubes. The addition of water and oil mists can sometimes aid sonic coagulation. Sulfuric acid mist [Danser, *Chem. Eng.* **57**(5): 158 (1950)] and carbon black [Stokes, *Chem. Eng. Prog.* **46:** 423 (1950)] have been successfully agglomerated with sonic energy. Sonic agglomeration is often unsuccessful because of its high energy requirements. Most sonic generators have very poor energy-transformation efficiency. Wegrzyn et al. (U.S. EPA Publ. EPA-600/7-79-004C, 1979, p. 233) reviewed acoustic agglomerators. Mednikov (*U.S.S.R. Akad. Soc.*, Moscow, 1963) suggested that the incorporation of sonic agglomeration with electrostatic precipitation could greatly reduce precipitator size.

**Other Collectors** Tarry particulates and other difficult-to-handle liquids have been collected on a dry, expendable phenol formaldehyde-bonded glass-fiber mat (Goldfield, *J. Air Pollut. Control Assoc.* **20:** 466 (1970)] in roll form that is advanced intermittently into a filter frame. Superficial gas velocities are 2.5 to 3.5 m/s (8.2 to 11.5 ft/s), and pressure drop is typically 41 to 46 cm (16 to 18 in) of water. Collection efficiencies of 99 percent have been obtained on submicrometer particles. Brady [*Chem. Eng. Prog.* **73**(8): 45 (1977)] discussed a cleanable modification of this approach in which the gas is passed through a reticulated foam filter that is slowly rotated and solvent-cleaned.

In collecting very fine (mainly submicron) mists of a hazardous nature where one of the collectors previously discussed has been used as the primary one ( fiber-mist eliminators of the Brownian diffusion type and electrically augmented collectors are primarily recommended), there is the chance that the effluent concentration may still be too high for atmospheric release when residual concentration must be in the range of 1 to 2 μm. In such situations, secondary treatment may be needed. Removal of the residual mist by adsorption will probably be in order. See Sec. 16, Adsorption and Ion Exchange. Another possibility might be treatment of the remaining gas by membrane separation. See the subsection Membrane Separation Processes in Sec. 20.

**Continuous Phase Uncertain** Some situations exist, such as in two-phase gas–liquid flow, where the volume of the liquid phase may approach being equal to the volume of the vapor phase, and where it may be difficult to be sure which phase is the continuous phase. Svrcek and Monnery [*Chem. Eng. Prog.* **89**(10): 53–60 (1993)] have discussed the design of two-phase separation in a tank with gas–liquid separation in the middle, mist elimination in the top, and entrained gas-bubble removal from the liquid in the bottom. A design approach for sizing the gas–liquid disengaging space in the vessel is given using a tangential tank inlet nozzle, followed by a wire mesh mist eliminator in the top of the vessel for final separation of entrained mist from the vapor.

## LIQUID-PHASE CONTINUOUS SYSTEMS

Practical separation techniques for gases dispersed in liquids are discussed in this subsection. Processes and methods for dispersing gas in liquid have been discussed earlier in this section, together with information for predicting the bubble size produced. Gas-in-liquid dispersions are also produced in chemical reactions and electrochemical cells in which a gas is liberated. Such dispersions are likely to be much finer than those produced by the dispersion of a gas. Dispersions may also be unintentionally created in the vaporization of a liquid.

**Types of Gas-in-Liquid Dispersions** "Gas-in-liquid dispersions" describes the formation of these dispersions. For separation, an important distinction is that between unstable dispersions, which separate readily under the influence of gravity once the mixture has been removed from the influence of the dispersing force, and stable dispersions or foam. Gas–liquid contacting equipment, such as bubble towers and gas-dispersing agitators, are typical examples of equipment that produces unstable dispersions. More difficulties may result in separation when the gas is dispersed in the form of bubbles only a few micrometers in size. An example is the evolution of gas from a liquid in which it has been dissolved or released through chemical reaction such as electrolysis. Coalescence of the dispersed phase can be helpful in such circumstances.

The second type of gas-in-liquid dispersion is a stable dispersion, or foam. Separation can be extremely difficult. In many chemical processes, preventing or managing the formation of foam is important for stable operation. A pure two-component system of gas and liquid cannot produce stable dispersions. Stable foams can be produced only when an additional substance is adsorbed at the liquid-surface interface. The substance adsorbed may be in true solution but with a chemical tendency to concentrate in the interface, such as that of a surface-active agent, or it may be a finely divided solid that concentrates in the interface because it is only poorly wetted by the liquid. Surfactants and proteins are examples of soluble materials, while dust particles and extraneous dirt that includes traces of nonmiscible liquids can be examples of poorly wetted materials.

The separation of gases and liquids always involves coalescence, but enhancement of the rate of coalescence may be required only in difficult separations.

**Separation of Unstable Systems** The buoyancy of bubbles suspended in liquid can often be depended upon to cause the bubbles to rise to the surface and separate. This is a special case of gravity settling. The mixture is allowed to stand at rest or is moved along a flow path in laminar flow until the bubbles have surfaced. Table 14-29 shows the calculated rate of rise of air bubbles at atmospheric pressure in water at 20°C (68°F) as a function of diameter. The velocity of rise for 10-μm bubbles is very low, so long separating times are required for gas that is more finely dispersed.

For liquids other than water, the rise velocity can be approximated from Table 14-29 by multiplying by the liquid's specific gravity and the reciprocal of its viscosity (in centipoises). For bubbles larger than 100 μm, this procedure is erroneous, but the error is less than 15 percent for bubbles up to 1000 μm. More serious is the underlying assumption of Table 14-29 that the bubbles are rigid spheres. Circulation within the bubble causes notable increases in velocity in the range of 100 μm to 1 mm, and the flattening of bubbles 1 cm and larger appreciably decreases their velocity. However, in this latter size range, the velocity is so high that separation is a trivial problem.

In the design of separating chambers, static vessels or continuous-flow tanks may be used. Care must be taken to protect the flow from turbulence, which could cause backmixing of partially separated fluids or which could carry unseparated liquids rapidly to the separated-liquid outlet. Vertical baffles are sometimes used to protect rising bubbles from flow currents. Unseparated fluids should be distributed to the separating region as uniformly and with as little velocity as possible. When the bubble rise velocity is quite low, shallow tanks or flow channels should be used to minimize the residence time required.

Quite low velocity rise of bubbles due either to small bubble size or to high liquid viscosity can cause difficult situations. With low-viscosity liquids, separation-enhancing possibilities in addition to those previously enumerated are to sparge the liquid with large-diameter gas bubbles or to atomize the mixture as a spray into a tower. Large gas bubbles rising rapidly through the liquid collide with small bubbles and aid their coalescence through capture. Atomizing of the continuous phase reduces the distance that small gas bubbles must travel to reach a gas interface. Evacuation of the spray space can also be beneficial in promoting small-bubble growth and especially in promoting gas evolution when the gas has appreciable liquid solubility. Liquid heating will also reduce solubility.

Surfaces in the settling zone for bubble coalescence such as closely spaced vertical or inclined plates or tubes are beneficial. When clean, low-viscosity fluids are involved, passage of the undegassed liquid through a tightly packed pad of mesh or fine fibers at low velocity will result in efficient bubble coalescence. Problems have been experienced in degassing a water-based organic solution that has been passed through an electrolytic cell for chemical reaction in which extremely fine bubbles of hydrogen gas

**TABLE 14-29 Terminal Velocity of Standard Air Bubbles Rising in Water at 20°C***

| Bubble diameter, μm | 10 | 30 | 50 | 100 | 200 | 300 |
|---|---|---|---|---|---|---|
| Terminal velocity, mm/s | 0.061 | 0.488 | 1.433 | 5.486 | 21.95 | 49.38 |

*Calculated from Stokes' law. To convert millimeters per second to feet per second, multiply by 0.003281.

are produced in the liquid within the cell. Near-total removal of hydrogen gas from the liquid is needed for process safety. This is very difficult to achieve by gravity settling alone because of the fine bubble size and the need for a coalescing surface. The use of a fine fiber medium is strongly recommended in such situations. A low-forward liquid flow through the medium is desirable to provide time for the bubbles to attach themselves to the fiber medium through Brownian diffusion. Spielman and Goren [*Ind. Eng. Chem.* **62**(10): (1970)] reviewed the literature on coalescence with porous media and reported their own experimental results [*Ind. Eng. Chem. Fundam.* **11**(1): 73 (1972)] on the coalescence of oil–water liquid emulsions. The principles are applicable to a gas-in-liquid system. Glass-fiber mats composed of 3.5-, 6-, or 12-μm-diameter fibers, varying in thickness from 1.3 to 3.3 mm, successfully coalesced and separated 1- to 7-μm oil droplets at superficial bed velocities of 0.02 to 1.5 cm/s (0.00067 to 0.049 ft/s).

In the deaeration of high-viscosity fluids such as polymers, the material is flowed in thin sheets along solid surfaces. Vacuum is applied to increase bubble size and hasten separation. The Versator (Cornell Machine Co.) degasses viscous liquids by spreading them into a thin film by centrifugal action as the liquids flow through an evacuated rotating bowl.

**Separation of Foam** Foams can be a severe problem in chemical-processing steps that involve gas–liquid interaction such as distillation, absorption, evaporation, chemical reaction, and particle separation and settling. It can also be a major problem in pulp and paper manufacture, oil-well drilling fluids, the production of water-based paints, the use of lubricants and hydraulic fluids, dyeing and sizing textiles, the operation of steam boilers, fermentation operations, polymerization, wet-process phosphoric acid concentration, adhesive production, and foam control in products such as detergents, waxes, printing inks, instant coffee, and glycol antifreeze.

Foam stability decreases as the liquid drainage rate increases. Drainage rate is influenced by surface viscosity, which is very temperature-sensitive. At a critical temperature, which is a function of the system, a temperature change of only a few degrees can change a slow-draining foam to a fast-draining foam. This change in drainage rate can be a factor of 100 or more; thus increasing the temperature of foam can cause its destruction. An increase in temperature may also cause liquid evaporation and lamella thinning. As the lamellae become thinner, they become more brittle and fragile. Thus, mechanical deformation or pressure changes, which cause a change in gas-bubble volume, can also cause rupture. Bendure [*Tappi* **58:** 83 (1975)] indicated 10 ways to increase foam stability: (1) increase bulk liquid viscosity, (2) increase surface viscosity, (3) maintain thick walls (higher liquid-to-gas ratio), (4) reduce liquid surface tension, (5) increase surface elasticity, (6) increase surface concentration, (7) reduce surfactant-adsorption rate, (8) prevent liquid evaporation, (9) avoid mechanical stresses, and (10) eliminate foam inhibitors. Obviously, the reverse of each of these actions, when possible, is a way to control and break foam.

**Physical Defoaming Techniques** Typical physical defoaming techniques include mechanical methods for producing foam stress, thermal methods involving heating or cooling, and electrical methods. Combinations of these methods may also be employed, or they may be used in conjunction with chemical defoamers. Some methods are only moderately successful when conditions are present to reform the foam, such as breaking foam on the surface of boiling liquids. In some cases it may be desirable to draw the foam off and treat it separately. Foam can always be stopped by removing the energy source creating it, but this is often impractical.

***Thermal Methods*** Heating is often a suitable means of destroying foam. As indicated previously, raising the foam above a critical temperature (which must be determined experimentally) can greatly decrease the surface viscosity of the film and change the foam from one that is slow-draining to one that is fast-draining. Coupling such heating with a mechanical force such as a revolving paddle to cause foam deformation is often successful. Other effects of heating include the expansion of the gas in the foam bubbles, which increases strain on the lamella walls and requires them to move and flex. Evaporation of solvent may occur, causing thinning of the walls. At sufficiently high temperatures, desorption or decomposition of stabilizing substances may occur. Placing a high-temperature bank of steam coils at the maximum foam level is one control method. As the foam approaches or touches the coil, it collapses. Designers should keep in mind that the coil will often become coated with solute.

The application of radiant heat to a foam surface is another option. Depending on the situation, the radiant source may be electric lamps, Glowbar units, or gas-fired radiant burners. Hot gases from burners will enhance film drying of the foam. Heat may also be applied by jetting or spraying hot water on the foam. This approach is a combination of methods since the jetting produces mechanical shear, and the water itself provides dilution and change in foam-film composition. Cooling can also destroy foam if it is carried to the point of freezing since the formation of solvent crystals destroys the foam structure. Less drastic cooling such as spraying a hot foam with cold water may be effective; cooling may cause foam bubbles to shrink, coupled with the effects of shear and dilution mentioned earlier. In general, moderate cooling will be less effective than heating since the surface viscosity is being modified in the direction of a more stable foam.

***Mechanical Methods*** Static or rotating breaker bars or slowly revolving paddles are sometimes successful. Their application in conjunction with other methods is often better. As indicated in the theory of foams, they will work better if installed at a level at which the foam has had some time to age and drain. A rotating breaker works by deforming the foam, which causes rupture of the lamella walls. Rapidly moving slingers will throw the foam against the vessel wall and may cause impact on other foam outside the envelope of the slinger. In some instances, stationary bars or closely spaced plates will limit the rise of foam. The action here is primarily one of providing surface for the coalescence of the foam. The wettability of the surface, whether moving or stationary, is often important. Usually a surface not wetted by the liquid is superior, as in the case of porous media for foam coalescence. However, in both cases there are exceptions for which wettable surfaces are preferred. Shkodin [*Kolloidn. Zh.* **14:** 213 (1952)] found molasses foam to be destroyed by contact with a wax-coated rod and unaffected by a clean glass rod.

Goldberg and Rubin [*Ind. Eng. Chem. Process Des. Dev.* **6:** 195 (1967)] showed in tests with a disk spinning vertically to the foam layer that most mechanical procedures, whether centrifugation, mixing, or blowing through nozzles, consist basically of the application of shear stress. Subjecting foam to an air-jet impact can also provide a source of drying and evaporation from the film, especially if the air is heated. Other effective means of destroying bubbles are to lower a frame of metal points periodically into the foam or to shower the foam with falling solid particles.

***Pressure and Acoustic Vibrations*** These methods for rupturing foam are really special forms of mechanical treatment. Change in pressure in the vessel containing the foam stresses the lamella walls by expanding or contracting the gas inside the foam bubbles. Oscillation of the vessel pressure subjects the foam to repeated film flexing. Parlow [*Zucker* **3:** 468 (1950)] controlled foam in sugar-syrup evaporators with high-frequency air pulses. It is by no means certain that high-frequency pulsing is needed in all cases. Lower frequency and higher amplitude could be equally beneficial. Acoustic vibration is a similar phenomenon, causing localized pressure oscillation by using sound waves. Impulses at 6 kHz have been found to break froth from coal flotation [Sun, *Min. Eng.* **3:** 865 (1958)]. Sonntag and Strenge (*Coagulation and Stability of Disperse Systems,* Halsted-Wiley, New York, 1972, p. 121) reported foam suppression with high-intensity sound waves (11 kHz, 150 dB) but indicated that the procedure was too expensive for large-scale application. The Sontrifuge (Teknika Inc., a subsidiary of Chemineer, Inc.) is a commercially available low-speed centrifuge employing sonic energy to break the foam. Walsh [*Chem. Process.* **29:** 91 (1966)], Carlson [*Pap. Trade J.* **151:** 38 (1967)], and Thorhildsen and Rich [*TAPPI* **49:** 95A (1966)] have described the unit.

***Electrical Methods*** As colloids, most foams typically have electrical double layers of charged ions that contribute to foam stability. Accordingly, foams can be broken by the influence of an external electric field. While few commercial applications have been developed, Sonntag and Strenge (1972, p. 114) indicated that foams can be broken by passage through devices much like electrostatic precipitators for dusts. Devices similar to two-stage precipitators having closely spaced plates of opposite polarity should be especially useful. Sonntag and Strenge, in experiments with liquid–liquid emulsions, indicated that the colloid structure can be broken at a field strength on the order of 8 to $9 \times 10^5$ V/cm.

**Chemical Defoaming Techniques** Sonntag and Strenge (1972, p. 111) described two chemical methods for foam breaking. One method is causing the stabilizing substances to be desorbed from the interface, such as by displacement with other more surface-active but nonstabilizing compounds. The second method is to effect chemical changes in the adsorption layer, leading to a new structure. Some defoamers may act purely by mechanical means but will be discussed in this subsection since their action is generally considered to be chemical in nature. Often chemical defoamers act in more than one way.

***Chemical Defoamers*** The addition of chemical foam breakers is the most elegant way to break a foam. Effective defoamers cause very rapid disintegration of the foam and often need be present only in parts per million. The great diversity of compounds used for defoamers and the many different systems in which they are applied make a brief and orderly discussion of their selection difficult. Compounds needed to break aqueous foams may be different from those needed for aqueous-free systems. Most defoamers are insoluble or nonmiscible in the foam continuous phase, but some work best because of their ready solubility. Lichtman (*Defoamers,* 3d ed., Wiley, New York, 1979) has presented a concise summary of the application and use of defoamers. Rubel (*Antifoaming and Defoaming Agents,* Noyes Data Corp., Park Ridge, N.J., 1972) has reviewed the extensive patent literature on defoamers. Defoamers are also discussed extensively in the General References at the beginning of this subsection.

**TABLE 14-30 Major Types and Applications of Defoamers**

| Classification | Examples | Applications |
|---|---|---|
| Silicones | Dimethyl silicone, trialkyl and tetraalkyl silanes | Lubricating oils; distillation; fermentation; jam and wine making; food processing |
| Aliphatic acids or esters | Mostly high-molecular-weight compounds; diethyl phthalate; lauric acid | Papermaking; wood-pulp suspensions; water-based paints; food processing |
| Alcohols | Moderate- to high-molecular-weight monohydric and polyhydric alcohols; octyl alcohol; C-12 to C-20 alcohols; lauryl alcohol | Distillation; fermentation; papermaking; glues and adhesives |
| Sulfates or sulfonates | Alkali metal salts of sulfated alcohols, sulfonic acid salts; alkyl-aryl sulfonates; sodium lauryl sulfate | Nonaqueous systems; mixed aqueous and nonaqueous systems; oil-well drilling muds; spent $H_2SO_4$ recovery; deep-fat frying |
| Amines or amides | Alkyl amines (undecyloctyl and diamyl methyl amine); polyamides (acyl derivatives of piperazine) | Boiler foam; sewage foam; fermentation; dye baths |
| Halogenated compounds | Fluochloro hydrocarbons with 5 to 50 C atoms; chlorinated hydrocarbons | Lubrication-oil and grease distillation; vegetable-protein glues |
| Natural products | Vegetable oils; waxes, mineral oils plus their sulfated derivatives (including those of animal oils and fats) | Sugar extraction; glue manufacture; cutting oils |
| Fatty-acid soaps | Alkali, alkaline earth, and other metal soaps; sodium stearate; aluminum stearate | Gear oils; paper stock; paper sizing; glue solutions |
| Inorganic compounds | Monosodium phosphate mixed with boric acid and ethyl carbonate, disodium phosphate; sodium aluminate, bentonite and other solids | Distillation; instant coffee; boiler feedwater; sugar extraction |
| Phosphates | Alkyl-alkalene diphosphates; tributyl phosphate in isopropanol | Petroleum-oil systems; foam control in soap solutions |
| Hydrophobic silica | Finely divided silica in polydimethyl siloxane | Aqueous foaming systems |
| Sulfides or thio derivatives | Metallic derivatives of thio ethers and disulfides, usually mixed with organic phosphite esters; long-chain alkyl thienyl ketones | Lubricating oils; boiler water |

One useful method of aqueous defoaming is to add a nonfoam stabilizing surfactant that is more surface-active than the stabilizing substance in the foam. Thus a foam stabilized with an ionic surfactant can be broken by the addition of a very surface-active but nonstabilizing silicone oil. The silicone displaces the foam stabilizer from the interface by virtue of its insolubility. However, it does not stabilize the foam because its foam films have poor elasticity and rupture easily.

A major requirement for a defoamer is cost-effectiveness. Accordingly, some useful characteristics are low volatility (to prevent stripping from the system before it is dispersed and does its work), ease of dispersion and strong spreading power, and surface attraction-orientation. Chemical defoamers must also be selected with regard to their possible effect on product quality and their environmental and health suitability. For instance, silicone antifoam agents are effective in textile jet dyeing but reduce the fire retardancy of the fabric. Mineral-oil defoamers in sugar evaporation have been replaced by specifically approved materials. The tendency is no longer to use a single defoamer compound but to use a formulation specially tailored for the application, comprising carriers, secondary antifoam agents, emulsifiers, and stabilizing agents in addition to the primary defoamer. Carriers, usually hydrocarbon oils or water, serve as the vehicle to support the release and spread of the primary defoamer. Secondary defoamers may provide a synergistic effect for the primary defoamer or modify its properties such as spreadability or solubility. Emulsifiers may enhance the speed of dispersion, while stabilizing agents may enhance defoamer stability or shelf life.

Hydrophobic silica defoamers work on a basis that may not be chemical at all. They are basically finely divided solid silica particles dispersed in a hydrocarbon or silicone oil that serves as a spreading vehicle. Kulkarni [*Ind. Eng. Chem. Fundam.* **16:** 472 (1977)] theorizes that this mixture defoams by the penetration of the silica particle into the bubble and the rupture of the wall. Table 14-30 lists major types of defoamers and typical applications.

***Other Chemical Methods*** These methods rely chiefly on destroying the foam stabilizer or neutralizing its effect through methods other than displacement and are applicable when the process will permit changing the chemical environment. Foams stabilized with alkali esters can be broken by acidification since the equivalent free acids do not stabilize foam. Foams containing sulfated and sulfonated ionic detergents can be broken with the addition of fatty-acid soaps and calcium salts.

Ionic surfactants adsorb at the foam interface and orient with the charged group immersed in the lamellae and their uncharged tails pointed into the gas stream. As the film drains, the charged groups, which repel each other, tend to be moved more closely together. The repulsive force between like charges hinders drainage and stabilizes the film. The addition of a salt or an electrolyte to the foam screens the repulsive effect, permits additional drainage, and can reduce foam stability.

**Foam Prevention** Chemical prevention of foam differs from defoaming only in that compounds or mixtures are added to a stream prior to processing to prevent the formation of foam either during processing or during customer use. Such additives, sometimes distinguished as antifoam agents, are usually in the same chemical class of materials as defoamers. However, they are usually specifically formulated for the application. The use of antifoam is very common in chemical processing applications. Typical examples of products formulated with antifoam agents are laundry detergents (to control excess foaming), automotive antifreeze, instant coffee, and jet-aircraft fuel. An alternative to antifoam agents in some chemical processes is the removal of trace impurities such as surface-active agents before processing such as by treatment with activated carbon [Pool, *Chem. Process.* **21**(9): 56 (1958)].

**Automatic Foam Control** In processing materials when foam can accumulate, it is often desirable to measure the height of the foam layer continuously and to dispense defoamer automatically as required to control the foam. Other corrective action can also be taken automatically. Methods of sensing the foam level have included electrodes in which the electrical circuit is completed when the foam touches the electrode [Nelson, *Ind. Eng. Chem.* **48:** 2183 (1956); Browne, U.S. Patent 2,981,693, 1961], floats designed to rise in a foam layer (Carter, U.S. Patent 3,154,577, 1964), and change in power input required to turn a foam-breaking impeller as the foam level rises (Yamashita, U.S. Patent 3,317,435, 1967). Timers to control the duration of defoamer addition have also been used. Browne suggested the automatic addition of defoamer through a porous wick when the foam level reached the level of the wick. Foam control was also discussed by Kroll [*Ind. Eng. Chem.* **48:** 2190 (1956)].

## Nomenclature

A given symbol may represent more than one property. The appropriate meaning should be apparent from the context. The equations given in Sec. 15 reflect the use of the SI or cgs system of units and not ft-lb-s units, unless otherwise noted in the text. The gravitational conversion factor $g_c$ needed to use ft-lb-s units is not included in the equations.

| Symbol | Definition | SI units | U.S. Customary System units |
|---|---|---|---|
| $a$ | Interfacial area per unit volume | $m^2/m^3$ | $ft^2/ft^3$ |
| $a_p$ | Specific packing surface area (area per unit volume) | $m^2/m^3$ | $ft^2/ft^3$ |
| $a_w$ | Specific wall surface area (area per unit volume) | $m^2/m^3$ | $ft^2/ft^3$ |
| $b_{ij}$ | NRTL model regression parameter | K | K |
| $A$ | Envelope-style downcomer area | $m^2$ | $ft^2$ |
| $A$ | Area between settled layers in a decanter | $m^2$ | $ft^2$ |
| $A_{col}$ | Column cross-sectional area | $m^2$ | $ft^2$ |
| $A_{dow}$ | Area for flow through a downcomer (or upcomer) | $m^2$ | $ft^2$ |
| $A_{ij}/RT$ | van Laar binary interaction parameter | Dimensionless | Dimensionless |
| $A_o$ | Cross-sectional area of a single hole | $m^2$ | $in^2$ |
| $C$ | Concentration (mass or moles per unit volume) | $kg/m^3$ or $kgmol/m^3$ or gmol/L | $lb/ft^3$ or $lbmol/ft^3$ |
| $C_A^i$ | Concentration of component $A$ at the interface | $kg/m^3$ or $kgmol/m^3$ or gmol/L | $lb/ft^3$ or $lbmol/ft^3$ |
| $C^*$ | Concentration at equilibrium | $kg/m^3$ or $kgmol/m^3$ or gmol/L | $lb/ft^3$ or $lbmol/ft^3$ |
| $C_D$ | Drag coefficient | Dimensionless | Dimensionless |
| $C_o$ | Initial concentration | $kg/m^3$ or $kgmol/m^3$ or gmol/L | $lb/ft^3$ or $lbmol/ft^3$ |
| $C_p$ | Packing constant (empirical) | Dimensionless | Dimensionless |
| $C_t$ | Concentration at time $t$ | $kg/m^3$ or $kgmol/m^3$ or gmol/L | $lb/ft^3$ or $lbmol/ft^3$ |
| $d$ | Drop diameter | m | in |
| $d_C$ | Critical packing dimension | m | in |
| $d_i$ | Diameter of an individual drop | m | in |
| $d_m$ | Characteristic diameter of media in a packed bed | m | in |
| $d_o$ | Orifice or nozzle diameter | m | in |
| $d_p$ | Sauter mean drop diameter | m | in |
| $d_{32}$ | Sauter mean drop diameter | m | in |
| $D_{col}$ | Column diameter | m | in or ft |
| $D_{eq}$ | Equivalent diameter giving the same area | m | in |
| $D_h$ | Equivalent hydraulic diameter | m | in |
| $\mathcal{D}_i$ | Distribution ratio for a given chemical species including all its forms (unspecified units) | | |
| $D_i$ | Impeller diameter or characteristic mixer diameter | m | in or ft |
| $D_{sm}$ | Static mixer diameter | m | in or ft |
| $D_t$ | Tank diameter | m | ft |
| $\mathcal{D}$ | Molecular diffusion coefficient (diffusivity) | $m^2/s$ | $cm^2/s$ |
| $\mathcal{D}_{AB}$ | Mutual diffusion coefficient for components $A$ and $B$ | $m^2/s$ | $cm^2/s$ |
| $E$ | Mass or mass flow rate of extract phase | kg or kg/s | lb or lb/h |
| $E'$ | Solvent mass or mass flow rate (in the extract phase) | kg or kg/s | lb or lb/h |
| $E$ | Axial mixing coefficient (eddy diffusivity) | $m^2/s$ | $cm^2/s$ |
| $\mathcal{E}^C$ | Extraction factor for case $C$ [Eq. (15-93)] | Dimensionless | Dimensionless |
| $\mathcal{E}_i$ | Extraction factor for component $i$ | Dimensionless | Dimensionless |
| $\mathcal{E}_s$ | Stripping section extraction factor | Dimensionless | Dimensionless |
| $\mathcal{E}_w$ | Washing section extraction factor | Dimensionless | Dimensionless |
| $f_{da}$ | Fractional downcomer area | Dimensionless | Dimensionless |
| $f_{ha}$ | Fractional hole area | Dimensionless | Dimensionless |
| $F$ | Mass or mass flow rate of feed phase | kg or kg/s | lb or lb/h |
| $F$ | Force | N | lbf |
| $F'$ | Feed mass or mass flow rate ( feed solvent only) | kg or kg/s | lb or lb/h |
| $F_R$ | Solute reduction factor (ratio of inlet to outlet concentrations) | Dimensionless | Dimensionless |
| $g$ | Gravitational acceleration | $9.807\ m/s^2$ | $32.17\ ft/s^2$ |
| $G_{ij}$ | NRTL model parameter | Dimensionless | Dimensionless |
| $h$ | Height of coalesced layer at a sieve tray | m | in |
| $h$ | Head loss due to frictional flow | m | in |
| $h$ | Height of dispersion band in batch decanter | m | in |
| $h_i^E$ | Excess enthalpy of mixing | J/gmol | Btu/lbmol or cal/gmol |
| $H$ | Dimensionless group defined by Eq. (15-118) | Dimensionless | Dimensionless |
| $H$ | Dimension of envelope-style downcomer [Fig. 15-37] | m | in or ft |
| $\Delta H$ | Steady-state dispersion band height in a continuously fed decanter | m | in |
| HDU | Height of a dispersion unit | m | in |
| $H_e$ | Height of a transfer unit due to resistance in extract phase | m | in |
| HETS | Height equivalent to a theoretical stage | m | in |
| $H_{oc}$ | Height of an overall mass-transfer unit based on continuous phase | m | in |
| $H_{or}$ | Height of an overall mass-transfer unit based on raffinate phase | m | in |
| $H_r$ | Height of a transfer unit due to resistance in raffinate phase | m | in |
| HTU | Height of a transfer unit (phase of reference evident from the context of its use) | m | in |
| $k$ | Individual mass-transfer coefficient | m/s or cm/s | ft/h |
| $k$ | Mass-transfer coefficient (unspecified units) | | |
| $k_m$ | Membrane-side mass-transfer coefficient | m/s or cm/s | ft/h |
| $k_o$ | Overall mass-transfer coefficient | m/s or cm/s | ft/h |
| $k_c$ | Continuous-phase mass-transfer coefficient | m/s or cm/s | ft/h |
| $k_d$ | Dispersed-phase mass-transfer coefficient | m/s or cm/s | ft/h |
| $k_s$ | Setschenow constant | L/gmol | L/gmol |
| $k_s$ | Shell-side mass-transfer coefficient | m/s or cm/s | ft/h |
| $k_t$ | Tube-side mass-transfer coefficient | m/s or cm/s | ft/h |
| $K$ | Partition ratio (unspecified units) | | |

**Nomenclature** (*Continued*)

| Symbol | Definition | SI units | U.S. Customary System units |
|---|---|---|---|
| $K_s'$ | Stripping section partition ratio (in Bancroft coordinates) | Mass ratio/ mass ratio | Mass ratio/ mass ratio |
| $K_w'$ | Washing section partition ratio (in Bancroft coordinates) | Mass ratio/ mass ratio | Mass ratio/ mass ratio |
| $K'$ | Partition ratio, mass ratio basis (Bancroft coordinates) | Mass ratio/ mass ratio | Mass ratio/ mass ratio |
| $K''$ | Partition ratio, mass fraction basis | Mass fraction/ mass fraction | Mass fraction/ mass fraction |
| $K^o$ | Partition ratio, mole fraction basis | Mole fraction/ mole fraction | Mole fraction/ mole fraction |
| $K^{vol}$ | Partition ratio (volumetric concentration basis) | Ratio of kg/m$^3$ or kgmol/m$^3$ or gmol/L | Ratio of lb/ft$^3$ or lbmol/ft$^3$ |
| $L$ | Downcomer (or upcomer) length | m | in or ft |
| $L_{fp}$ | Length of flow path in Eq. (15-143) | m | in or ft |
| $m$ | Local slope of equilibrium line (unspecified concentration units) | | |
| $m'$ | Local slope of equilibrium line (in Bancroft coordinates) | Mass ratio/ mass ratio | Mass ratio/ mass ratio |
| $m_{dc}$ | Local slope of equilibrium line for dispersed-phase concentration plotted versus continuous-phase concentration | | |
| $m_{er}$ | Local slope of equilibrium line for extract-phase concentration plotted versus raffinate-phase concentration | | |
| $m^{vol}$ | Local slope of equilibrium line (volumetric concentration basis) | Ratio of kg/m$^3$ or kgmol/m$^3$ or gmol/L | Ratio of lb/ft$^3$ or lbmol/ft$^3$ units |
| $M$ | Mass or mass flow rate | kg or kg/s | lb or lb/h |
| MW | Molecular weight | kg/kgmol or g/gmol | lb/lbmol |
| $N$ | Number of theoretical stages | Dimensionless | Dimensionless |
| $N_A$ | Flux of component $A$ (mass or mol/area/unit time) | (kg or kgmol)/ (m$^2$·s) | (lb or lbmol)/ (ft$^2$·s) |
| $N_{holes}$ | Number of holes | Dimensionless | Dimensionless |
| $N_{or}$ | Number of overall mass-transfer units based on the raffinate phase | Dimensionless | Dimensionless |
| $N_s$ | Number of theoretical stages in stripping section | Dimensionless | Dimensionless |
| $N_w$ | Number of theoretical stages in washing section | Dimensionless | Dimensionless |
| $P$ | Pressure | bar or Pa | atm or lbf/in$^2$ |
| $P$ | Dimensionless group defined by Eq. (15-117) | Dimensionless | Dimensionless |
| $P$ | Power | W or kW | HP or ft·lbf/h |
| Pe | Péclet number $Vb/E$, where $V$ is liquid velocity, $E$ is axial mixing coefficient, and $b$ is a characteristic equipment dimension | Dimensionless | Dimensionless |
| $P_{i,extract}$ | Purity of solute $i$ in extract (in wt%) | wt% | wt% |
| $P_{i,feed}$ | Purity of solute $i$ in feed (in wt%) | wt% | wt% |
| $P_o$ | Power number $P/(\rho_m\omega^3 D_i^5)$ | Dimensionless | Dimensionless |
| $\Delta P_{dow}$ | Pressure drop for flow through a downcomer (or upcomer) | bar or Pa | atm or lbf/in$^2$ |
| $\Delta P_o$ | Orifice pressure drop | bar or Pa | atm or lbf/in$^2$ |
| $Q$ | Volumetric flow rate | m$^3$/s | ft$^3$/min |
| $R$ | Universal gas constant | 8.31 J · K/kgmol | 1.99 Btu · °R/ lbmol |
| $R$ | Mass or mass flow rate of raffinate phase | kg or kg/s | lb or lb/h |
| $R_A$ | Rate of mass transfer (moles per unit time) | kgmol/s | lbmol/h |
| Re | Reynolds number: for pipe flow, $Vd\rho/\mu$; for an impeller, $\rho_m\omega D_i^2/\mu_m$; for drops, $V_{so}d_p\rho_c/\mu_c$; for flow in a packed-bed coalescer, $Vd_m\rho_c/\mu$; for flow through an orifice, $V_o d_o \rho_d/\mu_d$ | Dimensionless | Dimensionless |
| $Re_{Stokes}$ | $\rho_c\Delta\rho g d_p^2/18\mu_c^2$ | Dimensionless | Dimensionless |
| $S$ | Mass or mass flow rate of solvent phase | kg or kg/s | lb or lb/h |
| $S$ | Dimension of envelope-style downcomer (Fig. 15-37) | m | ft |
| $S'$ | Solvent mass or mass flow rate (extraction solvent only) | kg or kg/s | lb or lb/h |
| $S_s'$ | Mass flow rate of extraction solvent within stripping section | kg/s | lb/h |
| $S_w'$ | Mass flow rate of extraction solvent within washing section | kg/s | lb/h |
| $S_{i,j}$ | Separation power for separating component $i$ from component $j$ [defined by Eq. (15-100)] | Dimensionless | Dimensionless |
| $S_{tip}$ | Impeller tip speed | m/s | ft/s |
| $t_b$ | Batch mixing time | s or h | min or h |
| $T$ | Temperature (absolute) | K | °R |
| $u_t$ | Stokes' law terminal or settling velocity of a drop | m/s or cm/s | ft/s or ft/min |
| $u_{t\infty}$ | Unhindered settling velocity of a single drop | m/s or cm/s | ft/s or ft/min |
| $v$ | Molar volume | m$^3$/kgmol or cm$^3$/gmol | ft$^3$/lbmol |
| $V$ | Liquid velocity (or volumetric flow per unit area) | m/s | ft/s or ft/min |
| $\mathcal{V}$ | Volume | m$^3$ | ft$^3$ or gal |
| $V_{cf}$ | Continuous-phase flooding velocity | m/s | ft/s or ft/min |
| $V_{cflow}$ | Cross-flow velocity of continuous phase at sieve tray | m/s | ft/s or ft/min |
| $V_{df}$ | Dispersed-phase flooding velocity | m/s | ft/s or ft/min |
| $V_{drop}$ | Average velocity of a dispersed drop | m/s | ft/s or ft/min |
| $V_{ic}$ | Interstitial velocity of continuous phase | m/s | ft/s or ft/min |
| $V_{o,max}$ | Maximum velocity through an orifice or nozzle | m/s | ft/s or ft/min |
| $V_s$ | Slip velocity | m/s | ft/s or ft/min |
| $V_{so}$ | Slip velocity at low dispersed-phase flow rate | m/s | ft/s or ft/min |
| $V_{sm}$ | Static mixer superficial liquid velocity (entrance velocity) | m/s | ft/s or ft/min |
| $W$ | Mass or mass flow rate of wash solvent phase | kg or kg/s | lb or lb/h |
| $W_s'$ | Mass flow rate of wash solvent within stripping section | kg/s | lb/h |
| $W_w'$ | Mass flow rate of wash solvent within washing section | kg/s | lb/h |
| We | Weber number: for an impeller, $\rho_c\omega^2 D_i^3/\sigma$; for flow through an orifice or nozzle, $V_o^2 d_0 \rho_d/\sigma$; for a static mixer, $V'^2_{sm} D_{sm}\rho_c/\sigma$ | Dimensionless | Dimensionless |

**Nomenclature** (*Continued*)

| Symbol | Definition | SI units | U.S. Customary System units |
|---|---|---|---|
| $x$ | Mole fraction solute in feed or raffinate | Mole fraction | Mole fraction |
| $X$ | Concentration of solute in feed or raffinate (unspecified units) | | |
| $X''$ | Mass fraction solute in feed or raffinate | Mass fractions | Mass fractions |
| $X'$ | Mass solute/mass feed solvent in feed or raffinate | Mass ratios | Mass ratios |
| $X_f^B$ | Pseudoconcentration of solute in feed for case $B$ [Eq. (15-90)] | Mass ratios | Mass ratios |
| $X_f^C$ | Pseudoconcentration of solute in feed for case $C$ [Eq. (15-92)] | Mass ratios | Mass ratios |
| $X_{i,\text{extract}}$ | Concentration of solute $i$ in extract | Mass fraction | Mass fraction |
| $X_{i,\text{feed}}$ | Concentration of solute $i$ in feed | Mass fraction | Mass fraction |
| $X_{i,\text{raffinate}}$ | Concentration of solute $i$ in raffinate | Mass fraction | Mass fraction |
| $X_{ij}$ | Concentration of component $i$ in the phase richest in $j$ | Mass fraction | Mass fraction |
| $y$ | Mole fraction solute in solvent or extract | Mole fraction | Mole fraction |
| $Y$ | Concentration of solute in the solvent or extract (unspecified units) | | |
| $Y''$ | Mass fraction solute in solvent or extract | Mass fraction | Mass fraction |
| $Y'$ | Mass solute/mass extraction solvent in solvent or extract | Mass ratio | Mass ratio |
| $Y_s^B$ | Pseudoconcentration of solute in solvent for case $B$ [Eq. (15-91)] | Mass ratio | Mass ratio |
| $z$ | Dimension or direction of mass transfer | m | in or ft |
| $z$ | Sieve tray spacing | m | in or ft |
| $z$ | Point representing feed composition on a tie line | | |
| $z_i$ | Number of electronic charges on an ion | Dimensionless | Dimensionless |
| $Z_t$ | Total height of extractor | m | ft |
| | Greek symbols | | |
| $\alpha_{i,j}$ | Separation factor for solute $i$ with respect to solute $j$ | Dimensionless | Dimensionless |
| $\alpha_{i,j}$ | NRTL model parameter | Dimensionless | Dimensionless |
| $\gamma_{i,j}$ | Activity coefficient of $i$ dissolved in $j$ | Dimensionless | Dimensionless |
| $\gamma_i^I$ | Activity coefficient of component $i$ in phase I | Dimensionless | Dimensionless |
| $\gamma_i^R$ | Activity coefficient, residual part of UNIFAC | Dimensionless | Dimensionless |
| $\varepsilon$ | Void fraction | Dimensionless | Dimensionless |
| $\varepsilon$ | Fractional open area of a perforated plate | Dimensionless | Dimensionless |
| $\zeta$ | Tortuosity factor [Table 15-17] | Dimensionless | Dimensionless |
| $\theta$ | Residence time for total liquid | s | s or min |
| $\theta_i$ | Fraction of solute $i$ extracted from feed | Dimensionless | Dimensionless |
| $\lambda_m$ | Membrane thickness | mm | in |
| $\mu$ | Liquid viscosity | Pa·s | cP |
| $\mu_{i^s}^{\text{I}}$ | Chemical potential of component $i$ in phase I | J/gmol | Btu/lbmol |
| $\mu_m$ | Mixture mean viscosity defined in Eq. (15-162) | Pa·s | cP |
| $\mu_w$ | Reference viscosity (of water) | Pa·s | cP |
| $\xi_{\text{batch}}$ | Efficiency of a batch experiment [Eq. (15-157)] | Dimensionless | Dimensionless |
| $\xi_{\text{continuous}}$ | Efficiency of a continuous process [Eq. (15-158)] | Dimensionless | Dimensionless |
| $\xi_m$ | Murphree stage efficiency | Dimensionless | Dimensionless |
| $\xi_{md}$ | Murphree stage efficiency based on dispersed phase | Dimensionless | Dimensionless |
| $\xi_o$ | Overall stage efficiency | Dimensionless | Dimensionless |
| $\Delta\pi$ | Osmotic pressure gradient | bar or Pa | atm or lbf/in$^2$ |
| $\rho$ | Liquid density | kg/m$^3$ | lb/ft$^3$ |
| $\rho_m$ | Mixture mean density [Eq. (15-160)] | kg/m$^3$ | lb/ft$^3$ |
| $\sigma$ | Interfacial tension | N/m | dyn/cm |
| $\tau_{i,j}$ | NRTL model parameter | Dimensionless | Dimensionless |
| $\phi$ | Volume fraction | Dimensionless | Dimensionless |
| $\phi_d$ | Volume fraction of dispersed phase (holdup) | Dimensionless | Dimensionless |
| $\phi_{d,\text{feed}}$ | Volume fraction of dispersed phase in feed | Dimensionless | Dimensionless |
| $\phi_o$ | Initial dispersed-phase holdup in feed to a decanter | Dimensionless | Dimensionless |
| $\varphi$ | Volume fraction of voids in a packed bed | Dimensionless | Dimensionless |
| $\chi$ | Parameter indicating which phase is likely to be dispersed [Eq. (15-36)] | Dimensionless | Dimensionless |
| $\omega$ | Impeller speed | Rotations/s | Rotations/min |

| Additional subscripts | |
|---|---|
| $c$ | Continuous phase |
| $d$ | Dispersed phase |
| $e$ | Extract phase |
| $f$ | Feed phase or flooding condition (when combined with $d$ or $c$) |
| $i$ | Component $i$ |
| $j$ | Component $j$ |
| $H$ | Heavy liquid |
| $L$ | Light liquid |
| max | Maximum value |
| min | Minimum value |
| $o$ | Orifice or nozzle |
| $r$ | Raffinate phase |
| $s$ | Solvent |

## INTRODUCTION AND OVERVIEW

Liquid-liquid extraction is a process for separating the components of a liquid (the feed) by contact with a second liquid phase (the solvent). The process takes advantage of differences in the chemical properties of the feed components, such as differences in polarity and hydrophobic/hydrophilic character, to separate them. Stated more precisely, the transfer of components from one liquid to the other is driven by a deviation from thermodynamic equilibrium, and the equilibrium state depends on the nature of the molecular interactions between the feed components and the solvent. The potential for separating the feed components is determined by differences in these molecular interactions.

A liquid-liquid extraction process produces a solvent-rich stream called the extract that contains a portion of the feed, and an extracted-feed stream called the raffinate. A commercial process almost always includes two or more auxiliary operations in addition to the extraction operation itself. These extra operations are needed to treat the extract and raffinate streams for the purposes of isolating a desired product, recovering the solvent for recycle back to the extractor, and purging unwanted components from the process. A typical process includes two distillation operations in addition to extraction.

Liquid-liquid extraction is used to recover desired components from a crude liquid mixture or to remove unwanted contaminants. In developing a process, the project team must decide what solvent or solvent mixture to use, how to isolate product and solvent from the extract, and how to remove solvent residues from the raffinate. The team must also decide what temperature or range of temperatures should be used for the extraction, what process scheme to employ among many possibilities, and what type of equipment to use for liquid-liquid contacting and phase separation. The variety of commercial equipment options is large and includes stirred tanks and decanters (settlers), specialized mixer-settlers, a wide variety of agitated and nonagitated extraction columns or towers, and various types of centrifuges.

Because of the availability of hundreds of commercial solvents and extractants, as well as a wide variety of established process schemes and equipment options, liquid-liquid extraction is a versatile technology with a wide range of commercial applications. It is used in the processing of many commodity and specialty chemicals, including petrochemicals, coal- and wood-derived chemicals, complex organics such as pharmaceuticals and agricultural chemicals, and metals and nuclear fuel (hydrometallurgy). Liquid-liquid extraction also is an important operation in industrial wastewater treatment, food processing, and the recovery of biomolecules from fermentation broth and other forms of biomass.

### HISTORICAL PERSPECTIVE

The art of solvent extraction has been practiced in one form or another since ancient times. It appears that until the 19th century, solvent extraction was mainly used to isolate desired components such as perfumes and dyes from plant solids and other natural sources [Aftalion, F., *A History of the International Chemical Industry*, 2d ed., Chemical Heritage Foundation, Philadelphia, 2001; and Taylor, F. S., *A History of Industrial Chemistry*, Abelard-Schuman, New York, 1957]. However, several early applications involving liquid-liquid contacting are described by E. Blass, T. Liebel, and

M. Haeberl ["Solvent Extraction—A Historical Review," *International Solvent Extraction Conf. (ISEC) '96 Proceedings*, Univ. of Melbourne, Melbourne, 1996], including washing oil with water to remove color.

The modern practice of liquid-liquid extraction has its roots in the middle to late 19th century when extraction became an important laboratory technique. In 1855, Adolf Fick introduced fundamental concepts of diffusion underlying mass transfer [*Ann. Phys. (Berlin)* **170**(1): 59–86 (1855)]. Later, the partition ratio concept describing how a solute partitions between two liquid phases at equilibrium was introduced by M. Berthelot and E. Jungfleisch [*Ann. Chim. Phys.* (4th Ser.) **26:** 396–407 (1872)] and further defined by W. H. Nernst [*Z. Phys. Chem.* **8**(1): 110–139 (1891)]. At about the same time, J. Willard Gibbs published his landmark treatise on chemical thermodynamics [*Trans. Conn. Acad. Arts Sci.* **3:** 108–248 (1876); **3:** 343–527 (1878)]. These and other advances were accompanied by a growing chemical industry. In 1883, T. Göring received a patent for a countercurrent extraction process using ethyl acetate solvent to recover acetic acid from "pyroligneous acid" produced by pyrolysis of wood [Ger. Patent 28064 (1883)], and in 1901, L. C. Reese received a patent for a stirred extraction column [U.S. Patent 679,575 (1901)].

With the emergence of the chemical engineering profession in the 1890s and the early 20th century, additional attention was given to process fundamentals and development of a more quantitative basis for process design. Many of the advances made in the study of distillation and absorption were readily adapted to liquid-liquid extraction, owing to its similarity as another diffusion-based operation [Sherwood, T. K., *Ind. Eng. Chem.* **33**(4): 424–429 (1941)]. Examples include the introduction of the equilibrium-stage approach to analyzing performance [Sorel, E., *La Rectification de l'Alcohol*, Gauthier-Villars, Paris, 1893], the application of mass-transfer coefficients [Lewis, W. K., *Ind. Eng. Chem.* **8**(9): 825–833 (1916); and Lewis, W. K., and W. G. Whitman, *Ind. Eng. Chem.* **16**(12): 1215–1220 (1924)], the use of graphical stagewise design methods [McCabe, W. L., and E. W. Thiele, *Ind. Eng. Chem.* **17**(6): 605–611 (1925); Evans, T. W., *Ind. Eng. Chem.* **26**(8): 860–864 (1934); and Thiele, E. W., *Ind. Eng. Chem.* **27**(4): 392–396 (1935)], countercurrent theoretical-stage calculations [Kremser, A., *National Petroleum News* **22**(21): 43–49 (1930); and Souders, M., and G. G. Brown, *Ind. Eng. Chem.* **24**(5): 519–522 (1932)], and the transfer unit concept introduced in the late 1930s by A. P. Colburn and others [*Ind. Eng. Chem.* **33**(4): 459–467 (1941)]. Additional background is given by M. J. Hampe, S. Hartland, and M. J. Slater [Chap. 2 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994].

The number of commercial applications continued to grow, and by the 1930s liquid-liquid extraction had replaced various chemical treatment methods for refining mineral oil and coal tar products [Varteressian, K. A., and M. R. Fenske, *Ind. Eng. Chem.* **28**(8): 928–933 (1936)]. Extraction also was used to recover acetic acid from waste liquors generated in the production of cellulose acetate, and in various nitration and sulfonation processes [Hunter, T. G., and A. W. Nash, *The Industrial Chemist* **9**(102–104): 245–248, 263–266, 313–316 (1933)]. Here, Hunter and Nash also describe early mixer-settler equipment, mixing jets, and various extraction columns, including the spray column, baffle tray column, sieve tray column, and a packed column filled with Raschig rings or with coke breeze, a solid by-product of coal or petroleum.

Much of the liquid-liquid extraction technology in practice today was first introduced to industry during a period of vigorous innovation and growth of the chemical industry as a whole from about 1920 to 1970. This period saw the introduction of many new equipment designs, including specialized mixer-settler equipment, mechanically agitated extraction columns, and centrifugal extractors, as well as a great increase in the availability of different types of industrial solvents. A variety of alcohols, ketones, esters, and chlorinated hydrocarbons became available in large quantities beginning in the 1930s as petroleum refiners and chemical companies found ways to manufacture them inexpensively using the by-products of petroleum refining and natural gas processing. The advances of this period also included the development of fractional extraction process schemes, including work described by R. E. Cornish et al. [*Ind. Eng. Chem.* **26**(4): 397–406 (1934)] and by E. W. Thiele [*Ind. Eng. Chem.* **27**(4): 392–396 (1935)]. A well-known commercial example involving the use of extract reflux is the UDEX process for separating aromatic from aliphatic hydrocarbons, a process developed jointly by The Dow Chemical Company and Universal Oil Products in the 1940s. The early UDEX units used diethylene glycol and diglycolamine as extraction solvents. Over the years, these were supplanted by higher-boiling glycols for greater capacity and lower energy consumption in the associated distillation operations. Later, a number of specialty solvents were introduced by others, including sulfolane (2,3,4,5-tetrahydrothiophene-1,1-dioxide) and NMP (*N*-methyl-2-pyrrolidone).

The ready availability of many solvents and extractants, combined with the tremendous growth of the chemical industry, drove the development and implementation of many new industrial applications. Handbooks of chemical process technology provide a glimpse of some of these [*Kent and Riegel's Handbook of Industrial Chemistry and Biotechnology*, 11th ed., ed. J. A. Kent, Springer, Berlin, 2007; *Chemical Processing Handbook*, ed. J. J. McKetta, Marcel Dekker, New York, 1993; and Austin, G. T., *Shreve's Chemical Process Industries,* 5th ed., McGraw-Hill, New York, 1984], but many remain proprietary and are not widely known. The better-known examples include the separation of aromatics from aliphatics as mentioned previously, the extraction of phenolic compounds from coal tars and liquors, the recovery of ε-caprolactam for the production of polyamide-6 (nylon-6), the recovery of hydrogen peroxide from oxidized anthraquinone solution, many processes involving the washing of crude organic streams with alkaline or acidic solutions and water, and the detoxification of industrial wastewater prior to biotreatment using steam-strippable organic solvents. The pharmaceutical and specialty chemicals industry also began using liquid-liquid extraction in the production of new synthetic drug compounds and other complex organics. In these processes, often involving multiple batch reaction steps, liquid-liquid extraction generally is used for the recovery of intermediates or crude products prior to final isolation of a pure product by crystallization. In the mining and metals industry, specialty organophosphorus compounds and alkyl amines were developed as extractants for recovery and purification of metal ions in aqueous acid solution (hydrometallurgy), including the recovery of uranium from phosphate-rock acid leachate liquor (the PUREX technology originating with the Manhattan Project during World War II) and the purification of copper by removal of arsenic impurities. Extraction processes also were developed for bioprocessing applications. Examples include the use of amyl acetate to recover penicillin and other antibiotics from fermentation broth, the recovery of citric acid from broth using trialkylamine extractants, and the use of water-soluble polymers in aqueous two-phase extraction for the purification of proteins.

Since the 1970s, the use of supercritical or near-supercritical fluids as an alternative to using liquid solvents for extraction has received a great deal of attention in the R&D community. Some processes were developed many years before then; for example, the propane deasphalting process used to refine lubricating oils uses propane at near-supercritical conditions. This technology dates back to the 1930s [McHugh, M. A., and V. J. Krukonis, *Supercritical Fluid Processing*, 2d ed., Butterworth-Heinemann, Oxford, UK, 1993]. In recent years, the use of supercritical fluids has found a number of commercial applications and has displaced earlier liquid-liquid extraction applications, particularly for the recovery of high-value products meant for consumption by humans, including decaffeinated coffee, flavor components from citrus oils, and a variety of nutraceuticals from natural sources.

Progress continues to be made toward improving extraction technology and its application, including the introduction of improved methods for calculating solvent properties and screening candidate solvents and solvent blends, improved methods for overall process conceptualization and optimization, and improved methods for equipment design. Progress also is being made by applying the technology developed for a particular application in one industry to improve another application in another industry. For example, much can be learned by comparing equipment and practices used in organic chemical production with those used in the inorganic chemical industry (and vice versa), or by comparing practices used in commodity chemical processing with those used in the specialty chemicals industry. And new concepts offering potential for significant improvements continue to be described in the literature. (See the subsection Emerging Developments.)

## USES FOR LIQUID-LIQUID EXTRACTION

For many separation applications, the use of liquid-liquid extraction is an alternative to the various distillation schemes described in Sec. 13, Distillation. In many of these cases, a distillation process is more economical largely because the extraction process requires extra operations to process the extract and raffinate streams, and these operations usually involve the use of distillation anyway. However, in certain cases the use of liquid-liquid extraction is more cost-effective than using distillation alone because it can be implemented with smaller equipment and/or lower energy consumption. In effect, a difficult distillation is exchanged for an easier one by first using extraction to transfer specific feed components into a second liquid phase (the extract), enabling easier isolation of a key component by distillation of this second liquid. Normally, distillation also will be needed to remove solvent residues from the remaining feed (the raffinate), and the solvent should be chosen to make this an easy distillation as well.

In particular, liquid-liquid extraction may be preferred when the relative volatility of key components is less than 1.3 or so, such that distillation alone requires an unusually tall distillation tower or high reflux ratios and high energy consumption. In certain cases, the distillation option may be improved by adding a solvent (extractive distillation) or an entrainer (azeotropic distillation) directly to the distillation tower instead of first using

extraction (see Sec. 13). The driving force for these *enhanced distillation* processes is a function of specific molecular interactions *and* the vapor pressures of the components, whereas the driving force for liquid-liquid extraction is a function of molecular interactions alone. Which process scheme is best in terms of higher selectivity or lower solvent usage and lower energy consumption will vary depending on the specific chemical system and specific process requirements.

Extraction also may be preferred when the distillation option requires operation at pressures less than about 70 mbar (about 50 mmHg) and an unusually large-diameter distillation tower is required, or when most of the feed must be taken overhead to isolate a desired bottoms product. Extraction also may be attractive when distillation requires the use of high-pressure steam for the reboiler or refrigeration for overheads condensation [Null, H. R., *Chem. Eng. Prog.* **76**(8): 42–49 (1980)], or when the desired product is temperature sensitive and extraction can provide a gentler separation process.

Of course, liquid-liquid extraction also may be a useful option when the components of interest cannot be separated by using distillation methods simply because key components are not sufficiently volatile. An obvious example is the recovery of metal ions from aqueous solution in hydrometallurgy [Cox, M., Chap. 1 in *Science and Practice of Liquid-Liquid Extraction*, vol. 2, ed. J. D. Thornton, Oxford University Press, New York, 1992]. Another example is the use of liquid-liquid extraction employing a steam-strippable solvent to remove nonstrippable, low-volatility contaminants from wastewater [Robbins, L. A., *Chem. Eng. Prog.* **76**(10): 58–61 (1980)]. The same process scheme often provides a cost-effective alternative to direct distillation or stripping of volatile impurities when the relative volatility of the impurity with respect to water is less than about 10 [Robbins, L. A., U.S. Patent 4,236,973 (1980); Hwang, Y. L., G. E. Keller, and J. D. Olson, *Ind. Eng. Chem. Res.* **31:** 1753–1759 (1992); and Frank, T. C., et al., *Ind. Eng. Chem. Res.* **46**(11): 3774–3786 (2007)].

Liquid-liquid extraction also can be an attractive alternative to separation methods other than distillation—for example, as an alternative to crystallization from solution to remove dissolved salts from a crude organic feed. Extraction of the salt content into water eliminates the need to filter solids from the mother liquor, often a difficult or expensive operation. Extraction also may compete with process-scale chromatography, an example being the recovery of hydroxytyrosol (3,4-dihydroxy-phenylethanol), an antioxidant food additive, from olive-processing wastewaters [Guzman, J. F.-B., et al., U.S. Patent 6,849,770 (2005)]. In hydrometallurgy, extraction is an alternative to various fixed-bed ion-exchange processes.

The attractiveness of liquid-liquid extraction for a given application compared to alternative separation technologies often depends upon the concentration of solute in the feed. The recovery of acetic acid from aqueous solutions is a well-known example [Brown, W. V., *Chem. Eng. Prog.* **59**(10): 65–68 (1963)]. In this case, extraction generally is more economical than distillation when handling dilute to moderately concentrated feeds, while distillation is more economical at higher concentrations. In the treatment of water to remove trace amounts of organics, when the concentration of impurities in the feed is greater than about 20 to 50 ppm, liquid-liquid extraction may be more economical than adsorption of the impurities by using carbon beds because the latter may require frequent and costly replacement of the adsorbent [L. A. Robbins, *Chem. Eng. Prog.* **76**(10): 58–61 (1980)]. At lower concentrations of impurities, adsorption may be the more economical option because the usable lifetime of the carbon bed is longer.

Examples of cost-effective liquid-liquid extraction processes that use relatively low-boiling solvents include the recovery of acetic acid from aqueous solutions using diethyl ether or ethyl acetate [King, C. J., chap. 18.5 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991] and the recovery of phenolic compounds from water by using methyl isobutyl ketone [Greminger, D. C., et al., *Ind. Eng. Chem. Proc. Des. Dev.* **21**(1): 51–54 (1982)]. In these processes, the solvent is recovered from the extract by distillation, and dissolved solvent is removed from the raffinate by steam stripping (Fig. 15-1). The solvent circulates through the process in a closed loop.

A well-known application of liquid-liquid extraction in petrochemical operations involves the extraction of aromatic compounds from hydrocarbon mixtures using high-boiling (low volatility) polar solvents. The production rates are very large, and a high-boiling solvent (relative to the product solute) is used to minimize energy consumption in subsequent distillations of the extract. A number of processes have been developed to recover benzene, toluene, and xylene (BTX) as feedstock for chemical manufacturing or to refine hydrocarbon fractions for use as lubricants and fuels. This general technology is described in detail in the subsection Single-Solvent Fractional Extraction with Extract Reflux under Calculation Procedures. A typical flow diagram is shown in Fig. 15-2. For smaller-scale operations, a relatively light polar solvent may be used; processes using *N,N*-dimethylformamide or acetonitrile have been developed for the removal of polynuclear aromatic and

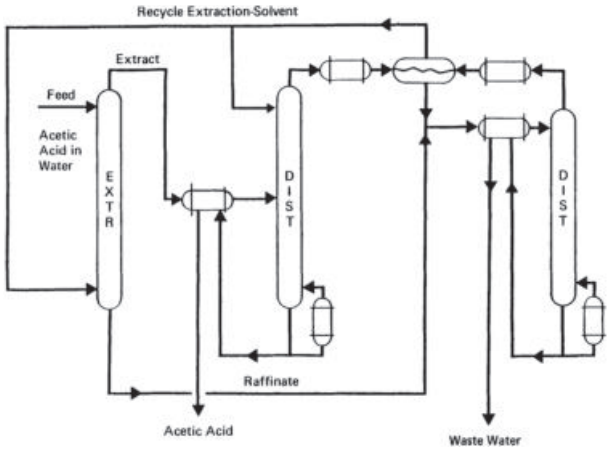

**FIG. 15-1** Typical process for extraction of acetic acid from water.

sulfur-containing contaminants from used motor oils [Sherman, J. H., J. W. Hershberger, and R. T. Taylor, U.S. Patent 6,320,090 (2001)]. An alternative process uses a blend of methyl ethyl ketone + 2-propanol and small amounts of aqueous KOH [Rincón, J., P. Cañizares, and M. T. García, *Ind. Eng. Chem. Res.* **44**(20): 7854–7859 (2005)].

Liquid-liquid extraction also is used to remove $CO_2$, $H_2S$, and other acidic contaminants from liquefied petroleum gas (LPG) generated during the operation of fluid catalytic crackers and cokers in petroleum refineries and from liquefied natural gas (LNG)—a process called sweetening. The acid gases are extracted from the liquefied hydrocarbons into water by reversible reaction with various aqueous amine extractants. Typical amines are methyldiethanolamine (MDEA), diethanolamine (DEA), monoethanolamine (MEA), and diglycolamine (DGA). In a typical process (Fig. 15-3), the treated hydrocarbon liquid (the raffinate) is washed with water to remove residual amine, and the loaded aqueous amine solution (the extract) is regenerated in a stripping tower for recycle back to the extractor [Nielsen, R. B., et al., *Hydrocarbon Proc.* **76:** 49–59 (1997)]. The technology is similar to that used to scrub $CO_2$ and $H_2S$ from gas streams [Oyenekan, B. A., and G. T. Rochelle, *Ind. Eng. Chem. Res.* **45**(8): 2465–2472 (2006); and Jassim, M. S., and G. T. Rochelle, *Ind. Eng. Chem. Res.* **45**(8): 2457–2464 (2006)], except that the process involves liquid-liquid contacting instead of gas-liquid contacting. Because of this, in a typical refinery, a single large stripping tower often will be used to regenerate aqueous amines coming from a variety of gas absorbers and liquid-liquid extractors (called *liquid treaters* in the industry). In certain applications, organic acids such as formic acid are present in low concentrations in the hydrocarbon feed. These contaminants will react with the amine to form heat-stable amine salts that accumulate in the extraction solvent recycle loop over time, requiring periodic purging or regeneration of the extractant [Price, J., and D. Burns, *Hydrocarb. Process.* **74:** 140–141 (1995)].

A typical extraction process used in hydrometallurgical applications is outlined in Fig. 15-4. This technology involves transferring the desired metal ion from the ore leachate liquor, an aqueous acid, into an organic solvent phase containing specialty extractants that form a reversible complex with the metal ion. The organic phase is later contacted with another aqueous solution to regenerate the solvent and transfer the metal ion into a clean solution from which it can be recovered by electrolysis or another method [Sole, K. C., A. M. Feather, and P. M. Cole, *Hydrometallurgy* **78:** 52–78 (2005); and Zhang, J., B. Zhao, and B. Schreiner, *Separation Hydrometallurgy of Rare Earth Metals,* Springer, Berlin, 2016]. In this industry, the initial extraction of metal ion from the aqueous acid leachate liquor into an organic phase is called *solvent extraction*, while the extraction of unwanted impurities from the loaded organic phase is called *washing* or *scrubbing*, and back-extraction of the metal ion of interest from the organic phase into clean aqueous solution is called *stripping*. Note that these terms have more general meanings in nonhydrometallurgical applications. (See the subsection Definitions.) Hydrometallurgy is discussed in more detail in the subsection Reaction-Enhanced Extraction under Commercial Process Schemes. A related process technology uses metals complexed with various organophosphorus compounds as recyclable homogeneous catalysts; liquid-liquid extraction is used to transfer the metal complex between the reaction phase and a separate liquid phase after reaction. Different ligands having different polarities are chosen to facilitate the use of various extraction and recycle schemes [Kanel, J. S., et al., U.S. Patents 6,294,700 (2001) and 6,303,829 (2001)].

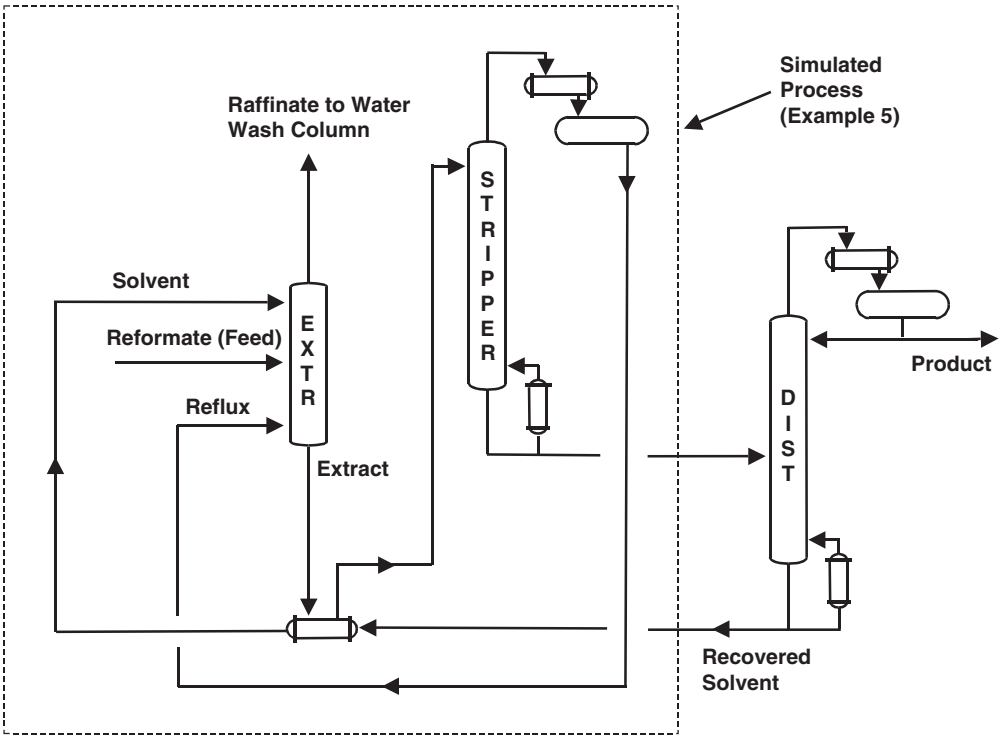

**FIG. 15-2** Flow sheet of a simplified aromatic extraction process (see Example 15-5).

Bioprocessing is another category of useful liquid-liquid extraction applications. A longstanding example involves the recovery of antibiotics and other complex organics from aqueous fermentation broth by using a variety of oxygenated organic solvents such as acetates and ketones. Although some of these products are unstable at the required extraction conditions (particularly if pH must be low for favorable partitioning), short-contact-time centrifugal extractors may be used to minimize exposure. Centrifugal extractors also help overcome problems associated with the formation of emulsions between solvent and broth. In a number of applications, the whole broth can be processed without prior removal of cell debris and other solids, a practice that can significantly reduce costs. For detailed information, see "The History of Penicillin Production," A. L. Elder, ed., *Chemical Engineering Progress Symposium Series No. 100*, vol. 66, pp. 37–42, American Institute of Chemical Engineers, New York, 1970; S. W. Queener and R. W. Swartz, "Penicillins: Biosynthetic and Semisynthetic," in *Secondary Products of Metabolism, Economic Microbiology*, vol. 3, ed. A. H. Rose, Academic, New York, 1979; and T. Z. Chaung et al., *J. Chinese Inst. Chem. Eng.* **20**(3): 155–161 (1989). Another well-known commercial application of liquid-liquid extraction in bioprocessing involves the recovery of citric acid from fermentation broth with tertiary amine extractants [Baniel, A. M., R. Blumberg, and

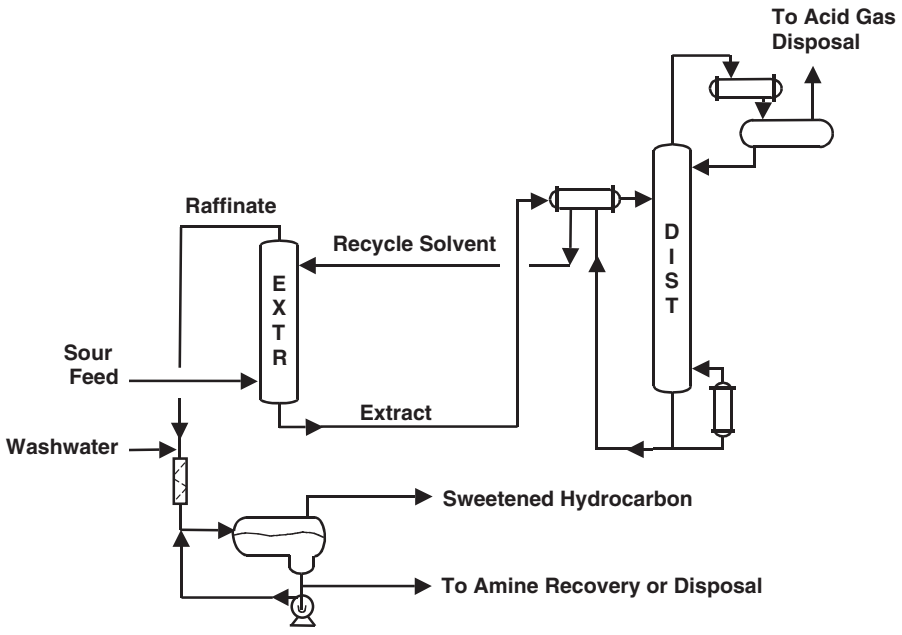

**FIG. 15-3** Typical process for extracting acid gases from LPG or LNG.

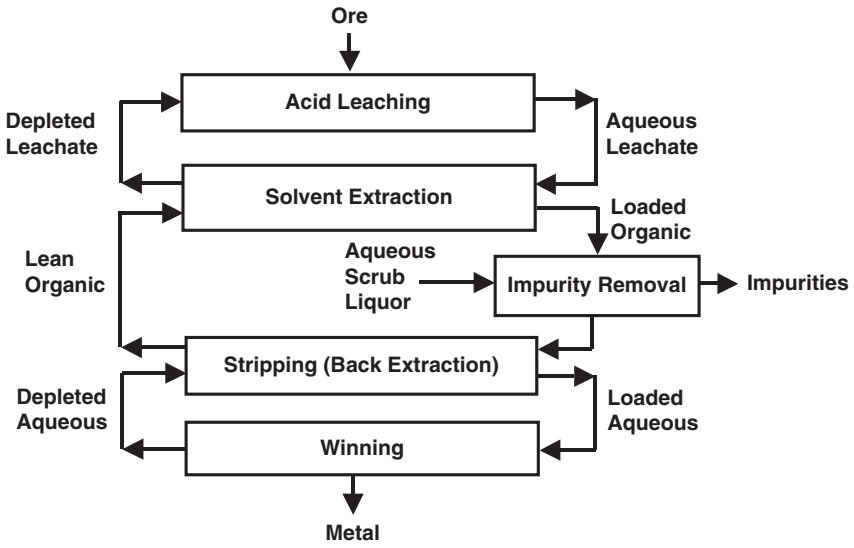

**FIG. 15-4** Example process scheme used in hydrometallurgical applications. [*Taken from Cox, Chap. 1 in* Science and Practice of Liquid-Liquid Extraction, *vol. 2, Thornton, (Oxford, 1992), with permission. Copyright 1992 Oxford University Press.*]

K. Hajdu, U.S. Patent 4,275,234 (1981)]. This type of process is discussed in Reaction-Enhanced Extraction under Commercial Process Schemes. Another bioprocessing example is the application of extraction in lignocellulosic ethanol production [Zhang, J., and B. Hu, "Liquid-Liquid Extraction," chap. 3 in *Separation and Purification Technologies in Biorefineries*, ed. S. Ramaswamy, H.-J. Huang, and B. V. Ramarao, Wiley, New York, 2013].

## DEFINITIONS

Extraction terms defined by the International Union of Pure and Applied Chemistry (IUPAC) generally are recommended. See N. M. Rice, H. M. N. H. Irving, and M. A. Leonard, *Pure Appl. Chem.* (IUPAC) **65**(11): 2373–2396 (1993); and J. Inczédy, *Pure Appl. Chem.* (IUPAC) **66**(12): 2501–2512 (1994). *Liquid-liquid extraction* is a process for separating components dissolved in a liquid feed by contact with a second liquid phase. *Solvent extraction* is a broader term that describes a process for separating the components of any matrix by contact with a liquid, and it includes liquid-solid extraction (leaching) as well as liquid-liquid extraction. The *feed* to a liquid-liquid extraction process is the solution that contains the components to be separated. The major liquid component (or components) in the feed can be referred to as the *feed solvent* or the *carrier solvent.* Minor components in solution often are referred to as *solutes.* The *extraction solvent* is the immiscible or partially miscible liquid added to the process to create a second liquid phase for the purpose of extracting one or more solutes from the feed. It is also called the *separating agent* and may be a mixture of several individual solvents (a *mixed solvent* or a *solvent blend*). The extraction solvent also may be a liquid comprised of an *extractant* dissolved in a liquid *diluent.* In this case, the extractant species is primarily responsible for the extraction of solute due to a relatively strong attractive interaction with the desired solute, forming a reversible adduct or molecular complex. The diluent itself does not contribute significantly to the extraction of solute, and in this respect it is not the same as a true extraction solvent, although a diluent may improve mass transfer by reducing viscosity. A *modifier* may be added to the diluent to increase the solubility of the extractant or otherwise enhance the effectiveness of the extractant. The phase leaving a liquid-liquid contactor rich in extraction solvent is called the *extract.* The *raffinate* is the liquid phase left from the feed after it is contacted by the extract phase. The word *raffinate* originally referred to a "refined product"; however, common usage has extended its meaning to describe the feed phase after extraction whether that phase is a product or not.

Industrial liquid-liquid extraction most often involves processing two immiscible or partially miscible liquids in the form of a *dispersion* of droplets of one liquid (the *dispersed phase*) suspended in the other liquid (the *continuous phase*). The dispersion will exhibit a distribution of drop diameters $d_i$ often characterized by the volume-to-surface-area average diameter or *Sauter mean drop diameter.* The term *emulsion* generally refers to a liquid-liquid dispersion with a dispersed-phase mean drop diameter on the order of 1 μm or less.

The tension that exists between two liquid phases is called the *interfacial tension*. It is a measure of the energy or work required to increase the surface area of the liquid-liquid interface, and it affects the size of dispersed drops. Its value, in units of force per unit length or energy per unit area, reflects the compatibility of the two liquids. Systems that have low compatibility (low mutual solubility) exhibit high interfacial tension. Such a system tends to form relatively large dispersed drops and low interfacial area to minimize contact between the phases. Systems that are more compatible (with higher mutual solubility) exhibit lower interfacial tension and more easily form small dispersed droplets.

A *theoretical* or *equilibrium stage* accomplishes the effect of intimately mixing two liquid phases until equilibrium concentrations are reached, then physically separating the two phases into clear layers. The *partition ratio K* commonly is defined for a given solute as the solute concentration in the extract phase divided by that in the raffinate phase after equilibrium is attained in a single stage of contacting. A variety of concentration units are used, so it is important to determine how partition ratios have been defined in the literature for a given application. The term *partition ratio* is preferred, but it also is referred to as the *distribution constant, distribution coefficient*, or the *K* value. It is a measure of the thermodynamic potential of a solvent for extracting a given solute and can be a strong function of composition and temperature. In some cases, the partition ratio transitions between a value less than unity and a value greater than unity as a function of solute concentration. A system of this type is called a *solutrope* [Smith, A. S., *Ind. Eng. Chem.* **42**(6): 1206–1209 (1950)]. The term *distribution ratio*, designated by $\mathcal{D}_i$, is used in analytical chemistry to describe the distribution of a species that undergoes chemical reaction or dissociation, in terms of the total concentration of analyte in one phase over that in the other, regardless of its chemical form.

The *extraction factor* $\mathcal{E}$ is a dimensionless process variable that characterizes the capacity of the extract phase to carry solute relative to the feed phase. Its value largely determines the number of theoretical stages required to transfer solute from the feed to the extract. The extraction factor is analogous to the stripping factor in distillation and is the ratio of the slope of the equilibrium line to the slope of the operating line in a McCabe-Thiele type of stagewise graphical calculation. For a dilute to moderately concentrated extraction process with straight equilibrium and operating lines, $\mathcal{E}$ is constant and equal to the partition ratio for the solute of interest times the ratio of the solvent flow rate to the feed flow rate. The separation factor $\alpha_{ij}$ measures the relative enrichment of solute *i* in the extract phase, compared to solute *j*, after one theoretical stage of extraction. It is equal to the ratio of *K* values for components *i* and *j* and is used to characterize the *selectivity* a solvent has for a given solute.

A *standard extraction* process is one in which the primary purpose is to transfer solute from the feed phase into the extract phase in a manner analogous to stripping in distillation. *Fractional extraction* refers to a process in which two or more solutes present in the feed are sharply separated from each other, one fraction leaving the extractor in the extract and the other in

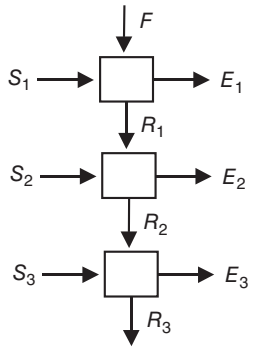

**FIG. 15-5** Cross-current extraction.

the raffinate. In the chemical process industries, *stripping* generally refers to a standard extraction process or the portion of a fractional extraction process where solute transfers from the feed phase into the extract phase. *Washing* refers to the portion of a fractional extraction process (or a separate operation) where unwanted impurities transfer out of the extract phase. *Cross-current or cross-flow extraction* (Fig. 15-5) is a series of discrete stages in which the raffinate *R* from one extraction stage is contacted with additional fresh solvent *S* in each subsequent stage. *Countercurrent extraction* (Fig. 15-6) is an extraction scheme in which the extraction solvent enters the process at the end of the extraction farthest from where the feed *F* enters, and the two phases pass each other in countercurrent fashion. The objective is to transfer one or more components from the feed solution *F* into the extract *E*. Compared to cross-current operation, countercurrent operation generally allows operation with less solvent. When a *staged contactor* is used, the two phases are mixed with droplets of one phase suspended in the other, but the phases are separated before leaving each stage. A *countercurrent cascade* uses multiple staged contactors with countercurrent flow of solvent and feed streams from stage to stage. When a *differential contactor* is used, one of the phases remains dispersed as drops throughout the contactor as the phases pass each other in countercurrent fashion. The dispersed phase is then allowed to coalesce at the end of the device before being discharged. For these types of processes, *mass-transfer units* (or the related *mass-transfer coefficients*) often are used instead of theoretical stages to characterize separation performance. For a given phase, mass-transfer units are defined as the integral of the differential change in solute concentration divided by the deviation from equilibrium, between the limits of inlet and outlet solute concentrations. A single transfer unit represents the change in solute concentration equal to that achieved by a single theoretical stage when the extraction factor is equal to 1.0. It differs from a theoretical stage at other values of the extraction factor.

*Flooding* generally refers to excessive breakthrough or entrainment of one liquid phase into the discharge stream of the other. The flooding characteristics of an extractor limit its hydraulic capacity. Flooding can be caused by excessive flow rates within the equipment, by *phase inversion* due to accumulation and coalescence of dispersed droplets, or by the formation of stable dispersions or emulsions due to the presence of surface-active impurities or excessive agitation. The *flood point* refers to the specific total volumetric *throughput* in $(m^3/h)/m^2$ or $gpm/ft^2$ of cross-sectional area (or the equivalent *phase velocity* in m/s or ft/s) at which flooding begins.

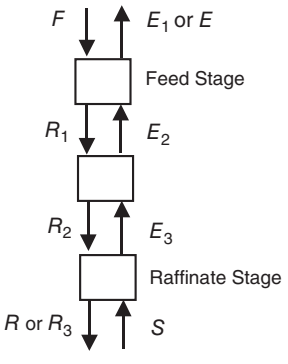

**FIG. 15-6** Standard countercurrent extraction.

## DESIRABLE SOLVENT PROPERTIES

Common industrial solvents generally are single-functionality organic solvents such as ketones, esters, alcohols, linear or branched aliphatic hydrocarbons, aromatic hydrocarbons, and so on; or water, which may contain acids or bases to adjust pH and may be mixed with water-soluble organic solvents. More complex solvents are sometimes used to obtain specific properties needed for a given application. These include compounds with multiple functional groups such as diols or triols, glycol ethers, and alkanol amines, as well as specialty organics such as pine-derived solvents (terpenes), citrus-derived solvents (such as limonene, a cyclic terpene), sulfolane (2,3,4,5-tetrahydrothiophene-1,1-dioxide), and NMP (*N*-methyl-2-pyrrolidone). Solvent properties have been summarized in a number of handbooks and databases, including those by N. P. Cheremisinoff, *Industrial Solvents Handbook*, 2d ed., revised and expanded, CRC Press, Boca Raton, Fla., 2003; G. Wypych, *Handbook of Solvents*, 2d ed., ChemTec, New York, 2014; A. Wypych and G. Wypych, *Databook of Solvents,* ChemTec, New York, 2014; *Solvents Database*, CD-ROM, ver. 4.0, ChemTec, New York, 2014; C. L. Yaws, *Thermodynamic and Physical Property Data*, 2d ed., Gulf, Houston, 1998; and E. W. Flick, *Industrial Solvents Handbook*, 5th ed., Noyes, Westwood, NJ, 1998. Also see D. Prat et al. [*Org. Process Res. Dev*. **17**(12): 1517–1525 (2013)] for a discussion of solvents used in pharmaceutical processing, and B. G. Cox [*Org. Proc. Res. Dev*. **19**(12): 1800–1808 (2015)] for a discussion of acids and bases in aqueous organic solvents.

Organic solvents are sometimes blended to obtain specific properties, another approach to achieving a multifunctional solvent with properties tailored for a given application. Examples are discussed by I. Escudero, J. L. Cabezas, and J. Coca [*Chem. Eng. Comm.* **173:** 135–146 (1999)] and by M. L. van Delden et al. [*Chem. Eng. Technol.* **29**(10): 1221–1226 (2006)]. As discussed earlier, a solvent also may be a liquid containing a dissolved extractant species, the extractant chosen because it forms an adduct or molecular complex with the desired solute.

In terms of desirable properties, no single solvent or solvent blend can be best in every respect. The choice of solvent often is a compromise, and the relative weighting given to the various considerations depends on the given situation. Assessments should take into account long-term sustainability and overall cost of ownership. An example case study is discussed by V. H. Shah et al. [*Ind. Eng. Chem. Res*. **55**(6): 1731–1739 (2016)]. Normally, the factors considered in choosing a solvent include the following:

1. *Loading capacity*. This property refers to the maximum concentration of solute the extract phase can hold before two liquid phases can no longer coexist or solute precipitates as a separate phase. If a specialized extractant is used, loading capacity may be determined by the point at which all the extractant in solution is completely occupied by solute and extractant solubility limits capacity. If loading capacity is low, a high solvent-to-feed ratio may be needed even if the partition ratio is high.

2. *Partition ratio* $K_i = Y_i/X_i$. Partition ratios on the order of $K_i = 10$ or higher are desired for an economical process because they allow operation with minimal amounts of solvent (more specifically, with a minimal solvent-to-feed ratio) and production of higher solute concentrations in the extract—unless the solute concentration in the feed already is high and a limitation in the solvent's loading capacity determines the required solvent-to-feed ratio. Because high partition ratios generally allow for low solvent use, smaller and less costly extraction equipment may be used, and costs for solvent recovery and recycle are lower. In principle, partition ratios less than $K_i = 1.0$ may be accommodated by using a high solvent-to-feed ratio, but usually at much higher cost.

3. *Solute selectivity*. In certain applications, it is important not only to recover a desired solute from the feed, but also to separate it from other solutes present in the feed and thereby achieve a degree of solute purification. The selectivity of a given solvent for solute *i* compared to solute *j* is characterized by the separation factor $\alpha_{i,j} = K_i/K_j$. Values must be greater than $\alpha_{i,j} = 1.0$ to achieve an increase in solute purity (on a solvent-free basis). When solvent blends are used in a commercial process, often it is because the blend provides higher selectivity, and often at the expense of a somewhat lower partition ratio. The degree of purification that can be achieved also depends on the extraction scheme chosen for the process, the amount of extraction solvent, and the number of stages employed.

4. *Mutual solubility*. Low liquid-liquid mutual solubility between feed and solvent phases is desirable because it reduces the separation requirements for removing solvents from the extract and raffinate streams. Low solubility of extraction solvent in the raffinate phase often results in high relative volatility for stripping the residual solvent in a raffinate stripper, allowing low-cost removal of solvent from the raffinate [Hwang, Y. L., G. E. Keller, and J. D. Olson, *Ind. Eng. Chem. Res.* **31**(7): 1753–1759 (1992)]. Low solubility of feed solvent in the extract phase reduces separation requirements for recovering solvent for recycle and producing a purified product solute. In some cases, if the solubility of feed solvent in the extract is high, more than one distillation operation will be required to separate the extract phase.

If mutual solubility is nil (as for aliphatic hydrocarbons dissolved in water), the need for stripping or another treatment method may be avoided as long as efficient liquid-liquid phase separation can be accomplished. However, very low mutual solubility normally is achieved at the expense of a lower partition ratio and loading capacity for extracting the desired solute. Mutual solubility also limits the solvent-to-feed ratios that can be used, because a point can be reached where the solvent stream is so large it dissolves the entire feed stream, or the solvent stream is so small it is dissolved by the feed, and these can be real limitations for systems with high mutual solubility.

5. *Stability.* The solvent should have little tendency to react with the product solute and form unwanted by-products, causing a loss in yield. Also it should not react with feed components or degrade to undesirable contaminants that cause the development of undesirable odors, colors, or tars that foul equipment over time, or cause difficulty achieving desired product purity, or accumulate in the process because they are difficult to purge.

6. *Density difference.* As a general rule, a difference in density between solvent and feed phases on the order of 0.1 to 0.3 g/mL is preferred. A value that is too low makes for poor or slow liquid-liquid phase separation and may require the use of a centrifuge. A value that is too high makes it difficult to build high dispersed-droplet population density for good mass transfer—that is, it is difficult to mix the two phases together and maintain high holdup of the dispersed phase within the extractor—but this depends on the viscosity of the continuous phase.

7. *Viscosity.* Low (waterlike) viscosity is preferred because higher viscosity generally increases mass-transfer resistance and makes liquid-liquid phase separation more difficult. Sometimes an extraction process is operated at an elevated temperature where viscosity is significantly lower for better mass-transfer performance, even when this results in a lower partition ratio. Low viscosity at ambient temperatures also facilitates the transfer of solvent from storage to processing equipment.

8. *Interfacial tension.* Preferred values for interfacial tension between the feed phase and the extraction solvent phase generally are in the range of 5 to 25 dyn/cm (1 dyn/cm is equivalent to $10^{-3}$ N/m). Systems with lower values easily emulsify. For systems with higher values, dispersed droplets tend to coalesce easily, resulting in low interfacial area and poor mass-transfer performance unless mechanical agitation is used.

9. *Recoverability.* The economical recovery of solvent from the extract and raffinate is critical to commercial success. Solvent physical properties should facilitate low-cost options for solvent recovery, recycle, and storage. For example, the use of relatively low-boiling organic solvents with low heats of vaporization generally allows cost-effective use of distillation and stripping for solvent recovery. Solvent properties also should enable low-cost methods for purging from the overall process impurities that may accumulate over time (both low-boiling and high-boiling impurities). One of the challenges often encountered in using a high-boiling solvent or extractant involves accumulation of high-boiling impurities in the solvent phase and difficulty in removing them from the process. Another consideration is the ease with which solvent residues can be reduced to low levels in final extract or raffinate products, particularly for food-grade products and pharmaceuticals.

10. *Freezing point.* Solvents that are liquids at all anticipated ambient temperatures are desirable because they avoid the need for freeze protection and/or thawing of frozen solvent prior to use. Sometimes an "antifreeze" additive such as water or an aliphatic hydrocarbon can be added to the solvent, or the solvent is supplied as a mixture of related compounds instead of a single pure component to suppress the freezing point.

11. *Safety and health.* Solvents with low toxicity and low potential for fire and reactive chemical hazards are preferred as inherently safe solvents. Low mammalian toxicity and low dermal absorption rate reduce the potential for injury through acute exposure. In all cases, solvents must be used with a full awareness of potential hazards and in a manner consistent with measures needed to avoid hazards and prevent injury. A detailed hazard assessment and safety review will be needed for any new process operation and for significant changes to an existing operation. For information on the safe use of solvents and their potential hazards, see Sec. 23, Safety and Handling of Hazardous Materials. Also see D. A. Crowl and J. F. Louvar, *Chemical Process Safety: Fundamentals with Applications*, 3d ed., Prentice-Hall, Upper Saddle River, NJ, 2011; C. L. Yaws, *Handbook of Chemical Compound Data for Process Safety*, Elsevier, Amsterdam, 1997; S. Mannan, *Lees' Loss Prevention in the Process Industries*, 4th ed., Butterworth-Heinemann, Oxford, UK, 2012; and *Bretherick's Handbook of Reactive Chemical Hazards*, 7th ed., ed. P. G. Urben, 2 vols., Academic Press, New York, 2007. A thorough review of the medical literature also must be conducted to ascertain chronic toxicity issues. Measures needed to avoid unsafe exposures must be incorporated into process designs and implemented in operating procedures. See D. L. Goetsch, *Occupational Safety and Health for Technologists, Engineers, and Managers*, 8th ed., Pearson, London, 2014.

12. *Environmental requirements.* The solvent must have physical or chemical properties that allow effective control of emissions in vents, wastewater, and other discharge streams. Preferred properties include low aquatic toxicity and low potential for fugitive emissions from leaks or spills. It also is desirable for a solvent to have low photoreactivity in the atmosphere and be biodegradable so it does not persist in the environment. Efficient technologies for capturing solvent vapors from vents and condensing them for recycle include activated carbon adsorption with steam regeneration or vacuum-swing regeneration [Smallwood, I. M., *Solvent Recovery Handbook*, 2d ed., Blackwell, Oxford, UK, 2002; Technical Bulletins EPA 452/B-02-001 and EPA 456/F-99-004, U.S. Environmental Protection Agency, 1999; and Pezolt, D. J., et al., *Environ. Prog.* **16**(1): 16–19 (1997)]. The optimization of a process to increase the efficiency of solvent utilization is a key aspect of waste minimization and reduction of environmental impact. An opportunity may exist to reduce solvent use through the application of countercurrent processing and other chemical engineering principles aimed at improving processing efficiencies. For a discussion of environmental issues in process design, see D. T. Allen and D. R. Shonnard, *Green Engineering: Environmentally Conscious Design of Chemical Processes*, Prentice-Hall, Upper Saddle River, NJ, 2002]. Also see Sec. 22, Waste Management.

13. *Multiple uses.* It is desirable to use as the extraction solvent a material that can serve a number of purposes in the manufacturing plant. This avoids the cost of storing and handling multiple solvents. It may be possible to use a single solvent for a number of different extraction processes practiced in the same facility, either in different equipment operated at the same time or by using the same equipment in a series of product campaigns. In other cases, the solvent used for extraction may be one of the raw materials for a reaction carried out in the same facility, or a solvent used in another operation such as crystallization.

14. *Materials of construction.* It is desirable for a solvent to allow the use of common, relatively inexpensive materials of construction at moderate temperatures and pressures. Material compatibility and potential for corrosion are discussed in Sec. 25, Materials of Construction.

15. *Availability and cost.* The solvent should be readily available at a reasonable cost. Considerations include the initial fill cost, the investment costs associated with maintaining a large solvent inventory in the plant (particularly when expensive extractants are used), as well as the cost of makeup solvent.

## COMMERCIAL PROCESS SCHEMES

For the purpose of illustrating process concepts, liquid-liquid extraction schemes typically practiced in industry may be categorized into a number of general types.

**Standard Extraction** Also called simple extraction or single-solvent extraction, standard extraction is by far the most widely practiced type of extraction operation. It can be practiced using single-stage or multistage processing, cross-current or countercurrent flow of solvent, and batch-wise or continuous operation. Figure 15-6 illustrates the contacting stages and liquid streams associated with a typical multistage, countercurrent scheme. Standard extraction is analogous to stripping in distillation (as defined in Sec. 13) because the process involves transferring or *stripping* components from the feed phase into another phase. Note that the feed ($F$) enters the process where the extract stream ($E$) leaves the process, analogous to feeding the top of a stripping tower. And the raffinate ($R$) leaves where the extraction solvent ($S$) enters. Standard extraction is used to remove contaminants from a crude liquid feed (product purification) or to recover valuable components from the feed (product recovery). Applications can involve very dilute feeds, such as when purifying a liquid product or detoxifying a wastewater stream, or concentrated feeds, such as when recovering a crude product from a reaction mixture. In either case, standard extraction can be used to transfer a high fraction of solute from the feed phase into the extract. Note, however, that transfer of the desired solute or solutes may be accompanied by transfer of unwanted solutes. Because of this, standard extraction normally cannot achieve satisfactory solute purity in the extract stream unless the separation factor for the desired solute with respect to unwanted solutes is at least $\alpha_{i,j} = K_i/K_j = 20$ and usually much higher. This depends on the crude feed purity and the product purity specification. (See the subsection Potential for Solute Purification Using Standard Extraction under Process Fundamentals and Basic Calculation Methods.)

**Fractional Extraction** Fractional extraction combines solute recovery with cosolute rejection. In principle, the process can achieve high solute recovery and high solute purity even when the solute separation factor is fairly low, as low as $\alpha_{i,j} = 4$ or so (see the subsection Dual-Solvent Fractional Extraction under Calculation Procedures. Lower values of $\alpha_{i,j}$ may be considered in special cases, but this will require using an unusually large number of contacting stages.) Dual-solvent fractional extraction uses an extraction solvent ($S$) and a wash solvent ($W$) and includes a stripping

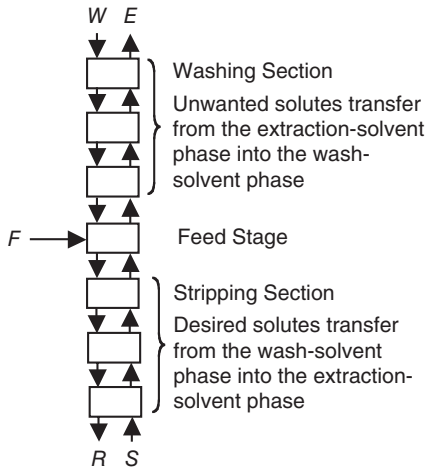

**FIG. 15-7** Dual-solvent fractional extraction without reflux.

section at the raffinate end of the process (for product-solute recovery) and a washing section at the extract end of the process (for cosolute rejection and product purification) (Fig. 15-7). The feed enters the process at an intermediate stage located between the extract and raffinate ends. In this respect, the process is analogous to a middle-fed fractional distillation, although the analogy is not exact; wash solvent is added to the extract end of the process instead of returning a reflux stream. The desired solutes transfer into the extraction solvent (the extract phase) within the stripping section, and unwanted solutes transfer into the wash solvent (the raffinate phase) within the washing section. Typically, the feed stream consists of feed solutes pre-dissolved in wash solvent or extraction solvent; or, if they are liquids, they may be injected directly into the process. To maximize performance, a fractional extraction process may be operated such that the washing and stripping sections are carried out in different equipment and at different temperatures. The stripping section is sometimes called the extraction section, and the washing section is sometimes called the enriching section, the scrubbing section, or the absorbing section. A dual-solvent fractional extraction process involving reflux to the washing section is shown in Fig. 15-8.

In a special case referred to as single-solvent fractional extraction with extract reflux, the wash solvent is comprised of components that enter the overall process with the feed and return as reflux (Fig. 15-9). This is the type of extraction scheme commonly used to recover aromatic components from crude hydrocarbon mixtures using high-boiling polar solvents (as in Fig. 15-2). A reflux stream rich in light aromatics including benzene

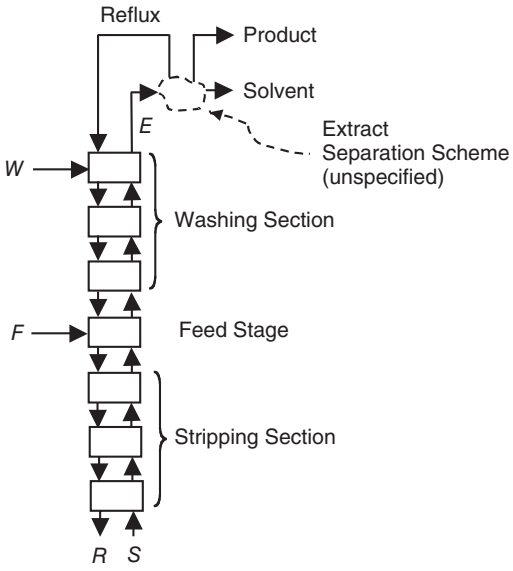

**FIG. 15-8** Process concepts for dual-solvent fractional extraction with extract reflux.

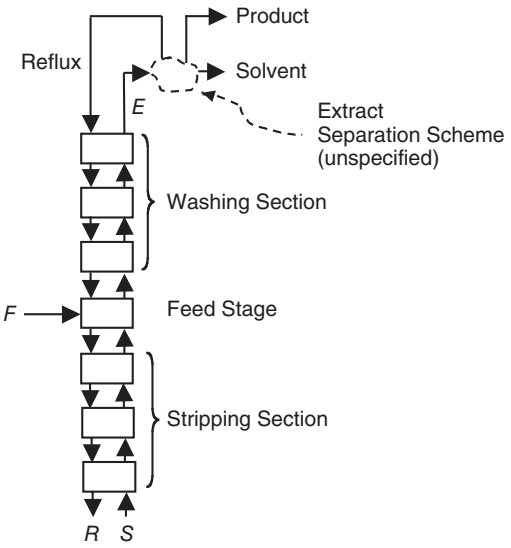

**FIG. 15-9** Process concepts for single-solvent fractional extraction with extract reflux. The process flow sheet shown in Fig. 15-2 is an example of this general process scheme.

is refluxed to the washing section to serve as wash solvent. This process scheme is very similar in concept to fractional distillation. In practice, it is used only for a very limited number of chemical systems [Stevens, G. W., and H. R. C. Pratt, Chap. 6, in *Science and Practice of Liquid-Liquid Extraction*, vol. 1, ed. J. D. Thornton, Oxford University Press, Oxford, UK, 1992, pp. 379–395]. More detailed discussion is given in Single-Solvent Fractional Extraction with Extract Reflux under Calculation Procedures.

In terms of common practice, fractional extraction operations may be classified into several types: (1) standard extraction augmented by addition of a washing section utilizing a relatively small amount of feed solvent as the wash solvent; (2) full fractionation (less common); and (3) full fractionation with solute reflux (much less common). The first two categories are examples of dual-solvent fractional extraction. The third category can be practiced as dual-solvent or single-solvent fractional extraction.

In the first type of operation, a relatively small amount of feed solvent is added to a short washing section as wash solvent. (The word *short* is used here in an extraction column context, but refers in general to a relatively few theoretical stages.) This approach is useful for systems exhibiting a moderate to high solute separation factor ($\alpha_{i,j} > 20$ or so) and requiring a boost in product-solute purity. An example involves recovery of an organic solute from a dilute brine feed by using a partially miscible organic solvent. In this case, the inorganic salt present in the aqueous feed stream has some solubility in the organic solvent phase because of water that saturates that phase, and the partition ratio for transfer of salt into the organic phase is small (i.e., the partition ratio for transfer of salt into wash water is high). Adding wash water to the extract end of the process has the effect of washing a portion of the soluble salt content out of the organic extract. The reduction in salt content depends on how much wash water is added and how many washing stages or transfer units are used in the design.

The second type of fractional extraction operation involves the use of stripping and washing sections without reflux (Fig. 15-7) to separate a mixture of feed solutes with close $K$ values. In this case, the solute separation factor is low to moderate. Normally, $\alpha_{i,j}$ must be greater than about 4 for a commercially viable process (which requires only a moderate number of contacting stages). E. G. Scheibel [*Chem. Eng. Prog.* **44**(9): 681–690 (1948); and **44**(10): 771–782 (1948)] gives several instructive examples of fractional extraction: (1) separation of ortho and para chloronitrobenzenes using heptane and 85 percent aqueous methanol as solvents ($\alpha_{\text{para,ortho}} \approx$ 1.6 to 1.8); (2) separation of ethanol and isopropanol by using water and xylene ($\alpha_{\text{ethanol,isopropanol}} \approx 2$); and (3) separation of ethanol and methyl ethyl ketone (MEK) by using water and kerosene ($\alpha_{\text{ethanol,MEK}} \approx 10$ to 20). The first two applications demonstrate fractional extraction concepts, but a sharp separation is not achieved using a moderate number of stages because the selectivity of the solvent is too low. In these kinds of applications, fractional extraction might be combined with another separation operation to complete the separation. (See the subsection Hybrid Extraction Processes.) In Scheibel's third example, the selectivity is much higher, and nearly complete separation is achieved by using a total of about seven theoretical stages.

In another example, D. L. Venter and I. Nieuwoudt [*Ind. Eng. Chem. Res.* **37**(10): 4099–4106 (1998)] describe a dual-solvent extraction process using hexane and aqueous tetraethylene glycol to selectively recover *m*-cresol from coal pyrolysis liquors also containing *o*-toluonitrile. This process has been successfully implemented in industry. The separation factor for *m*-cresol with respect to *o*-toluonitrile varies from 5 to 70 depending upon solvent ratios and the resulting liquid compositions. The authors compare a standard extraction configuration (bringing the feed into the first stage) with a fractional extraction configuration (bringing the feed into the second stage of a seven theoretical-stage process).

Another example of the use of dual-solvent fractional extraction concepts involves the recovery of ε-caprolactam monomer ( for nylon-6 production) from a two-liquid-phase reaction mixture containing ammonium sulfate plus smaller amounts of other impurities, using water and benzene as solvents [Simons, A. J. F., and N. F. Haasen, chap. 18.4 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991]. In this application, the separation factor for caprolactam with respect to ammonium sulfate is high because the salt greatly favors partitioning into water; however, separation factors with respect to the other impurities are smaller. V. Alessi et al. [*Chem. Eng. Technol.* **20:** 445–454 (1997)] describe two process schemes used in industry. These are outlined in Fig. 15-10. The simpler scheme (Fig. 15-10*a*) is a straightforward dual-solvent fractional extraction process that isolates caprolactam (CPL) in a benzene extract stream and ammonium sulfate (AS) in the aqueous raffinate. The feed stage is comprised of mixer M1 and settler S1, and separate extraction columns are used for the washing and stripping sections. In Fig. 15-10*a*, these are denoted by C1 and C2, respectively. Minor impurity components also present in the feed must exit the process in either the extract or the raffinate. The more complex scheme (Fig. 15-10*b*) eliminates addition of benzene to the feed stage and adds a back-extraction section at the extract end of the process (denoted by C4) to extract CPL from the benzene phase leaving the washing section. Also, a separate fractional extractor (denoted as C1 in Fig. 15-10*b*) is added between the original stripping and washing sections in order to treat the benzene phase leaving the stripping section and to recover the CPL content of the CPL-rich aqueous stream leaving the feed stage. In the C1 extractor, the CPL transfers into the benzene stream that ultimately enters the upper washing section, leaving hydrophilic impurities in an aqueous purge stream that exits at the bottom. The resulting process scheme includes two purge streams for rejecting minor impurities: a stream rich in high-boiling organic impurities leaving the bottom of the benzene distillation tower, and the aqueous stream rich in hydrophilic impurities leaving the bottom of the C1 extractor. This sophisticated design separates the feed into four streams instead of just two, allowing separate removal of two impurity fractions to increase the purity of the two main products. The caprolactam is made to transfer into either an aqueous or a benzene-rich stream as desired, by judicious choice of solvent-to-feed ratio at the various sections in the process.

A dual-solvent fractional extraction process can provide a powerful separation scheme, and some authors suggest that fractional extraction is not used as much as it could be. In many cases, instead of using full fractional extraction, standard extraction is used to recover solute from a crude feed; and if the solvent-to-feed ratio is less than 1.0, concentrate the solute in a smaller solute-bearing stream. Another operation such as crystallization, adsorption, or process chromatography is then used downstream for solute purification. Perhaps fractional extraction schemes should be evaluated more often as alternative processing schemes that may have advantages.

The third type of fractional extraction operation involves refluxing a portion of the extract stream back to the extract end (washing section) of the process. As mentioned earlier, this process can be practiced as a dual-solvent process (Fig. 15-8) or as a single-solvent process (Figs. 15-2 and 15-9). The process for extracting aromatics from aliphatics in petrochemical operations is one of the best known commercial examples. But fractional extraction processes employing extract reflux also have been developed in other industries, including selected applications in hydrometallurgy [Xie, F., et al., *Minerals Engineering* **56:** 10–28 (2014)]. Unlike in distillation, however, the use of reflux is not common. The reflux consists of a portion of the extract stream from which a significant amount of solvent has been removed. Injection of this solvent-lean, concentrated extract back into the washing section increases the total amount of solute and the amount of raffinate phase present in that section of the extractor. This can boost separation performance by allowing the process to operate at a more favorable location within the phase diagram, resulting in a reduction in the number of theoretical stages or transfer units needed within the washing section. This also allows the process to boost the concentration of solute in the extract phase above that in equilibrium with the feed phase. The increased amount of solute present within the process may require the use of extra solvent to avoid approaching the plait point at the feed stage (the composition at which only a single liquid

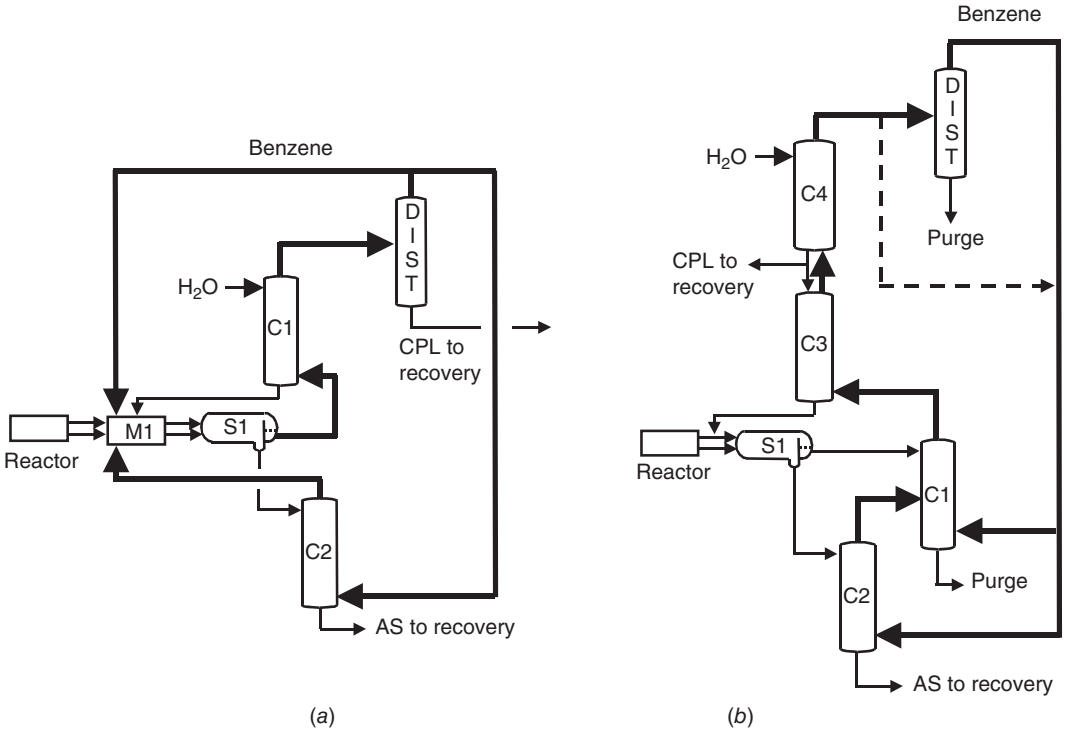

**FIG. 15-10** Two industrial extraction processes for separation of caprolactam (CPL) and ammonium sulfate (AS): (*a*) a simpler fractional extraction scheme; (*b*) a more complex scheme. Heavy lines denote benzene-rich streams; light lines denote aqueous streams. [*Taken from Alessi, Penzo, Slater, and Tessari,* Chem. Eng. Technol. ***20****(7), pp. 445–454 (1997), with permission. Copyright 1997 Wiley-VCH.*]

phase can exist at equilibrium). Because of this, using reflux may involve a tradeoff between a reduction in the number of theoretical stages and an increase in the total liquid traffic within the process equipment, requiring larger-capacity equipment and increasing the cost of solvent recovery and recycle. This tradeoff is discussed by E. G. Scheibel with regard to extraction column design [*Ind. Eng. Chem.* **47**(11): 2290–2293 (1955)]. The potential benefit that can be derived from the use of extract reflux is greatest for applications utilizing solvents with a low solute separation factor and low partition ratios (as in the example illustrated in Fig. 15-2). In these cases, reflux serves to reduce the number of required theoretical stages or transfer units to a practical number (normally on the order of 10 or so) or to reduce the solvent-to-feed ratio required for the desired separation.

The fractional extraction schemes just described are typical of those practiced in industry. A related kind of process employs a second solvent in a separate extraction operation to wash the raffinate produced in an upstream extraction operation. This process scheme is particularly useful when the wash solvent is only slightly soluble in the raffinate and can easily be removed. An example is the use of water to remove residual amine solvent from the treated hydrocarbon stream in an acid-gas extraction process (Fig. 15-3).

A fourth type of fractional extraction operation involves the use of reflux at both ends of a dual-solvent process—that is, reflux to the raffinate end of the process (the stripping section) as well as reflux to the extract end of the process (the washing section). E. G. Scheibel discusses several potential flow sheets of this type [*Chem. Eng. Prog.* **62**(9): 76–81 (1966)]. Although rare, selected applications are described by F. Xie et al. for processing of rare earth elements in hydrometallurgy [*Minerals Engineering* **56:** 10–28 (2014)]. In this case, the number of contacting stages required by the separation is unusually high (with some applications requiring hundreds of mixer-settler stages), and dual reflux helps to minimize this number. In the special case of *single-solvent* fractional extraction with extract reflux, A. H. P. Skelland [*Ind. Eng. Chem.* **53**(10): 799–800 (1961)] has pointed out that the addition of raffinate reflux is not effective from a strictly thermodynamic point of view as it cannot reduce the required number of theoretical stages in this special case.

**Dissociative Extraction** This process scheme normally involves partitioning of weak organic acids or bases between water and an organic solvent phase. Whether the solute partitions mainly into one phase or the other depends upon whether it is in its neutral state or its charged ionic state and the ability of each phase to solvate that form of the solute. In general, water interacts much more strongly with the charged species, and the ionic form will strongly favor partitioning into the aqueous phase. The nonionic form generally will favor partitioning into the organic phase.

The $pK_a$ is the pH at which 50 percent of the solute is in the dissociated (ionized) state. It is a function of solute concentration and normally is reported for dilute conditions. For an organic acid (RCOOH) dissolved in aqueous solution, the amount of solute in the dissociated state relative to that in the nondissociated state is $[RCOO^-]/[RCOOH] = 10^{pH-pK_a}$. Extraction of an organic acid out of an organic feed into an aqueous phase is greatly facilitated by operating at a pH above the acid's $pK_a$ value because most of the acid will be deprotonated to yield the dissociated form ($RCOO^-$). On the other hand, partitioning of the organic acid from an aqueous feed into an organic solvent is favored by operating at a pH below its $pK_a$ to ensure that most of the acid is in the protonated (nondissociated) form. Another example involves extraction of a weak base, such as a compound with amine functionality ($RNH_2$), out of an organic phase into water at a pH below the $pK_a$. This will protonate or neutralize most of the base, yielding the ionized form ($RNH_3^+$), and will favor extraction into water. It follows that extracting an organic base out of an aqueous feed into an organic solvent is favored by operating at a pH above its $pK_a$ because this yields most of the solute in the free base (nonionized) form. For weak bases, $pK_a = 14 - pK_b$, and the relative amount of solute in the dissociated state in the aqueous phase is given by $10^{pK_a-pH}$. As a rule, to obtain the maximum partition ratio for an extraction, the pH should be maintained about 2 pH units from the solute's $pK_a$ value to obtain essentially complete dissociation or nondissociation, as appropriate for the extraction. In a typical continuous extraction process, the pH of the aqueous stream leaving the process is controlled at a constant pH set point by injection of acid or base at the opposite end of the process, and a pH gradient exists within the process. The pH set point may be adjusted to optimize performance. The effect of pH on the partition ratio is discussed in Effect of pH for Ionizable Organic Solutes under Thermodynamic Basis for Liquid-Liquid Extraction. Determination of the optimum pH for the extraction of compounds with multiple ionizable groups and thus multiple $pK_a$ values is discussed by L. S. Crocker, Y. Wang, and J. A. McCauley [*Org. Process Res. Dev.* **5**(1): 77–79 (2001)].

In fractional dissociative extraction, a sharp separation of feed solutes is achieved by taking advantage of a difference in their $pK_a$ values. If the difference in $pK_a$ is sufficient, controlling pH at a specific value can yield high $K$ values for one solute fraction and very low $K$ values for another fraction, thus allowing a sharp separation. For example, a mixture of two organic bases can be separated by contacting the mixture with an aqueous acid containing less than the stoichiometric amount of acid needed to neutralize (ionize) both bases. The stronger of the two bases reacts with the acid to yield the dissociated form in the aqueous phase, while the other base remains nondissociated in a separate organic phase. Buffer compounds may be used to control pH within a desired range for improved separation results [Ma, G., and A. Jha, *Org. Process Res. Dev.* **9**(6): 847–852 (2005)]. Buffers are discussed by D. D. Perrin and B. Dempsey [*Buffers for pH and Metal Ion Control*, Chapman and Hall, London, 1979]. For additional discussion, see M. W. T. Pratt, chap. 21 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991, and M. M. Anwar, A. S. Arif, and D. W. Pritchard, *Solvent Ext. Ion Exch.* **16:** 931 (1998).

**pH-Swing Extraction** A pH-swing extraction process uses dissociative extraction concepts to recover and purify ionizable organic solutes in a forward- and back-extraction scheme, each extraction operation carried out at a different pH. For example, in the forward extraction, the desired solute may be in its nonionized state so it can be extracted out of a crude aqueous feed into an organic solvent. The extract stream from this operation is then fed to a separate extraction operation where the solute is ionized by readjustment of pH and back-extracted into clean water. This scheme can achieve both high recovery and high purity if the impurity solutes are not ionizable or have $pK_a$ values that differ greatly from those of the desired solute. A pH-swing extraction scheme commonly is used for recovery and purification of antibiotics and other complex organic solutes with some ionizable functionality.

**Reaction-Enhanced Extraction** This scheme involves enhancement of the partition ratio for extraction through the use of a reactive extractant that forms a reversible adduct or molecular complex with the desired solute. For a discussion of process fundamentals, see C. J. King, chap. 15 in *Handbook of Separation Process Technology*, ed. R. W. Rousseau, Wiley, New York, 1987, and H.-J. Bart, *Reactive Extraction*, Springer, Berlin, 2001. Because reactive extractants form strong specific interactions with the solute molecule, they can provide much higher partition ratios and generally are more selective than conventional physical solvents. For extraction of solute from an aqueous feed solution, the extractant compound often is dissolved in a diluent liquid such as kerosene or another high-boiling hydrocarbon, and the resulting molecular complex resides in the organic phase. Well-known examples include recovery of metals from acid leachate solutions in hydrometallurgy (Fig. 15-4) and extraction of carboxylic acids from aqueous fermentation broth, as discussed below. The same principle may be applied in reverse to extract compounds from an organic feed, the extractant being dissolved in aqueous solution and the resulting complex residing mainly in the aqueous phase. A commercial example of this kind is the extraction of dissolved acid gases (primarily $CO_2$ and $H_2S$) from liquefied hydrocarbons using aqueous alkanolamines (Fig. 15-3), an application that is closely related to the removal of acid gases from vapor-phase hydrocarbons by absorption into the same or similar fluids [R. B. Nielsen et al., *Hydrocarbon Proc.* **76:** 49–59 (1997)]. Another example involves extraction of terpenyl amine from organic solution using aqueous acetic acid [R. Schulz et al., *Ind. Eng. Chem. Res.* **55**(19): 5763–5769 (2016)].

Although there are many successful commercial applications, it is important to note that the use of high-boiling extractants can present severe difficulties whenever high-boiling impurities are present. A number of commercial processes have failed because there was no economical option for purging high-boiling contaminants that accumulated in the solvent phase over time, so care must be taken to address this possibility when developing a new application. The advantages and disadvantages of using high-boiling solvents or extractants versus low-boiling solvents are discussed by C. J. King in the context of acetic acid recovery [chap. 18.5 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991]. Also see the discussion by J. Price and D. Burns regarding accumulation of high-boiling impurities in hydrocarbon sweetening operations [*Hydrocarb. Process.* **74:** 140–141 (1995)].

Reviews of reactive extractants used in hydrometallurgy are given by M. Cox [chap. 1 in *Science and Practice of Liquid-Liquid Extraction*, vol. 2, ed. J. D. Thornton, Oxford University Press, Oxford, UK, 1992, pp. 1–27], by A. M. Wilson et al., *Chem. Soc. Rev.* **43:** 123–134 (2014); and by J. Zhang, B. Zhao, and B. Schreiner [*Separation Hydrometallurgy of Rare Earth Metals*, Springer, Berlin, 2016]. Also see *Solvent Extraction Principles and Practice*, 2d ed., ed. J. Rydberg et al., Marcel Dekker, New York, 2004; and V. S. Kislik, *Solvent Extraction: Classical and Novel Approaches*, Elsevier, Oxford, UK, 2012. Extractants used in hydrometallurgy generally are classified according to the mechanism of solute-solvent interaction in solution: (1) cationic (carboxylic and organophosphorus acids);

(2) anionic (primary amines and quaternary amines); (3) chelating (compounds such as hydroxyoximes that form multiple bonds to a central metal ion); (4) ion-pair-forming (such as trialklyamines) and (5) solvating (nonionic compounds including tri-*n*-butyl phosphate). Blends of the different types also are sometimes used (called synergistic extraction).

Another well-known class of applications involves the formation of ion-pair interactions between a carboxylic acid dissolved in an aqueous feed and alkylamine extractants such as trioctylamine dissolved in a hydrocarbon diluent, as discussed by R. Wennersten [*J. Chem. Technol. Biotechnol.* **33B:** 85–94 (1983)], by C. J. King and others [*Ind. Eng. Chem. Res.* **29**(7): 1319–1338 (1990); and *Chemtech* **22:** 285 (1992)], and by A. Schunk and G. Maurer [*Ind. Eng. Chem. Res.* **44**(23): 8837–8851 (2005)]. Extractants also may be used to facilitate the extraction of other ionizable organic solutes, including certain antibiotics [R. A. Pai, M. F. Doherty, and M. F. Malone, *AIChE J.* **48**(3): 514–526 (2002)]. Sometimes mixing extractants with promoter compounds (called modifiers) provides synergistic effects that dramatically enhance the partition ratio. An example is discussed by M. Atanassova and I. Dukov [*Sep. Purif. Technol.* **40:** 171–176 (2004)]. Also see the discussion of combined physical (hydrogen-bonding) and reaction-enhanced extraction by S. C. Lee [*Biotechnol. Prog.* **22**(3): 731–736 (2006)].

The chemistry involved in the removal of acid gases from hydrocarbons using aqueous alkanolamines is discussed by P. V. Danckwerts [*Chem. Eng. Sci.* **34:** 443–446 (1979)] and by G. S. Hwang et al. [*Phys. Chem. Chem. Phys.* **17:** 831–839 (2015)].

**Extractive Reaction** This scheme combines reaction and separation in the same unit operation for the purpose of facilitating a desired reaction to produce a desired product. For a discussion of process fundamentals, see K. D. Samant and K. M. Ng, *AIChE J.* **44**(6): 1363–1381 (1998). To avoid confusion, the term *extractive reaction* is recommended for this type of process, while the term *reaction-enhanced extraction* is recommended for a process involving formation of reversible solute-extractant complexes and enhanced partition ratios for the purpose of facilitating a desired separation. The term *reactive extraction* is a more general term commonly used for both types of processes.

In general, extractive reaction involves conducting a reaction in the presence of two liquid phases and taking advantage of differences in the partitioning of reactants, products, and homogeneous catalyst (if used) between the two liquids to improve reaction performance. The second liquid phase either is deliberately added to the system or it naturally forms during the course of the reaction. The classes of reactions that can benefit from an extractive reaction scheme include chemical-equilibrium-limited reactions (such as esterifications, transesterifications, and hydrolysis reactions), where it is important to remove a product or coproduct from the reaction zone to drive conversion, and consecutive or sequential reactions (such as nitrations, sulfonations, and alkylations), where the goal may be to produce only the mono- or difunctional product and minimize the formation of subsequent addition products. For additional discussion, see H. J. Gorissen, *Chem Eng. Sci.* **58:** 809–814 (2003); and V. Van Brunt and J. S. Kanel, chap. 3 in *Reactive Separation Processes*, ed. S. Kulprathipanja, Taylor & Francis, Abingdon, UK, 2002, pp. 51–92.

The manufacture of fatty acid methyl esters (FAME) for use as biodiesel fuel by transesterification of triglyceride oils and greases provides an example of a chemical-equilibrium-limited extractive reaction [Kiss, A. A., *Process Intensification Technologies for Biodiesel Production—Reactive Separation Processes*, Springer, Berlin, 2014; and Van Gerpen, J., *Fuel Process Technol.* **86:** 1097–1107 (2005)]. Low-grade triglycerides are reacted with methanol to produce FAME plus glycerol as a by-product. Because glycerol is only partially miscible with the feed and the FAME product, it transfers from the reaction zone into a separate glycerol-rich liquid phase. Excess methanol normally is needed to obtain complete conversion, but periodic removal of the glycerol-rich phase helps minimize the required amount. In another example, M. Minotti, M. F. Doherty, and M. F. Malone [*Ind. Eng. Chem. Res.* **37**(12): 4748–4755 (1998)] studied the esterification of aqueous acetic acid by reaction with butanol in an extractive reaction process involving the extraction of the butyl acetate product into a separate butanol-rich phase. The authors concluded that cocurrent processing is preferred over countercurrent processing in this case. Their general conclusions likely apply to other applications involving extraction of a reaction product out of the reaction phase to drive conversion. The cocurrent scheme is equivalent to a series of two-liquid-phase stirred-tank reactors approaching the performance of a plug-flow reactor. C. Rohde, R. Marr, and M. Siebenhofer [Paper No. 232f, AIChE Annual Meeting, Austin, Tex., 2004] studied the esterification of acetic acid with methanol to produce methyl acetate. Their extractive reaction scheme involves selective transfer of methyl acetate into a high-boiling solvent such as *n*-nonane.

An example of a sequential-reaction extractive reaction is the manufacture of 2,4-dinitrotoluene as a precursor to 2,4-diaminotoluene and toluene diisocyanate (TDI) based polyurethanes. In traditional processes, liquid-phase nitration of toluene is conducted using concentrated nitric and sulfuric acids, which form a separate liquid phase. Toluene transfers into the acid phase, where it reacts with nitronium ion, and the reaction product transfers back into the organic phase [*Nitration—Recent Laboratory and Industrial Developments*, ed. L. F. Albright, R. V. C. Carr, and R. J. Schmitt, *ACS Symposium Series*, vol. 623, American Chemical Society, Washington, 1996)]. In these processes, careful control of liquid-liquid contacting conditions is required to obtain high yield of the desired product and to minimize the formation of impurities. A similar process is used for nitration of benzene to mononitrobenzene, a precursor to aniline used in the manufacture of many products, including methylenediphenylisocyanate (MDI) for polyurethanes [Quadros, P. A., M. S. Reis, and C. M. S. G. Baptista, *Ind. Eng. Chem. Res.* **44**(25): 9414–9421 (2005)].

Another category of extractive reaction involves the extraction of a product solute during microbial fermentation (biological reaction) to avoid microbe inhibition effects, allowing an increase in fermenter productivity. An example involving the production of ethanol is discussed by C. Weilnhammer and E. Blass [*Chem. Eng. Technol.* **17:** 365–373 (1994)], and an example involving the production of propionic acid is discussed by Z. Gu, B. A. Glatz, and C. E. Glatz [*Biotechnol. and Bioeng.* **57**(4): 454–461 (1998)].

**Temperature-Swing Extraction** Temperature-swing processes take advantage of a change in $K$ value with temperature. An extraction example is the commercial process used to recover citric acid from whole fermentation broth by using trioctylamine (TOA) extractant [Baniel, A. M., R. Blumberg, and K. Hajdu, U.S. Patent 4,275,234 (1981); Wennersten, R., *J. Chem. Biotechnol.* **33B:** 85–94 (1983); and Pazouki, M., and T. Panda, *Bioprocess Eng.* **19:** 435–439 (1998)]. This process involves a forward reaction-enhanced extraction carried out at 20 to 30°C in which citric acid transfers from the aqueous phase into the extract phase. Relatively pure citric acid is subsequently recovered by back extraction into clean water at 80 to 100°C, also liberating the TOA extractant for recycle. This temperature-swing process is feasible because partitioning of citric acid into the organic phase is favored at the lower temperature but not at 80 to 100°C.

Partition ratios can be particularly sensitive to temperature when solute-solvent interactions in one or both phases involve specific attractive interactions such as formation of ion-pair bonds (as in trialkyamine–carboxylic acid interactions) or hydrogen bonds, or when mutual solubility between feed and extraction solvent involves hydrogen bonding. An interesting example is the extraction of citric acid from water with 1-butoxy-2-propanol (common name propylene glycol *n*-butyl ether) as solvent (Fig. 15-11). This example illustrates how important it can be when developing and optimizing an extraction operation to understand how $K$ varies with temperature, regardless of whether a temperature-swing process is contemplated. Of course, changes in other properties such as mutual solubility and viscosity also must be considered. For additional discussion, see the subsection Temperature Effect under Thermodynamic Basis for Liquid-Liquid Extraction.

**Reversed Micellar Extraction** This scheme involves use of microscopic water-in-oil micelles formed by surfactants and suspended within a hydrophobic organic solvent to isolate proteins from an aqueous feed. The micelles essentially are microdroplets of water having dimensions on the order of the protein to be isolated. These stabilized water droplets provide a compatible environment for the protein, allowing its recovery from a crude aqueous feed without significant loss of protein activity [Ayala, G. A., et al., *Biotechnol. and Bioeng.* **39:** 806–814 (1992); and Bordier, C., *J. Biolog. Chem.* **256**(4): 1604–1607 (February 1981)]. Also see the discussion of ultrafiltration membranes for concentrating micelles in Membrane-Based Coalescers under Liquid-Liquid Phase Separation Equipment.

**Aqueous Two-Phase Extraction** Also called aqueous biphasic extraction, this technique generally involves the use of two incompatible water-miscible polymers [normally polyethylene glycol (PEG) and dextran, a starch-based polymer], or a water-miscible polymer and a salt (such as PEG and $Na_2SO_4$), to form two immiscible aqueous phases each containing 75+ percent water. This technology provides mild conditions for recovery of proteins and other biomolecules from broth or other aqueous feeds with minimal loss of activity (Walter, H., and G. Johansson, eds., *Aqueous Two Phase Systems, Methods in Enzymology*, vol. 228, Academic Press, New York, 1994; Zaslavsky, B. Y., *Aqueous Two-Phase Partitioning*, Marcel Dekker, New York, 1994; and Blanch, H. W., and D. S. Clark, Chap. 6 in *Biochemical Engineering*, Marcel Dekker, New York, 1997, pp. 474–482). The effect of salts on the liquid-liquid phase equilibrium of polyethylene glycol + water mixtures has been extensively studied [Salabat, A., *Fluid Phase Equilibr.* **187–188:** 489–498 (2001)]. A typical phase diagram, for PEG 6000 + $Na_2SO_4$ + water, is shown in Fig. 15-12. The hydraulic characteristics of the aqueous two-phase system PEG 4000 + $Na_2SO_4$ + water in a countercurrent sieve plate column have been reported by A. Hamidi et al. [*J. Chem. Technol. Biotechnol.* **74:** 244–249 (1999)].

$$K = \frac{\text{mass CA per mass solvent in the organic phase}}{\text{mass CA per mass water in the aqueous phase}}$$

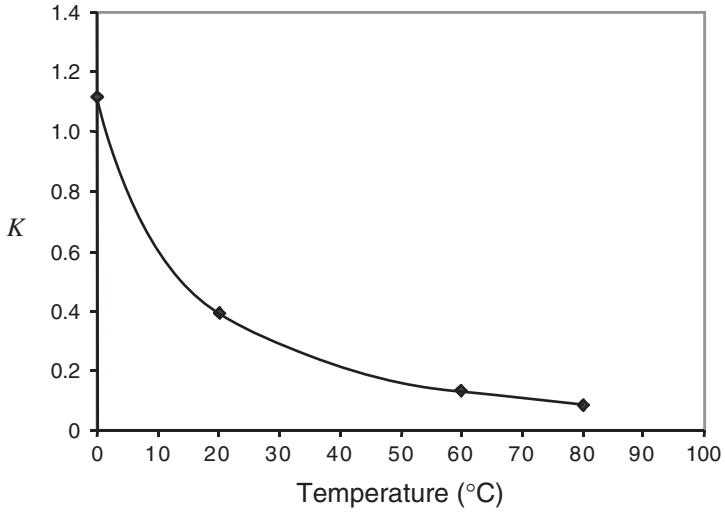

**FIG. 15-11** Partition ratio as a function of temperature for recovery of citric acid (CA) from water using 1-butoxy-2-propanol (propylene glycol *n*-butyl ether). (*Data generated by The Dow Chemical Company.*)

Two immiscible aqueous phases also may be formed by using two incompatible salts. An example is the system formed by using the hydrophilic organic salt 1-butyl-3-methylimidazolium chloride and a water-structuring (kosmotropic) salt such as $K_3PO_4$ [K. E. Gutowski et al., *J. Am. Chem. Soc.* **125:** 6632 (2003)].

**Enantioselective Extraction** The isolation of specific enantiomers from racemic mixtures is of increasing importance in the production of pharmaceutical active ingredients, flavor and aroma chemicals, agricultural chemicals, and other biologically active products. Although most published studies involve use of chromatography or crystallization, a number of liquid-liquid extraction applications involving specialized chiral extractants have been reported. Selectivity generally is not high, so multistage processing is required. This subject is reviewed by B. Schuur et al. [*Org. Biomol. Chem.* **9:** 36–51 (2011)]. Recent studies are reported by R. Lavie [*Ind. Eng. Chem. Res.* **50**(22): 12750–12756 (2011)], by Z. Ren et al. [*J. Chem. Eng. Data* **59**(8): 2517–2522 (2014)], by B. Schuur et al. [*Chirality* **27:** 123–130 (2015)], and by Y. Wang et al. [*Org. Process Res. Dev.* **19**(9): 1082–1087 (2015)].

**Hybrid Extraction Processes** Hybrid processes employ an extraction operation in close association with another unit operation. A hybrid scheme is employed because an individual unit operation cannot achieve all the separation goals, or because the hybrid process is more economical. Common examples include the following.

***Extraction-Distillation*** An example involves the use of extraction to break the methanol + dichloromethane azeotrope. The near-azeotropic overheads from a distillation tower can be fed to an extractor where water is used to extract the methanol content and generate nearly methanol-free dichloromethane (saturated with roughly 2000 ppm water). A related type of extraction-distillation operation involves closely coupling extraction with the distillate or bottoms stream produced by a distillation tower, such that the distillation specification for that stream can be relaxed. This approach has been used to facilitate distillation of aqueous acetic acid to produce acetic acid as a bottoms product, taking a mixture of acetic acid and water overhead [R. G. Gualy et al., U.S. Patent 5,492,603 (1996)]. The distillate is sent to an extraction tower to recover the acetic acid content

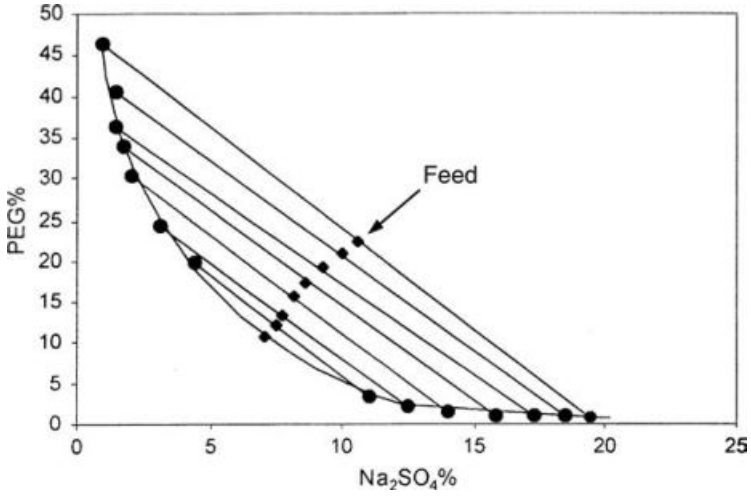

**FIG. 15-12** Equilibrium phase diagram for PEG 6000 + $Na_2SO_4$ + water at 25°C. [*Reprinted from Salabat,* Fluid Phase Equilibr. ***187–188,*** *pp. 489–498 (2001), with permission. Copyright 2001 Elsevier B. V.*]

for recycle back to the process. The hybrid process allows operation with lower energy consumption compared to distillation alone because it allows the distillation tower to operate with a reduced requirement for recovering acetic acid in the bottoms stream, which permits relaxation of the minimum concentration of acetic acid allowed in the distillate. Another type of hybrid process involves combining liquid-liquid extraction with azeotropic or extractive distillation of the extract (Skelland, A. H. P., and D. W. Tedder, chap. 7 in *Handbook of Separation Process Technology*, ed. R. W. Rousseau, Wiley, New York, 1987, pp. 449–453). The solvent serves both as the extraction solvent for the upstream liquid-liquid extraction operation and as the entrainer for a subsequent azeotropic distillation or as the distillation solvent for a subsequent extractive distillation. (For a detailed discussion of azeotropic and extraction distillation concepts, see Sec. 13, Distillation.) The solvent-to-feed ratio must be optimized with regard to both the liquid-liquid extraction operation and the downstream distillation operation. An example is the use of ethyl acetate to extract acetic acid from an aqueous feed, followed by azeotropic distillation of the extract to produce a dry acetic acid bottoms product and an ethyl acetate + water overheads stream. In this example, ethyl acetate serves as the extraction solvent in the extractor and as the entrainer for removing water overhead in the distillation tower. Another hybrid extraction-distillation design, also employing a relatively low-boiling solvent, is described by Y.-C. Chen et al. [*Ind. Eng. Chem. Res.* **54**(31): 7715–7727 (2015)]. Examples involving extractive distillation and high-boiling solvents can be seen in the various processes used to recover aromatics from aliphatic hydrocarbons. See the subsection Single-Solvent Fractional Extraction with Extract Reflux under Calculation Procedures.

***Extraction-Crystallization*** Extraction often is used in association with a crystallization operation. In the pharmaceutical and specialty chemical industries, extraction is used to recover a product compound (or remove impurities) from a crude reaction mixture, with subsequent crystallization of the product from the extract (or from the pre-extracted reaction mixture). In many of these applications, the product needs to be delivered as a pure crystalline solid, so crystallization is a necessary operation. (For a detailed discussion of crystallization operations, see Sec. 18, Liquid-Solid Operations and Equipment.) The desired solute can sometimes be crystallized directly from the reaction mixture with sufficient purity and yield, thus avoiding the cost of the extraction operation; however, direct crystallization generally is more difficult because of higher impurity concentrations. In cases where direct crystallization is feasible, deciding whether to use extraction prior to crystallization or crystallization alone involves consideration of a number of tradeoffs and ultimately depends on the relative robustness and economics of each approach [Anderson, N. G., *Org. Process Res. Dev.* **8**(2): 260–265 (2004)]. A well-known example of extraction-crystallization is the recovery of penicillin from fermentation broth by using a pH-swing forward and back extraction scheme followed by final purification using crystallization [Queener, S., and R. Swartz, "Penicillins: Biosynthetic and Semisynthetic," in *Secondary Products of Metabolism, Economic Microbiology*, vol. 3, ed. A. H. Rose, Academic, New York, 1979]. Extraction is used for solute recovery and initial purification, followed by crystallization for final purification and isolation as a crystalline solid. Another category of extraction-crystallization processes involves the use of extraction to recover solute from the spent mother liquor leaving a crystallization operation. In yet another example, K. Maeda et al. [*Ind. Eng. Chem. Res.* **38**(6): 2428–2433 (1999)] describe a crystallization-extraction hybrid process for separating fatty acids (lauric and myristic acids). In comparing these process options, the potential uses of extraction should include efficient countercurrent processing schemes, because these may significantly reduce solvent usage and cost.

***Neutralization-Extraction*** A common example of neutralization-extraction involves neutralization of residual acidity (or basicity) in a crude organic feed by injection of an aqueous base (or aqueous acid) combined with washing the resulting salts into water. The neutralization and washing operations may be combined within a single extraction column as illustrated in Fig. 15-13. Also see the discussion by K. L. A. Koolen [*Design of Simple and Robust Process Plants,* Wiley-VCH, Weinheim, 2001, pp. 159–161].

***Reaction-Extraction*** This technique involves chemical modification of solutes in solution in order to more easily extract them in a subsequent extraction operation. Applications generally involve modification of impurity compounds to facilitate purification of a desired product. An example is the oxygenation of sulfur-containing aromatic impurities present in fuel oil by using $H_2O_2$ and acetic acid, followed by liquid-liquid extraction into an aqueous acetonitrile solution [Y. Shiraishi and T. Hirai, *Energy and Fuels* **18**(1): 37–40 (2004); and Y. Shiraishi et al., *Ind. Eng. Chem. Res.* **41:** 4362–4375 (2002)]. Another example involves esterification of aromatic alcohol impurities to facilitate their separation from apolar hydrocarbons by using an aqueous extractant solution [B. Kuzmanović et al., *Ind. Eng. Chem. Res.* **43**(23): 7572–7580 (2004)]. Another type of reaction-extraction hybrid process involves closely coupled reaction-extraction steps in batchwise, multistep processing of specialty chemicals [McConvey, I. F., and P. Nancarrow, chap. 10 in *Pharmaceutical Process Development*, ed. A. J. Blacker and M. T. Williams, RSC Publishing, Cambridge, UK, 2011]. Also see the discussion of OATS processing in Phase Transition Extraction and Tunable Solvents under Emerging Developments.

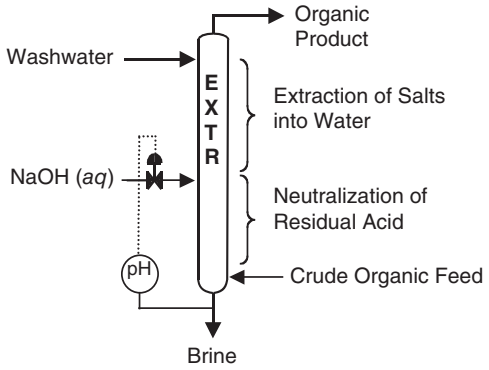

**FIG. 15-13** Example of neutralization-extraction hybrid process implemented in an extraction column.

***Reverse Osmosis–Extraction*** In certain applications, reverse osmosis (RO) or nanofiltration membranes may be used to reduce the volume of an aqueous stream and increase the solute concentration, in order to reduce the size of downstream extraction and solvent recovery equipment. R. W. Wytcherley, J. C. Gentry, and R. G. Gualy [U.S. Patents 5,492,625 (1996) and 5,624,566 (1997)] describe such a process for carboxylic acid solutes. Water is forced through the membrane when the operating pressure drop exceeds the natural osmotic pressure difference generated by the concentration gradient:

$$\text{Flux} = \frac{\mathcal{P}}{\lambda_m}(\Delta P - \Delta\pi) \tag{15-1}$$

where $\mathcal{P}$ is a permeability coefficient for water, $\lambda_m$ is the membrane thickness, $\Delta P$ is the operating pressure drop, and $\Delta\pi$ is the osmotic pressure gradient, a function of solute concentration on each side of the membrane. Normally the solute also will permeate the membrane to a small extent. The maximum possible concentration of solute in the concentrate is limited by that corresponding to an osmotic pressure of about 70 bar (about 1000 psig), as this is the maximum pressure rating of commercially available membrane modules (typical). For acetic acid, this maximum concentration is about 25 wt%. Depending upon whether the particular organic permeate of interest can swell or degrade the membrane material, the concentration achieved in practice may need to be reduced well below this limit to avoid excessive membrane deterioration. In general, a membrane preconcentrator is considered for feeds containing on the order of 3 wt% solute or less. In these cases, a more moderate membrane operating pressure may be used, and the preconcentrator can provide a significant reduction in the volume of feed entering the extraction process. The stream entering the membrane module normally must be carefully prefiltered to avoid fouling the membrane. The modeling of mass transfer through RO membranes, with an emphasis on cases involving solute-membrane interactions, is discussed by H. Mehdizadeh, Kh. Molaiee-Nejad, and Y. C. Chong [*J. Membrane Sci.* **267:** 27–40 (2005)]. Most pressure-driven membrane-based separations of this type have been developed for aqueous feeds; however, specialized solvent resistant nanofiltration membranes also are available and may be used to concentrate non-aqueous feeds through permeation of small-molecule solvents. For a detailed review, see P. Marchetti et al., *Chemical Reviews* **114:** 10735–10806 (2014).

**Liquid-Solid Extraction (Leaching)** Extraction of solubles from porous solids is a form of solvent extraction that has much in common with liquid-liquid extraction [Prabhudesai, R. K., "Leaching," Sec. 5.1 in *Handbook of Separation Techniques for Chemical Engineers*, ed. P. A. Schweitzer, McGraw-Hill, New York, 1997, pp. 5-3 to 5-31]. The main differences come from the need to handle solids and the fact that mass transfer of soluble components out of porous solids generally is much slower than mass transfer between liquids. Because of this, different types of contacting equipment operating at longer residence times often are required. Washing of nonporous solids is a related operation that generally exhibits faster mass-transfer rates compared to leaching. On the other hand, purification of nonporous solids or crystals by removal of impurities that reside within the bulk solid

phase often is not economical or even feasible by using these methods, because the rate of mass transfer of impurities through the bulk solid is extremely slow. Liquid-solid extraction is covered in Sec. 18, Liquid-Solid Operations and Equipment.

**Liquid-Liquid Partitioning of Fine Solids** This process involves separation of small-particle solids suspended in a feed liquid, by contact with a second liquid phase. L. A. Robbins describes such a process for removing ash from pulverized coal [U.S. Patent 4,575,418 (1986)]. The process involves slurrying pulverized coal fines into a hydrocarbon liquid and contacting the resulting slurry with water. The coal slurry is cleaned by preferential transfer of ash particles into the aqueous phase. The process takes advantage of differences in surface-wetting properties to separate the different types of solid particles present in the feed.

**Supercritical Fluid Extraction** This process generally involves the use of $CO_2$ or light hydrocarbons to extract components from liquids or porous solids [Brunner, G., *Gas Extraction: An Introduction to Fundamentals of Supercritical Fluids and the Application to Separation Processes*, Springer-Verlag, Berlin, 1994; Brunner, G., ed., *Supercritical Fluids as Solvents and Reaction Media*, Elsevier, Amsterdam, 2004; and McHugh, M. A., and V. Krukonis, *Supercritical Fluid Extraction*, 2d ed., Butterworth-Heinemann, Oxford, UK, 1993]. Supercritical fluid extraction differs from liquid-liquid or liquid-solid extraction in that the operation is carried out at supercritical (or near-supercritical) conditions where the extraction fluid exhibits physical and transport properties that are inbetween those of liquid and vapor phases (intermediate density, viscosity, and solute diffusivity). Most applications involve the use of $CO_2$ (critical pressure = 73.8 bar at 31°C) or propane (critical pressure = 42.5 bar at 97°C). Other supercritical fluids and their critical-point properties are discussed by B. E. Poling, J. M. Prausnitz, and J. P. O'Connell [*The Properties of Gas and Liquids*, 5th ed., McGraw-Hill, New York, 2001].

Supercritical $CO_2$ extraction often is considered for extracting high-value soluble components from natural materials or for purifying low-volume specialty chemicals [Reverchon, E., and I. De Marco, *J. Supercrit. Fluids* **38:** 146–166 (2006)]. For products derived from natural materials, this can involve initial processing of solids followed by further processing of a crude liquid extract. Applications include decaffeination of coffee and recovery of desired compounds from plant- and animal-derived feeds, including recovery of flavor and fragrance components, neutraceuticals, and other active ingredients. An example is the use of supercritical $CO_2$ fractional extraction to remove terpenes from cold-pressed bergamot oil [Kondo, M., et al., *Ind. Eng. Chem. Res.* **39**(12): 4745–4748 (2000)]. A nonfood example involves the removal of unreacted dodecanol from nonionic surfactant mixtures and fractionation of the surfactant mixture based on polymer chain length [Eckert, C. A., et al., *Ind. Eng. Chem. Res.* **31**(4): 1105–1110 (1992)]. In these applications, process advantages may be obtained because solvent residues are easily removed or are nontoxic, the process can be operated at mild temperatures that avoid product degradation, the product is easily recovered from the extract fluid, or the solute separation factor and product purity can be adjusted by making small changes in the operating temperature and pressure. Although the loading capacity of supercritical $CO_2$ typically is low, addition of cosolvents such as methanol, ethanol, or tributylphosphate can dramatically boost capacity and enhance selectivity [Brennecke, J. F., and C. A. Eckert, *AIChE J.* **35**(9): 1409–1427 (1989)].

For processing liquid feeds, some supercritical fluid extraction processes use packed columns, in which the liquid feed phase wets the packing and flows through the column in film flow, with the supercritical fluid forming the continuous phase. In other applications, sieve trays give improved performance [Seibert, A. F., and D. G. Moosberg, *Sep. Sci. Technol.* **23:** 2049 (1988)]. In a number of these applications, concentrated solute is added back to the column as reflux to boost separation power (a form of single-solvent fractional extraction). Supercritical fluid extraction requires high-pressure equipment and may involve a high-pressure compressor. These requirements add considerable capital and operating cost. In certain cases, pumps can be used instead of compressors, to bring down the cost. The separators are run slightly below the critical point at slightly elevated pressure and reduced temperature to ensure the material is in the liquid state so it can be pumped. As a rule, supercritical fluid extraction is considerably more expensive than liquid-liquid extraction, so when the required separation can be accomplished by using a liquid solvent, liquid-liquid extraction often is more cost-effective.

Although most commercial applications of supercritical fluid extraction involve processing of high-value, low-volume products, a notable exception is the propane deasphalting process used to refine lubricating oils. This is a large-scale, commodity chemical process dating back to the 1930s. In this process and more recent versions, lube oils are extracted into propane at near-supercritical conditions. The extract phase is depressurized or cooled in stages to isolate various fractions. Compared to operation at lower pressures, operation at near-supercritical conditions minimizes the required pressure or temperature change, so the process can be more efficient. This technology also has been used for decolorization of tallow obtained from rendered animal fat [Moore, E. B., *J. Am. Oil Chem. Soc.* **27**(3): 75–80 (1950)]. For further discussion of supercritical fluid separation processes, see G. Brunner, *Annu. Rev. Chem. Biomol. Eng.* **1:** 321–342 (2010); J. Fernandes, R. Ruivo, and P. Simões, *AIChE J.* **53**(4): 825–837 (2007); and F. Gironi and M. Maschietti, *Chem. Eng. Sci.* **61:** 5114–5126 (2006).

## KEY CONSIDERATIONS IN THE DESIGN OF AN EXTRACTION OPERATION

Successful approaches to designing an extraction process begin with an appreciation of the fundamentals (basic phase equilibrium and mass-transfer principles) and generally rely on both experimental studies and mathematical models or process simulations to define the commercial technology. Small-scale experiments using representative feed usually are needed to accurately quantify physical properties and phase equilibrium. Additionally, it is common practice in industry to perform miniplant or pilot-plant tests to accurately characterize the mass-transfer capabilities of the required equipment as a function of throughput [Glatz, D. J., B. C. Cross, and T. D. Lightfoot, *Chem. Eng. Prog.* **114**(2): 24–29 (2018)]. In many cases, mass-transfer resistance changes with increasing scale of operation, so an ability to accurately scale up the data also is needed. The required scale-up know-how often comes from experience operating commercial equipment of various sizes or from running pilot-scale equipment of sufficient size to develop and validate a scale-up correlation. Mathematical models are used as a framework for planning and analyzing the experiments, for correlating the data, and for estimating performance at untested conditions by extrapolation. Increasingly, designers and researchers are utilizing computational fluid dynamics (CFD) software or other simulation tools as an aid to scale-up.

Typical steps in the work process for designing and implementing an extraction operation include the following:

1. Outline the design basis, including specification of feed composition, required solute recovery or removal, product purity, and production rate.
2. Search the published literature (including patents) for information relevant to the application.
3. For dilute feeds, consider options for preconcentrating the feed to reduce the volumes of feed and solvent that must be handled by the extraction operation. Consider evaporation or distillation of a low-boiling feed solvent or the use of reverse-osmosis/nanofiltration membranes to concentrate the feed. (See the subsection Hybrid Extraction Processes under Commercial Process Schemes.)
4. Generate a list of candidate solvents based on chemical knowledge and experience. Consider solvents similar to those used in analogous applications. Use one or more of the methods described in Solvent Screening Methods to identify additional candidates. Include consideration of solvent blends and extractants.
5. Estimate key physical properties and review desirable solvent properties. Give careful consideration to safety, industrial hygiene, and environmental requirements. Use this preliminary information to trim the list of candidate solvents to a manageable size. (See the subsection Desirable Solvent Properties.)
6. Measure partition ratios for selected solvents at representative conditions.
7. Evaluate the potential for trace chemistry under extraction and solvent recovery conditions to determine whether solutes and candidate solvents are likely to degrade or react to produce unwanted impurities. For example, it is well known that penicillin G easily degrades at commercial extraction conditions, and short contact time is required for good results. Also under certain conditions acetate solvents may hydrolyze to form alcohols, certain alcohols and ethers can form peroxides, sulfur-containing solvents may degrade at elevated regeneration temperatures to form acids, chlorinated solvents may hydrolyze at elevated temperatures to form trace HCl with severe corrosion implications, and so on. In other cases, leakage of air into the process may cause formation of trace oxidation products. Understanding the potential for trace chemistry, the fate of potential impurities (i.e., where they go in the process), their possible effects on the process (including impact on product purity and interfacial tension), and devising means to avoid or successfully deal with impurities often are critical to a successful process design. Laboratory tests designed to probe the stability of feed and solvent mixtures may be needed.
8. Characterize mass-transfer difficulty in terms of the required number of theoretical stages or transfer units as a function of the solvent-to-feed ratio. Keep in mind that there will be a limit to the number of theoretical stages that can be achieved. For most cost-effective extraction operations, this limit will be in the range of 3 to 10 theoretical stages, although some can achieve more, depending upon the chemical system, type of equipment, and flow rate (throughput).

9. Estimate the cost of the proposed extraction operation relative to alternative separation technologies, such as extractive distillation, adsorption, and crystallization. Explore other options if they appear less expensive or offer other advantages.

10. If technical and economic feasibility look good, determine accurate values of physical properties and phase equilibria, particularly liquid densities, mutual solubilities (miscibility), viscosities, interfacial tension, and $K$ values (at feed, extract, and raffinate ends of the proposed process), as well as data needed to evaluate solvent recycle options. Search available literature and databases. Assess data quality and generate additional data as needed. Develop the appropriate data correlations. Be careful to check the results of process simulation programs and other estimation methods by comparison with actual experimental data. Finalize the choice of solvent.

11. Outline an overall process flow sheet and material balance, including solvent recovery and recycle. This should be done with the aid of process simulation software. In the flow sheet, include methods needed for controlling emissions and managing wastes. Carefully consider the possibility that impurities may accumulate in the recycled solvent, and devise methods for purging these impurities. For general guidelines, see W. D. Seider, J. D. Seader, D. R. Lewin, and S. Widagdo, *Product and Process Design Principles: Synthesis, Analysis, and Evaluation*, 3d ed., Wiley, New York, 2009; and R. Turton, R. C. Bailie, W. B. Whiting, J. A. Shaeiwitz, and D. Bhattacharyya, *Analysis, Synthesis, and Design of Chemical Processes*, 4th ed., Prentice-Hall, Upper Saddle River, NJ, 2012.

12. In some cases, especially with multiple solutes and complex phase equilibria, it may be useful to perform laboratory batch experiments to simulate a continuous, countercurrent, multistage process. These experiments can be used to test/verify calculation results and determine the correct distribution of components. For additional information, see R. E. Treybal, chap. 9 in *Liquid Extraction*, 2d ed., McGraw-Hill, New York, 1963, pp. 359–393; and M. H. I. Baird and T. C. Lo, chap. 17.1 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991.

13. Identify useful equipment options for liquid-liquid contacting and liquid-liquid phase separation, estimate approximate equipment size, and outline preliminary design specifications. (See the subsection Extractor Selection under Liquid-Liquid Extraction Equipment.) Where appropriate, consult with equipment vendors. Using small-scale experiments, determine whether sludgelike materials are likely to accumulate at the liquid-liquid interface (called formation of a rag layer). If so, it will be important to identify equipment options that can tolerate a rag layer and allow the rag to be drained or otherwise purged periodically.

14. For the most promising equipment option, run miniplant or pilot-plant tests over a range of operating conditions. Use representative feed, including all anticipated impurities, because even small concentrations of surface-active components can dramatically affect interfacial behavior. Whenever possible, the miniplant tests should be conducted by using actual material from the manufacturing plant, and they should include solvent recycle to evaluate the effects of impurity accumulation or possible solvent degradation. Run the miniplant long enough that the solvent encounters numerous cycles so that recycle effects can be seen. If difficulties arise, consider alternative solvents or process options for purging accumulated impurities.

15. Analyze miniplant data and update the preliminary design. Carefully evaluate loss of solvent to the raffinate, and devise methods to minimize losses as needed. Consult equipment vendors or other specialists regarding recommended scale-up methods.

16. Specify the final material balance for the overall process and carry out detailed equipment design calculations. Try to add some flexibility (depending on the cost) to allow for some adjustment of the process equipment during operation, to compensate for uncertainties in the design.

17. Install and start up the equipment in the manufacturing plant.

18. Troubleshoot and improve the operation as needed. Once a unit is operational, carefully measure the material balance and characterize mass-transfer performance. If performance does not meet expectations, look for defects in the equipment installation. If none are found, revisit the scale-up methodology and its assumptions.

## LABORATORY PRACTICES

An equilibrium or theoretical stage in liquid-liquid extraction, as defined earlier, is routinely used in laboratory procedures. A feed solution is contacted with a solvent to remove one or more of the solutes from the feed. This can be carried out in a separating funnel or, preferably, in an agitated vessel that can produce droplets about 1 mm in diameter. After agitation has stopped and the phases separate, the two clear liquid layers are isolated by decantation. The partition ratio can then be determined directly by measuring the concentration of solute in the extract and raffinate layers. (Additional discussion is given in Liquid-Liquid Equilibrium Experimental Methods under Thermodynamic Basis for Liquid-Liquid Extraction.) When an appropriate analytical method is available only for the feed phase, the partition ratio can be determined by measuring the solute concentration in the feed and raffinate phases and calculating the partition ratio from the material balance. For the case of zero initial concentration of solute in the extraction solvent (before extraction), the partition ratio expressed in terms of mass fractions is given by

$$K'' = \frac{Y_e''}{X_r''} = \frac{M_r}{M_e}\left[\frac{M_f X_f''}{M_r X_r''} - 1\right] \tag{15-2}$$

where $K''$ = mass fraction solute in extract divided by that in raffinate
$M_f$ = total mass of feed added to vial
$M_s$ = total mass of extraction solvent before extraction
$M_r$ = mass of raffinate phase after extraction
$M_e$ = mass of extract phase after extraction
$X_f''$ = mass fraction solute in feed prior to extraction
$X_r''$ = mass fraction solute in raffinate, at equilibrium
$Y_e''$ = mass fraction solute in extract, at equilibrium

For systems with low mutual solubility between phases, $K'' \approx (M_f/M_s)(X_f''/X_r'' - 1)$. While this approach can provide useful results, laboratory procedures that include actual analysis of solute concentration in both the extract and raffinate layers plus measurement of feed and solvent weight before and after extraction are preferred because they allow calculation of the component material balances (a check of solute accountability). If the material balances are poor, the resulting $K$ values are uncertain, and the procedures and analytical methods will need careful review and improvement.

After a single stage of liquid-liquid contact, the phase remaining from the feed solution (the raffinate) can be contacted with another quantity of fresh extraction solvent. This cross-current (or cross-flow) extraction scheme is an excellent laboratory procedure because the extract and raffinate phases can be analyzed after each stage to generate equilibrium data for a range of solute concentrations. Also, the feasibility of solute removal to low levels can be demonstrated (or shown to be problematic because of the presence of "extractable" and "nonextractable" forms of a given species). The number of cross-current treatments needed for a given separation, assuming a constant $K$ value, can be estimated from

$$N = \frac{\ln\left(\dfrac{X_{\text{in}} - Y_{\text{in}}/K}{X_{\text{out}} - Y_{\text{in}}/K}\right)}{\ln\left(KS^*/F + 1\right)} \tag{15-3}$$

where $F$ is the amount of feed, the feed and solvent are presaturated, and equal amounts of solvent (denoted by $S^*$) are used for each treatment [Treybal, R. E., *Liquid Extraction*, 2d ed., McGraw-Hill, New York, 1963, pp. 209–216]. The total amount of solvent is $N \times S^*$. The variable $Y_{\text{in}}$ is the concentration of solute in the fresh solvent, normally equal to zero. Equation (15-3) is written in a general form without specifying the units. Any consistent system of units may be used. (See the subsection Process Fundamentals and Basic Calculation Methods.)

A cross-current scheme, although convenient for laboratory practice, is not generally cost effective for large commercial processes because solvent usage is high and the solute concentration in the combined extract is low. A number of batchwise countercurrent laboratory techniques have been developed and can be used to demonstrate countercurrent performance. (See item 12 in the previous subsection, Key Considerations in the Design of an Extraction Operation.) Several equipment vendors also make available continuously fed laboratory-scale extraction equipment. Examples include small-scale mixer-settler extraction batteries offered by Normag, MEAB, Rousselet-Robatel, Schott/QVF, and Sulzer. Small-diameter extraction columns also may be used, such as the 5/8-in (16-mm) diameter reciprocating-plate agitated column offered by Koch Modular Process Systems, and a 60-mm-diameter Kühni rotary-impeller agitated column offered by Sulzer. For a discussion of mixer-settler studies in the laboratory, see K. Benz et al. [*Chem. Eng. Technol.* **24**(1): 11–17 (2001)].

For additional discussion of laboratory techniques, see the subsections Liquid-Liquid Equilibrium Experimental Methods under Thermodynamic Basis for Liquid-Liquid Extraction and High-Throughput Experimental Methods under Solvent Screening Methods.

## ACTIVITY COEFFICIENTS AND THE PARTITION RATIO

**Phase Equilibrium** Two phases are at equilibrium when the total Gibbs energy for the system is at a minimum. This criterion can be restated as follows: Two nonreacting phases are at equilibrium when the chemical potential of each distributed component is the same in each phase; that is, for equilibrium between two phases I and II containing $n$ components

$$\mu_i^{\mathrm{I}} = \mu_i^{\mathrm{II}} \qquad i = 1, 2, \ldots, n \tag{15-4}$$

For two phases at the same temperature and pressure, component activities are the same in each phase, and Eq. (15-4) can be expressed in terms of mole fractions and activity coefficients, giving

$$y_i \gamma_i^{\mathrm{I}} = x_i \gamma_i^{\mathrm{II}} \qquad i = 1, 2, \ldots, n \tag{15-5}$$

where $y_i$ and $x_i$ represent mole fractions of component $i$ in phases I and II, respectively. The equilibrium partition ratio, in units of mole fraction, is then given by

$$K_i^o = \frac{y_i}{x_i} = \frac{\gamma_i^{\text{raffinate}}}{\gamma_i^{\text{extract}}} \tag{15-6}$$

where $y_i$ is the mole fraction in the extract phase and $x_i$ is the mole fraction in the raffinate. Note that, in general, activity coefficients and $K_i^o$ are functions of temperature and composition. For ionic compounds that dissociate in solution, the species that form and the extent of dissociation in each phase also must be taken into account. Similarly, for extractions involving adduct formation, molecular complexation, or other chemical reactions, the reaction stoichiometry is an important factor. For discussion of these special cases, see G. R. Choppin, chap. 3, and J. Rydberg et al., chap. 4, in *Solvent Extraction Principles and Practice*, 2d ed., ed. J. Rydberg et al., Marcel Dekker, New York, 2004; H.-J. Bart, *Reactive Extraction*, Springer, Berlin, 2001; F. Xie et al., *Minerals Engineering* **56:** 10–28 (2014); and R. Schulz et al., *Ind. Eng. Chem. Res.* **55**(19): 5763–5769 (2016).

The activity coefficient for a given solute is a measure of the nonideality of solute-solvent interactions in solution. In this context, the solvent is either the feed solvent or the extraction solvent depending upon which phase is considered, and the composition of the "solvent" includes all components present in that phase. For an ideal solution, activity coefficients are unity. For solute-solvent interactions that are repulsive relative to solvent-solvent interactions, $\gamma_i$ is greater than 1. This is said to correspond to a positive deviation from ideal solution behavior. For attractive interactions, $\gamma_i$ is less than 1, corresponding to a negative deviation. Activity coefficients often are reported for binary pairs in the limit of very dilute conditions (infinite dilution) because this represents the interaction of solute completely surrounded by solvent molecules, and this normally gives the largest value of the activity coefficient (denoted as $\gamma_i^{\infty}$). Normally, useful approximations of the activity coefficients at more concentrated conditions can be obtained by extrapolation from infinite dilution using an appropriate activity coefficient correlation equation. (See Sec. 4, Thermodynamics.) Extrapolation in the reverse direction, that is, from finite concentration to infinite dilution, often does not provide reliable results.

In units of mass fraction, the partition ratio for a nonreacting/nondissociating solute is given by

$$K_i''(\text{mass frac. basis}) = \frac{Y_i''}{X_i''}$$

$$= K_i^o\,(\text{mole frac. basis}) \times \left[ \frac{y_i(\mathrm{MW}_i - \mathrm{MW}_{\text{raffinate}}) + \mathrm{MW}_{\text{raffinate}}}{x_i(\mathrm{MW}_i - \mathrm{MW}_{\text{extract}}) + \mathrm{MW}_{\text{extract}}} \right] \tag{15-7}$$

Here, the notation MW refers to the molecular weight of solute $i$ and the effective average molecular weights of the extract and raffinate phases, as indicated by the subscripts. For dilute systems, $K_i'' \approx K_i^o \times (\mathrm{MW}_{\text{raffinate}}/\mathrm{MW}_{\text{extract}})$. For theoretical stage or transfer unit calculations, often it is useful to express the partition ratio in terms of mass ratio coordinates introduced by W. D. Bancroft [*Phys. Rev.* **3**(1): 21–33; **3**(2): 114–136; and **3**(3): 193–209 (1895)]:

$$K_i' = \frac{Y_i'}{X_i'} = \frac{M_{\text{solute}}/M_{\text{extraction solvent}} \text{ in extract phase}}{M_{\text{solute}}/M_{\text{feed solvent}} \text{ in raffinate phase}} \tag{15-8}$$

Partition ratios also may be expressed on a volumetric basis. In that case,

$$K_i^{\text{vol}}\,(\text{mole/vol. basis}) = K_i'' \frac{\rho_{\text{extract}}}{\rho_{\text{raffinate}}} \tag{15-9}$$

$$K_i^{\text{vol}}\,(\text{mole/vol. basis}) = K_i^o \left( \frac{\rho_{\text{extract}}}{\rho_{\text{raffinate}}} \right) \left( \frac{\mathrm{MW}_{\text{raffinate}}}{\mathrm{MW}_{\text{extract}}} \right) \tag{15-10}$$

**Extraction Factor** The extraction factor is defined by

$$\mathcal{E}_i = m_i \frac{S}{F} \tag{15-11}$$

where $m_i = dY_i/dX_i$, the slope of the equilibrium line, and $F$ and $S$ are the flow rates of the feed phase and the extraction-solvent phase, respectively. On a McCabe-Thiele type of diagram, $\mathcal{E}$ is the slope of the equilibrium line divided by the slope of the operating line $F/S$. (See McCabe-Thiele Type of Graphical Method under Process Fundamentals and Basic Calculation Methods.) For dilute systems with straight equilibrium lines, the slope of the equilibrium line is equal to the partition ratio, $m_i = K_i$.

To illustrate the significance of the extraction factor, consider an application where $K_i$, $S$, and $F$ are constant (or nearly so) and the extraction solvent entering the process contains no solute. When $\mathcal{E}_i = 1$, the extract stream has just enough capacity to carry all the solute present in the feed:

$$SY_{i,\text{extract}} = FX_{i,\text{feed}} \qquad \text{at } \mathcal{E}_i = 1 \text{ and equilibrium conditions} \tag{15-12}$$

At $\mathcal{E}_i < 1.0$, the extract's capacity to carry solute is less than this amount, and the maximum fraction that can be extracted $\theta_i$ is numerically equal to the extraction factor:

$$(\theta_i)_{\max} = \mathcal{E}_i \qquad \text{when } \mathcal{E}_i < 1.0 \tag{15-13}$$

At $\mathcal{E}_i > 1.0$, the extract phase has more than sufficient carrying capacity (in principle), and the actual amount extracted depends on the extraction scheme, number of contacting stages, and mass-transfer resistance. Even a solute for which $m_i < 1.0$ (or $K_i < 1.0$) can, in principle, be extracted to a very high degree by adjusting $S/F$ so that $\mathcal{E}_i > 1$.

Thus, the extraction factor characterizes the relative capacity of the extract phase to carry solute present in the feed phase. Its value is a major factor determining the required number of theoretical stages or transfer units. (For further discussion, see the subsection Extraction Factor and General Performance Trends.) In general, the value of the extraction factor can vary at each point along the equilibrium curve, although in many cases it is nearly constant. Many commercial extraction processes are designed to operate with an average or overall extraction factor in the range of 1.3 to 5. Exceptions include applications where the partition ratio is very large and the solvent-to-feed ratio is set by hydraulic considerations.

Because the extraction factor is a dimensionless variable, its value should be independent of the units used in Eq. (15-11), as long as they are

consistently applied. Engineering calculations often are carried out by using mole fraction, mass fraction, or mass ratio units (Bancroft coordinates). The flow rates $S$ and $F$ then need to be expressed in terms of total molar flow rates, total mass flow rates, or solute-free mass flow rates, respectively. In the design of extraction equipment, volume-based units often are used. Then the appropriate concentration units are mass or mole per unit volume, and flow rates are expressed in terms of the volumetric flow rate of each phase.

**Separation Factor** The separation factor in extraction is analogous to relative volatility in distillation. It is a dimensionless factor that measures the relative enrichment of a given component in the extract phase after one theoretical stage of extraction. For cosolutes $i$ and $j$,

$$\alpha_{i,\,j} = \frac{(Y_i/Y_j)_{\text{extract}}}{(X_i/X_j)_{\text{raffinate}}} = \frac{(Y_i)_{\text{extract}}/(X_i)_{\text{raffinate}}}{(Y_j)_{\text{extract}}/(X_j)_{\text{raffinate}}} = \frac{K_i}{K_j} \tag{15-14}$$

The enrichment of solute $i$ with respect to solute $j$ can be further increased with the use of multiple contacting stages. The solute separation factor $\alpha_{ij}$ is used to characterize the selectivity a solvent has for extracting a desired solute from a feed containing other solutes. It can be calculated by using any consistent units. As in distillation, $\alpha_{ij}$ must be greater than 1.0 to achieve an increase in product-solute purity (on a solvent-free basis). In practice, if solute purity is an important requirement of a given application, $\alpha_{ij}$ must be greater than 20 for standard extraction (at least) and greater than about 4 for fractional extraction, in order to have sufficient separation power using a moderate number of contacting stages. (See the subsection Potential for Solute Purification Using Standard Extraction in Process Fundamentals and Basic Calculation Methods and Dual-Solvent Fractional Extraction in Calculation Procedures.)

The separation factor also can be evaluated for solute $i$ with respect to the feed solvent denoted as component $f$. The value of $\alpha_{if}$ must be greater than 1.0 if the proposed separation is to be feasible, that is, in order to be able to enrich solute $i$ in a separate extract phase. Note that the feed may still be separated if $\alpha_{if} < 1.0$, but this would have to involve concentrating solute $i$ in the feed phase by preferential transfer of component $f$ into the extract phase. Although $\alpha_{if} > 1.0$ represents a minimum theoretical requirement for enriching solute $i$ in a separate extract phase, most commercial extraction processes operate with values of $\alpha_{if}$ on the order of 20 or higher. There are exceptions to this rule, such as the UDEX process and similar processes involving extraction of aromatics from aliphatic hydrocarbons. In these applications, $\alpha_{if}$ can be as low as 10 and sometimes even lower. Applications such as these involve particularly difficult design challenges because of low solute partition ratios and high mutual solubility between phases. (For more detailed discussion of these kinds of systems, see the subsection Single-Solvent Fractional Extraction with Extract Reflux in Fractional Extraction Calculations.)

**Minimum and Maximum Solvent-to-Feed Ratios** Normally, it is possible to quickly estimate the physical constraints on solvent usage for a standard extraction application in terms of minimum and maximum solvent-to-feed ratios. As discussed earlier, the minimum theoretical amount of solvent needed to transfer a high fraction of solute $i$ is the amount corresponding to $\mathcal{E}_i = 1$. In practice, the minimum practical extraction factor is about 1.3, because at lower values the required number of theoretical stages increases dramatically. This gives a minimum solvent-to-feed ratio for a practical process equal to

$$\left(\frac{S}{F}\right)_{\min} \approx \frac{1.3}{K_i} \tag{15-15}$$

Note that this minimum is achievable only if a sufficient number of contacting stages or transfer units can be used. (For additional discussion, see the subsection Extraction Factor and General Performance Trends.) It is also achievable only if the amount of solvent added to the feed is greater than the solubility limit in the feed phase (including solute); otherwise, only one liquid phase can exist. In certain cases involving fairly high mutual solubilities, this can be an important consideration when running a process using minimal solvent—because if the process operates close to the solubility limit, an upset in the solvent-to-feed ratio may cause the solvent phase to disappear. The maximum possible solvent-to-feed ratio is obtained when the amount of extraction solvent is so large that it dissolves the feed phase. Assuming the feed entering the process does not contain extraction solvent,

$$\left(\frac{S}{F}\right)_{\max} = \frac{1}{Y^{\text{SAT}}_{\text{feed solvent}}} \tag{15-16}$$

where $Y^{\text{SAT}}_{\text{feed solvent}}$ denotes the concentration of feed solvent in the extract phase at equilibrium.

If an application proves to be technically feasible, the choice of solvent-to-feed ratio is determined by identifying the most cost-effective ratio between the minimum and maximum limits. For most applications, the maximum solvent-to-feed ratio will be much larger than the ratio chosen for the commercial process; however, the maximum ratio can be a real constraint when dealing with applications exhibiting high mutual solubility, especially for systems that involve high solute concentrations. Solvent ratios are further constrained for a fractional extraction scheme, as discussed in Fractional Extraction Calculations.

**Temperature Effect** The effect of temperature on the value of the partition ratio can vary greatly from one system to another. This depends on how the activity coefficients of the components in each phase are affected by changes in temperature, including any effects due to changes in mutual solubility. For a given phase, the Gibbs-Helmholtz equation indicates that

$$\left[\frac{\partial \ln \gamma_i^{\infty}}{\partial (1/T)}\right]_{P,x} = -\frac{h_i^{E,\infty}}{R} \tag{15-17}$$

where $\gamma_i^{\infty}$ is the activity coefficient for solute $i$ at infinite dilution and $h^E_i$ is the excess enthalpy of mixing relative to ideal solution behavior [Atik, Z., D. Gruber, M. Krummen, and J. Gmehling, *J. Chem. Eng. Data* **49**(5): 1429–1432 (2004)]. Calculating the temperature dependence of $K$ from these basic principles is not a common practice, in part because in many cases the required enthalpy of mixing data are not available (or they are difficult to predict with sufficient accuracy), and changes in mutual solubility complicate the analysis. The temperature dependence of activity coefficients for various classes of compounds is discussed in Sec. 4, Thermodynamics, and by T. C. Frank, S. G. Arturo, and B. S. Holden, *AIChE J.* **60**(10): 3675–3690 (2014).

Systems with specific interactions between solute and solvent, such as hydrogen bonds or ion-pair bonds, often are particularly sensitive to changes in temperature because the specific interactions are strongly temperature-dependent. In general, hydrogen bonding and ion-pair formation are disrupted by increasing temperature (increasing molecular motion), and this can dominate the overall temperature dependence of the partition ratio. An example of a temperature-sensitive hydrogen bonding system is toluene + diethylamine + water [Morello, V. S., and R. B. Beckmann, *Ind. Eng. Chem.* **42:** 1079–1087 (1950)]. The partition ratio for transfer of diethylamine from water into toluene increases with increasing temperature (on a weight percent basis, $K = 0.7$ at 20°C and $K = 2.8$ at 58°C). For further discussion of the temperature dependence of $K$ for this type of system, see T. C. Frank et al., *Ind. Eng. Chem. Res.* **46**(11): 3774–3786 (2007). An example of a temperature-sensitive system involving ion-pair formation is the commercial process used to recover citric acid from fermentation broth using trioctylamine (TOA) extractant [Pazouki, M., and T. Panda, *Bioprocess Engineering* **19:** 435–439 (1998)]. In this case, the partition ratio for transfer of citric acid into the TOA phase decreases with increasing temperature [Canari, R., and A. M. Eyal, *Ind. Eng. Chem. Res.* **43:** 7608–7617 (2004)]. Also see the discussion of Temperature-Swing Extraction in the subsection Commercial Process Schemes.

**Salting-Out and Salting-In Effects for Nonionic Solutes** It is well known that the presence of an inorganic salt can significantly affect the solubility of a nonionic (nonelectrolyte) organic solute dissolved in water. In most cases the inorganic salt reduces the organic solute's solubility (salting-out effect). Here, the salt increases the ionic strength of the aqueous solution, and this results in an increase in the organic solute's activity coefficient. As a result, certain solutes that are not easily extracted from water may be quite easily extracted from brine, depending upon the type of solute and the salt. In principle, the deliberate addition of a salt to an aqueous feed is an option for enhancing partition ratios and reducing the mutual solubility of the two liquid phases; however, this approach complicates the overall process and normally is not cost-effective. Difficulties include the added complexity and costs associated with recovery and recycle of the salt in the overall process, or disposal of the brine after extraction and the need to purchase makeup salt. The potential use of NaCl to enhance the extraction of ethanol from fermentation broth is discussed by V. Gomis et al. [*Ind. Eng. Chem. Res.* **37**(2): 599–603 (1998)].

When an aqueous feed contains a salt, the effect of the dissolved salt on the partition ratio for a given organic solute may be estimated by using an expression introduced by J. Setschenow [*Z. Physik. Chem.* **4:** 117–128 (1889)] and commonly written in the form

$$\log \frac{\gamma_{i,\,\text{brine}}}{\gamma_{i,\,\text{water}}} = k_s\, C_{\text{salt}} \tag{15-18}$$

where $C_{\text{salt}}$ is the concentration of salt in the aqueous phase in units of gmol/L and $k_s$ is the Setschenow constant. Equation (15-18) generally is valid for dilute organic solute concentrations and low to moderate salt concentrations.

In many cases, the salt has no appreciable effect on the activity coefficient in the organic phase because the salt solubility in that phase is low or negligible. Then

$$\log \frac{K_{i,\text{brine}}}{K_{i,\text{water}}} \approx \log \frac{\gamma_{i,\text{brine}}}{\gamma_{i,\text{water}}} = k_s C_{\text{salt}} \tag{15-19}$$

for extraction from the aqueous phase into an organic phase. For aromatic solutes dissolved in NaCl brine at room temperature, typical values of $k_s$ fall within the range of 0.2 to 0.3 L/gmol. In general, $k_s$ is found to vary with salt composition (i.e., with the type of salt) and increase with increasing organic-solute molar volume. I. Kojima and S. S. Davis [*Int. J. Pharm.* **20**(1–2): 203–207 (1984)] showed that partition ratio data for the extraction of phenol dissolved in NaCl brine (at low concentration) using $CCl_4$ solvent is well fit by a Setschenow equation for salt concentrations up to 4 gmol/L (about 20 wt% NaCl). Experimental values and methods for estimating Setschenow constants are discussed by N. Ni and S. H. Yalkowski [*Int. J. Pharm.* **254**(2): 167–172 (2003)] and by W.-H. Xie, W.-Y. Shiu, and D. MacKay [*Marine Environ. Res.* **44:** 429–444 (1997)]. For a detailed review of general principles, see A. M. Hyde et al., *Org Process Res. Dev.* **21:** 1355–1370 (2017).

Salts with large ions (such as tetramethylammonium chloride and sodium toluene sulfonate) may cause a "salting in" or "hydrotropic" effect whereby the salt increases the solubility of an organic solute in water, apparently by disordering the structure of associated water molecules in solution or by forming specific interactions with the organic solute. M. Agrawal and V. G. Gaikar [*Sep. Technol.* **2:** 79–84 (1992)] discuss the use of hydrotropic salts to facilitate extraction processes. For additional discussion, see E. Ruckenstein and I. Shulgin, *Ind. Eng. Chem. Res.* **41**(18): 4674–4680 (2002); and M. Akia and F. Feyzi, *AIChE J.* **52**(1): 333–341 (2006).

**Effect of pH for Ionizable Organic Solutes** The distribution of weak acids and bases between organic and aqueous phases is dramatically affected by the pH of the aqueous phase relative to the p$K_a$ of the solute. As discussed earlier, the p$K_a$ is the pH at which 50 percent of the solute is in the ionized state. (See the subsection Dissociative Extraction in Commercial Process Schemes.) For a weak organic acid (RCOOH) that dissociates into $RCOO^-$ and $H^+$, the overall partition ratio for extraction into an organic phase depends upon the extent of dissociation such that

$$K_{\text{weak acid}} = K_{\text{nonionized}} \div \left( 1 + \frac{[\text{RCOO}^-]_{\text{aq}}}{[\text{RCOOH}]_{\text{aq}}} \right) \tag{15-20}$$

where $K_{\text{weak acid}} = [\text{RCOOH}]_{\text{org}}/([\text{RCOO}^-]_{\text{aq}} + [\text{RCOOH}]_{\text{aq}})$ is the partition ratio for both ionized and nonionized forms of the acid, and $K_{\text{nonionized}} = [\text{RCOOH}]_{\text{org}}/[\text{RCOOH}]_{\text{aq}}$ is the partition ratio for the nonionized form alone [R. E. Treybal, *Liquid Extraction*, 2d ed., McGraw-Hill, New York, 1963, pp. 38–40]. Equation (15-20) can be rewritten in terms of the p$K_a$ for a weak acid or weak base:

$$K_{\text{weak acid}} = K_{\text{nonionized}} \div (1 + 10^{\text{pH}-\text{p}K_a}) \tag{15-21}$$

and

$$K_{\text{weak base}} = K_{\text{nonionized}} \div (1 + 10^{\text{p}K_a-\text{pH}}) \tag{15-22}$$

For weak bases, p$K_a$ = 14 − p$K_b$. Appropriate values for $K_{\text{nonionized}}$ may be obtained by measuring the partition ratio at sufficiently low pH (for acids) or high pH (for bases) to ensure the solute is in its nonionized form (normally at a pH at least 2 units from the p$K_a$ value). In Eqs. (15-21) and (15-22), it is assumed that concentrations are dilute, that dissociation occurs only in the aqueous phase, and that the acid does not associate (dimerize) in the organic phase. The effect of pH on the partition ratio for extraction of penicillin G, a complex organic containing a carboxylic acid group, is illustrated in Fig. 15-14. For a discussion of the effect of pH on the extraction of carboxylic acids with tertiary amines, see S. T. Yang, S. A. White, and S. T. Hsu, *Ind. Eng. Chem. Res.* **30**(6): 1335–1342 (1991). Another example is discussed by D. C. Greminger et al. [*Ind. Eng. Chem. Proc. Des. Dev.* **21**(1): 51–54 (1982)]; they present partition ratio data for various phenolic compounds as a function of pH.

For compounds with multiple ionizable groups, such as amino acids, the effect of pH on partitioning behavior is more complex. Amino acid partitioning is discussed by K. Schügerl [*Solvent Extraction in Biotechnology,* Springer-Verlag, Berlin, 1994] and by M. T. Gude et al. [*Ind. Eng. Chem. Res.* **35:** 4700–4712 (1996)]. Amino acids are zwitterionic (dipolar) molecules with both acid and base functionality; the p$K_a$ values corresponding to acidic RCOOH groups generally are between 2 and 6, and p$K_a$ values for basic $RNH_3^+$ amino groups are between 9 and 10 [Fuchs, D., et al., *Ind. Eng. Chem. Res.* **45**(19): 6578–6584 (2006)]. For amino acids, proteins (complex polymers of amino acids), and other such compounds containing both acid and base functionality, aqueous solubility is lowest at the pH corresponding to the compound's isoelectric point (IEP). The IEP is the pH at which all negative charges are balanced by all positive charges and the molecule has zero net charge [van Holde, K. E., W. C. Johnson, and P. S. Ho, *Principles of Physical Biochemistry*, Prentice-Hall, Upper Saddle River, NJ, 1998]. Aqueous solubility is higher at a pH away from the IEP due to a net charge on the molecule, allowing the formation of an ionic species in solution. Above the IEP, acid groups become deprotonated, yielding a net negative charge. Below the IEP, amine groups become protonated, yielding a net positive charge. The IEP of amino acids varies widely depending on the specific acid/base functional groups. Most proteins exhibit an IEP in the range of pH 5 to 8. The well-known chelating agent ethylenediaminetetraacetic acid (EDTA) provides another example. Minimum EDTA solubility occurs at pH 2 to 3 (the IEP), which can vary somewhat depending on electrolyte concentration (ionic strength) [Battaglia, G., et al., *J. Chem. Eng. Data* **53**(2): 363–367 (2008)]. At higher pH, the carboxylic acid groups begin to deprotonate, yielding various ionized acid species ($EDTA^{1-}$ to $EDTA^{4-}$), so solubility in water is higher than the minimum. At strong acid conditions (pH < 2), the fully protonated diamine is formed ($H_6EDTA^{2+}$), and solubility again is higher than the minimum.

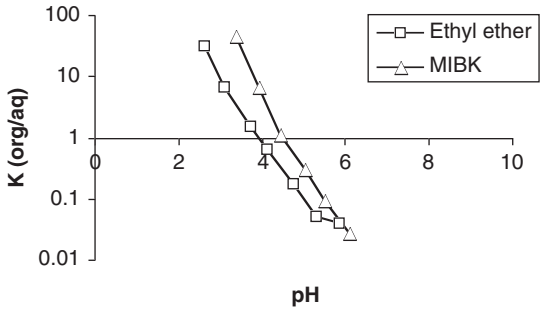

**FIG. 15-14** The effect of pH on the partition ratio for extraction of penicillin G (p$K_a$ = 2.75) from broth using an oxygenated organic solvent. The partition ratio is expressed in units of g/L in the organic phase over that in the aqueous phase. [*Data from R. L. Feder, M.S. thesis (Polytechnic Institute of Brooklyn, 1947).*]

For general discussions of organic acid and base ionic equilibria, see J. N. Butler, *Ionic Equilibrium: Solubility and pH Calculations*, Wiley, New York, 1998; and M. B. Smith, *March's Advanced Organic Chemistry: Reactions, Mechanisms, and Structure*, 7th ed., chap. 8, Wiley, New York, 2013. The dissociation of inorganic salts is discussed in the book edited by D. D. Perrin [*Ionization Constants of Inorganic Acids and Bases in Aqueous Solution*, vol. 29, Pergamon, Oxford, UK, 1982]. Compilations of p$K_a$ values are given in several handbooks [Jencks, W. P., and J. Regenstein, "Ionization Constants of Acids and Bases," in *Handbook of Biochemistry and Molecular Biology; Physical and Chemical Data*, vol. 1, 3d ed., ed. G. D. Fasman, CRC Press, Boca Raton, Fla., 1976, pp. 305–351; and *CRC Handbook of Chemistry and Physics*, 95th ed., ed. W. M. Haynes, CRC Press, Boca Raton, Fla., 2014–2015]. Also see D. D. Perrin, B. Dempsey, and E. P. Serjeant, *p$K_a$ Prediction for Organic Acids and Bases*, Chapman and Hall, London, 1981.

## PHASE DIAGRAMS

Phase diagrams are used to display liquid-liquid equilibrium data across a wide composition range. Consider the binary system of water + 2-butoxyethanol (common name ethylene glycol *n*-butyl ether) plotted in Fig. 15-15. This system exhibits both an upper critical solution temperature (UCST), also called the upper consolute temperature, and a lower critical solution temperature (LCST), or lower consolute temperature. The mixture is only partially miscible at temperatures between 48°C (the LCST) and 130°C (the UCST). Most mixtures tend to become more soluble in each other as the temperature increases; that is, they exhibit UCST behavior. The presence of an LCST in the phase diagram is less common. Mixtures that exhibit LCST behavior include hydrogen-bonding mixtures such as an amine, a ketone, or an etheric alcohol plus water. Numerous water + glycol ether mixtures behave in this way [S. P. Christensen et al., *J. Chem. Eng. Data* **50**(3): 869–877 (2005)]. For these systems, hydrogen bonding leads to complete miscibility below the LCST. As temperature increases, hydrogen bonding is disrupted by increasing thermal (kinetic) energy, and hydrophobic interactions begin to dominate, leading to partial miscibility at temperatures above the LCST. The ethylene glycol + triethylamine system shown in Fig. 15-16 is another example.

Most of the ternary or pseudoternary systems used in extraction are of two types: one binary pair has limited miscibility (termed a type I system), or two

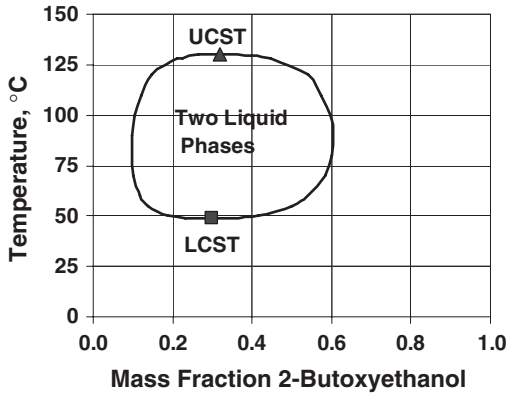

**FIG. 15-15** Temperature-composition diagram for water + 2-butoxyethanol (ethylene glycol *n*-butyl ether). [*Reprinted from Christensen, Donate, Frank, LaTulip, and Wilson,* J. Chem. Eng. Data ***50****(3), pp. 869–877 (2005), with permission. Copyright 2005 American Chemical Society.*]

binary pairs have limited miscibility (a type II system). The water + acetic acid + methyl isobutyl ketone (MIBK) system shown in Fig. 15-17 is a type I system where only one of the binary pairs, water + MIBK, exhibits partial miscibility. The heptane + toluene + sulfolane system is another example of a type I system. In this case, only the heptane + sulfolane binary is partially miscible (Fig. 15-18). For a type II system, the solute has limited solubility in one of the liquids. An example of a type II system is MIBK + phenol + water (Fig. 15-19), where MIBK + water and phenol + water are only partially miscible. Some systems form more complicated phase diagrams. For example, the system water + dodecane + 2-butoxyethanol can form three liquid phases in equilibrium at 25°C [B.-J. Lin and L.-J. Chen, *J. Chem. Eng. Data* **47**(4): 992–996 (2002)]. Complex systems such as this rarely are encountered in extraction applications; however, S. Shen, Z. Chang, and H. Liu [*Sep. Purif. Technol.* **49**(3): 217–222 (2006)] describe a single-stage, three-liquid-phase extraction process for transferring phenol and *p*-nitrophenol from wastewater in separate phases. In this process, the three-phase system consists of ethylene oxide–propylene oxide copolymer + ammonium sulfate + water + an oxygenated organic solvent such as butyl acetate or 2-octanol.

For ternary systems, a three-dimensional plot is required to represent the effects of both composition and temperature on the phase behavior. Normally, ternary phase data are plotted on isothermal, two-dimensional triangular diagrams. These can be right-triangle plots, as in Fig. 15-17, or equilateral-triangle plots, as in Figs. 15-18 and 15-19. In Fig. 15-18, the line delineating the region where two liquid phases form is called the binodal locus. The lines connecting equilibrium compositions for each phase are called tie lines, as illustrated by lines *ab* and *cd*. The tie lines converge on the plait point, the point on the bimodal locus where both liquid phases attain the same composition and the tie line length goes to zero. To calculate the relative amounts of the liquid phases, the lever rule is used. For the total feed composition *z*, the fraction of phase 1 with the composition *e* is equal to the ratio of the lengths of the line segments given by *fz*/*ez* in Fig. 15-18. Data often are plotted on a mass fraction basis when differences in the molecular weights of the components are large. Plotting the phase diagram on a mole basis tends to compress the data into a small region, and details are hidden by the scale. This often is the case for systems involving water, for example.

An extraction application normally involves more than three components, including the key solute, the feed solvent, and extraction solvent (or solvent blend), plus impurity solutes. Usually, the minor impurity components do not have a major impact on the phase equilibrium. Phase equilibrium data for multicomponent systems may be represented by using an appropriate activity coefficient correlation. (See the subsection Data Correlation Equations.) However, for many dilute and moderately concentrated feeds, process design calculations are carried out as if the system were a ternary system comprised only of a single solute plus the feed solvent and extraction solvent (a pseudoternary). Partition ratios are determined for major and minor solutes by using a representative feed, and solute transfer calculations are carried out using solute *K* values as if they were completely independent of one another. This approach often is satisfactory, but its validity should be checked with a few key experiments. For industrial mixtures containing numerous impurities, a mass fraction or mass ratio basis often is used to avoid difficulties accounting for impurities of unknown structure and molecular weight.

## LIQUID-LIQUID EQUILIBRIUM EXPERIMENTAL METHODS

**GENERAL REFERENCES:** Chap. 8, "Liquid-Liquid Equilibrium," in *Measurement of the Thermodynamic Properties of Multiple Phases*, Experimental Thermodynamics, vol. VII, ed. R. D. Weir and T. W. de Loos, Elsevier, Amsterdam, 2005; Chap. 3, "Liquid-Liquid Equilibrium Measurements," in J. D. Raal and A. L. Mühlbauer, *Phase Equilibria: Measurements and Computation*, Taylor & Francis, Abingdon, UK, 1998; Newsham, D. M. T., chap. 1 in *Science and Practice of Liquid-Liquid Extraction*, vol. 1, ed. J. D. Thornton, Oxford University Press, Oxford, UK, 1992; and Novak, J. P., J. Matous, and J. Pick, *Liquid-Liquid Equilibria, Studies in Modern Thermodynamics Series,* vol. 7, Elsevier, Amsterdam, 1987, pp. 266–282.

Three general types of experimental methods commonly are used to generate liquid-liquid equilibrium data: (1) titration with visual observation of liquid clarity or turbidity (cloud point detection); (2) visual observation of clarity or turbidity for known compositions as a function of temperature; and (3) direct analysis of equilibrated liquids typically using GC or LC methods. In the titration method, one compound is slowly titrated into a known mass of

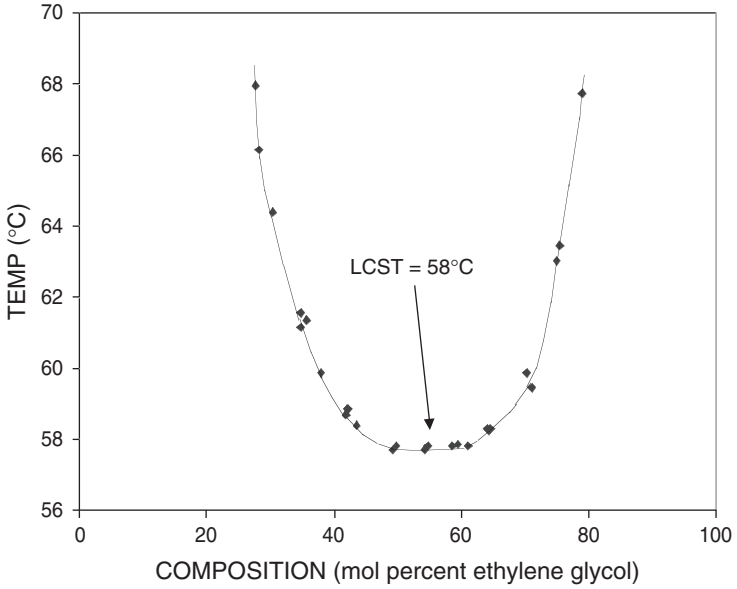

**FIG. 15-16** Temperature-composition diagram for ethylene glycol + triethylamine. [*Data taken from Sørensen and Arlt,* Liquid-Liquid Equilibrium Data Collection, *DECHEMA, Binary Systems, vol. V*, pt. 1, 1979.]

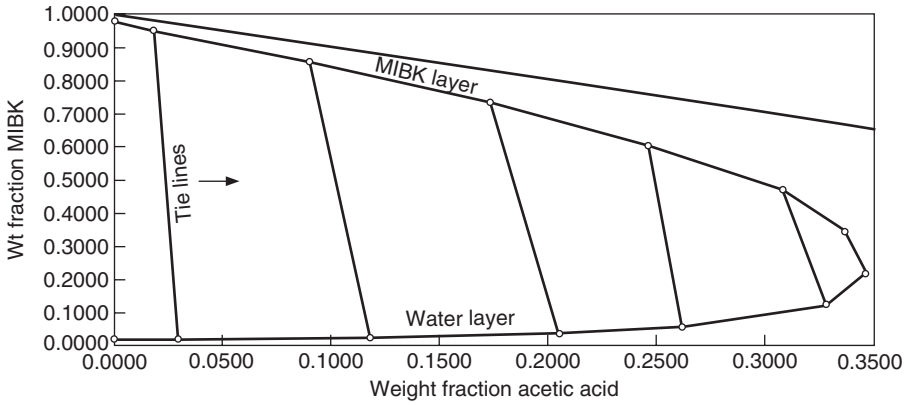

**FIG. 15-17** Water + acetic acid + methyl isobutyl ketone at 25°C, a type I system.

the second compound during mixing. The titration is terminated when the mixture becomes cloudy, indicating that a second liquid phase has formed. A tie line may be determined by titrating the second compound into the first at the same temperature. This method is reasonably accurate for binary systems composed of pure materials. Because the method is visual, a trace impurity in the "titrant" that is less soluble in the second compound may cause cloudiness at a lower concentration than if pure materials were used. This method has poor precision for sparingly soluble systems.

In the second method, several mixtures of known composition are formulated and placed in glass vials or ampoules. These are placed in a bath or oven and heated or cooled until two phases become one, or vice versa. In this way, the phase boundaries of a binary system may be determined. Again, impurities in the starting materials may affect the results, and this method does not work well for sparingly soluble systems or for systems that develop significant pressure.

To obtain tie-line data for systems that involve three or more significant components, or for systems that cannot be handled in open containers, both phases must be sampled and analyzed. This generally requires the greatest effort but gives the most accurate results and can be used over the widest range of solubilities, temperatures, and pressures. This method also may be used on multicomponent systems, which are more likely to be encountered in an industrial process. For this method, an appropriate glass vessel or autoclave is selected, based on the temperature, pressure, and compounds in the mixture. It is best to either place the vessel in an oven or submerge it in a bath to ensure there are no cold or hot spots. The mixture is introduced, thermostatted, and thoroughly mixed, and the phases are allowed to separate fully. Samples are then carefully withdrawn through lines that have the minimum dead volume feasible. The sampling should be done isothermally; otherwise the collected sample may not be exactly the same as what was in the equilibrated vessel. Adding a carefully chosen, nonreactive diluent to the sample container will prevent phase splitting, and this can be an important step to ensure accuracy in the subsequent sample workup and analysis. Take sufficient purges and at least three samples from each phase. Use the appropriate analytical method and analyze a calibration standard along with the samples. Try to minimize the time between sampling and analysis.

Rydberg and others describe automated equipment for generating tie-line data, including an apparatus called AKUFVE offered by MEAB [J. Rydberg et al., chap. 4 in *Solvent Extraction Principles and Practice*, 2d ed., ed. J. Rydberg et al., Marcel Dekker, New York, 2004, pp. 193–197]. The AKUFVE apparatus employs a stirred cell, a centrifuge for phase separation, and online instrumentation for rapid generation of data. As an alternative, B. Kuzmanović et al. [*J. Chem. Eng. Data* **48:** 1237–1244 (2003)] describe a fully automated workstation for rapid measurement of liquid-liquid equilibrium using robotics for automated sampling. Reviews of phase equilibria measurement at high pressure are available elsewhere [J. M. S. Fonseca, R. Dohrn, and S. Peper, *Fluid Phase Equilibr.* **300:** 1–69 (2011); and R. Dohrn, J. M. S. Fonseca, and S. Peper, *Annu. Rev. Chem. Biomol. Eng.* **3:** 343–367 (2012)].

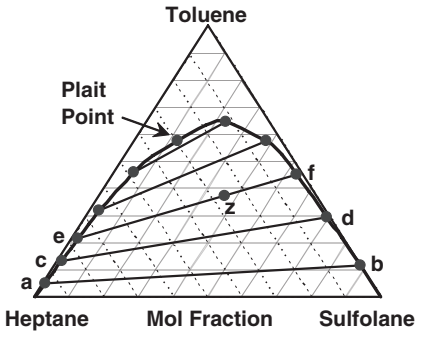

**FIG. 15-18** Heptane + toluene + sulfolane at 25°C, a type I system. [*Data taken from De Fre and Verhoeye,* J. Appl. Chem. Biotechnol. ***26:** 1-19 (1976).*]

## DATA CORRELATION EQUATIONS

**Tie-Line Correlations** Useful correlations of ternary data may be obtained by using the methods of D. B. Hand [*J. Phys. Chem.* **34**(9): 1961–2000 (1930)] and D. F. Othmer and P. E. Tobias [*Ind. Eng. Chem.* **34**(6): 693–696 (1942)]. Hand observed that plotting the equilibrium line in terms of mass ratio units on a log-log scale often gave a straight line. This relationship commonly is expressed as

$$\log \frac{X_{23}}{X_{33}} = a + b \log \frac{X_{21}}{X_{11}} \tag{15-23}$$

where $X_{ij}$ represents the mass fraction of component $i$ dissolved in the phase richest in component $j$, and $a$ and $b$ are empirical constants. Subscript 2 denotes the solute, while subscripts 1 and 3 denote feed solvent and extraction solvent, respectively. An equivalent expression can be written by using the Bancroft coordinate notation introduced earlier: $Y' = cX'^{b}$, where $c = 10^{a}$. Othmer and Tobias proposed a similar correlation:

$$\log \frac{1 - X_{33}}{X_{33}} = d + e \log \frac{1 - X_{11}}{X_{11}} \tag{15-24}$$

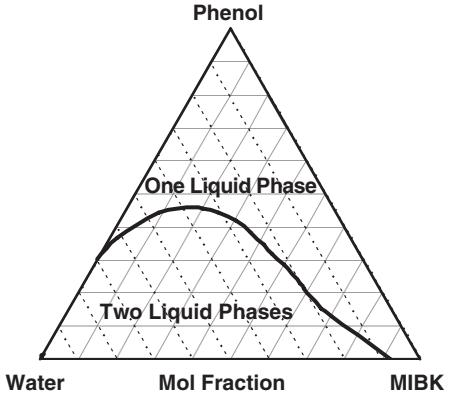

**FIG. 15-19** Methyl isobutyl ketone + phenol + water at 30°C, a type II system. [*Data taken from Narashimhan, Reddy, and Chari,* J. Chem. Eng. Data ***7, p. 457 (1962).***]

where $d$ and $e$ are constants. Equations (15-23) and (15-24) may be used to check the consistency of tie-line data, as discussed by A. M. Awwad et al. [*J. Chem. Eng. Data* **50**(3): 788–791 (2005)] and by I. Kirbaslar et al. [*Braz. J. Chem. Eng.* **17**(2): 191–197 (2000)].

A useful diagram is obtained by plotting the solute equilibrium line on log-log scales as $X_{23}/X_{33}$ versus $X_{21}/X_{11}$ [from Eq. (15-23)] along with a second plot consisting of $X_{23}/X_{33}$ versus $X_{23}/X_{13}$ and $X_{21}/X_{31}$ versus $X_{21}/X_{11}$. This second plot is termed the limiting solubility curve. The plait point may easily be found from the intersection of the solute equilibrium line with this curve, as shown by R. E. Treybal, L. D. Weber, and J. F. Daley [*Ind. Eng. Chem.* **38**(8): 817–821 (1946)]. This type of diagram also is helpful for interpolation and limited extrapolation when equilibrium data are scarce. An example diagram is shown in Fig. 15-20 for the water + acetic acid + methyl isobutyl ketone (MIBK) system. For additional discussion of various correlation methods, see G. S. Laddha and T. E. Degaleesan, chap. 2 in *Transport Phenomena in Liquid Extraction*, McGraw-Hill, New York, 1978.

**Thermodynamic Models** The thermodynamic theories and equations used to model phase equilibria are reviewed in Sec. 4, Thermodynamics. These equations provide a framework for data that can help minimize the required number of experiments. An accurate liquid-liquid equilibrium (LLE) model is particularly useful for applications involving concentrated feeds where partition ratios and mutual solubility between phases are significant functions of solute concentration. Sometimes it is difficult to model LLE behavior across the entire composition range with a high degree of accuracy, depending upon the chemical system. In that case, it is best to focus on the composition range specific to the particular application at hand—to ensure the model accurately represents the data in that region of the phase diagram for accurate design calculations. Such a model can be a powerful tool for extractor design or when used with process simulation software to conceptualize, evaluate, and optimize process options. However, whether a complete LLE model is needed will depend on the application. For dilute applications where partition ratios do not vary much with composition, it may be satisfactory to characterize equilibrium in terms of partition ratios measured over the range of anticipated feed and raffinate compositions. Also, when partition ratios are always very large, on the order of 100 or larger, as can occur when washing salts from an organic phase into water, a continuous extractor is likely to operate far from equilibrium. In this case, a precise equilibrium model may not be needed because the extraction factor always is very large, and mass-transfer rates dominate performance. (See the subsection Rate-Based Calculations under Process Fundamentals and Basic Calculation Methods.)

LLE models for nonionic systems generally are developed by using either the NRTL or UNIQUAC correlation equations (see Sec. 4). Most commercial simulation software packages include these models and allow regression of data to determine model parameters. One should refer to the process simulator's operating manual for specific details. Not all simulation software will use exactly the same equation format and parameter definitions, so parameters reported in the literature may not be appropriate for direct input to the program but need to be converted to the appropriate form. In theory, activity coefficient data from binary or ternary vapor-liquid equilibria can be used for calculating liquid-liquid equilibria. While this may provide a reasonable starting point, in practice at least some of the binary parameters will need to be determined from liquid-liquid tie-line data to obtain an accurate model [D. S. Lafyatis et al., *Ind. Eng. Chem. Res.* **28**(5): 585–590 (1989)]. Detailed discussion of the application and use of NRTL and UNIQUAC is given by S. M. Walas [*Phase Equilibria in Chemical Engineering*, Butterworth-Heinemann, Oxford, UK, 1985]. The application of NRTL in the design of a liquid-liquid extraction process is discussed by D. L. Venter and I. Nieuwoudt [*Ind. Eng. Chem. Res.* **37**(10): 4099–4106 (1998)], by R. van Grieken et al. [*Ind. Eng. Chem. Res.* **44**(21): 8106–8112 (2005)], by B. Coto et al. [*Chem. Eng. Sci.* **61:** 8028–8039 (2006)]; and by Z. Li et al. [*J. Chem. Eng. Data* **59**(8): 2485–2489 (2014)]. The use of the NRTL model also is discussed in Example 15-5 under Single-Solvent Fractional Extraction with Extract Reflux in Calculation Procedures.

Although the NRTL or UNIQUAC equations generally are recommended for nonionic systems, a number of alternative approaches have been introduced. An example is the statistical associating fluid theory (SAFT) equation of state introduced by W. G. Chapman et al. [*Ind. Eng. Chem. Res.* **29**(8): 1709–1721 (1990)]. M.-L. Yu and Y.-P. Chen discuss the application of SAFT to correlate data for 41 binary and 8 ternary liquid-liquid systems [*Fluid Phase Equilibr.* **94:** 149–165 (1994)]. The SAFT equation often is used to correlate LLE data for polymer-solvent systems [P. K. Jog et al., *Ind. Eng. Chem. Res.* **41**(5): 887–891 (2002)]. Other methods are used to describe the behavior of ionic species (electrolytes), as discussed in Sec. 4.

**Data Quality** Normally it is not possible to evaluate LLE data for thermodynamic consistency [J. M. Sørensen and W. Arlt, *Liquid-Liquid Equilibrium Data Collection*, Binary Systems, vol. V, pt. 1, DECHEMA, 1979, p. 12]. The thermodynamic consistency test for VLE data involves calculating an independently measured variable from the others (usually the vapor composition from the temperature, pressure, and liquid composition) and comparing the measurement with the calculated value. Because LLE data are only very weakly affected by change in pressure, this method is not feasible for LLE. However, if the data were produced by equilibration and analysis of both phases, then at least the data can be checked to determine how well the material balance closes. This can be done by plotting the total feed composition used in the experiments along with the measured tie-line compositions on a ternary diagram. The feed composition should lie on the tie line. For very low solute concentrations, this plot may be unrevealing. Alternatively, a plot of $Y_i''/Z_i''$ versus $X_i''/Z_i''$ (where $Y_i''$ is the mass fraction of component $i$ in the extract phase, $X_i''$ is the mass fraction of component $i$ in the raffinate phase, and $Z_i''$ is the mass fraction of component $i$ in the total feed) should give a smooth line that passes through the point (1, 1). The tie-line data also may be checked for consistency by plotting the data in the form of a Hand plot or Othmer-Tobias plot, as described in Tie-Line Correlations, and looking for outliers. Another approach is to plot the partition ratio as a function of solute concentration and look for data points that deviate significantly from otherwise smooth trends.

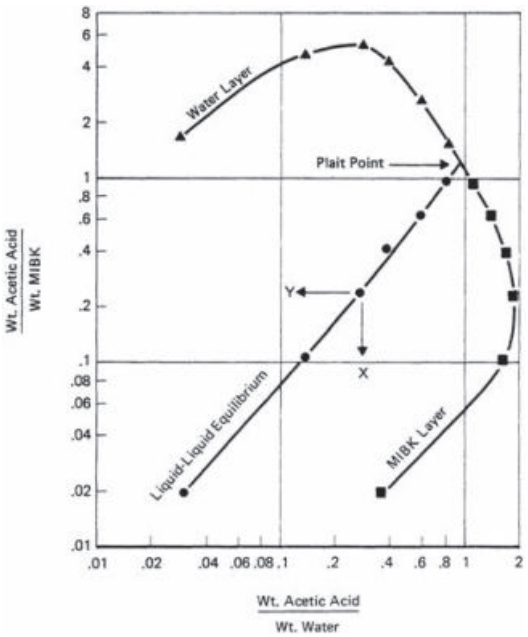

**FIG. 15-20** Hand-type ternary diagram for water + acetic acid + MIBK at 25°C.

## TABLE OF SELECTED PARTITION RATIO DATA

Table 15-1 summarizes typical partition ratio data for selected systems.

## PHASE EQUILIBRIUM DATA SOURCES

A comprehensive collection of phase equilibrium data (including vapor-liquid, liquid-liquid, and solid-liquid data), known as the Dortmund Data Bank, includes LLE measurements as well as NRTL and UNIQUAC fitted parameters. The data bank also includes a compilation of infinite-dilution activity coefficients. The LLE collection is available as a series of books [J. M. Sørensen and W. Arlt, *Chemistry Data Series: Liquid-Liquid Equilibrium Data Collection*, *Binary Systems*, vol. V, pts. 1–4, DECHEMA, Frankfurt, 1979–1980] and as an online database that includes retrieval and modeling software. Another online database is Infotherm from Wiley. Other sources of thermodynamic data include the online IUPAC-NIST Solubility Data Series distributed by the Office of Data and Informatics of the National Institute of Standards and Technology (NIST) and compilations prepared by the Thermodynamics Research Center (TRC) in Boulder, Colo., a part of the Physical and Chemical Properties Division of NIST. An older but still useful data collection is that of H. Stephen and T. Stephen [*Solubilities of Inorganic and Organic Compounds*, vol. 1, pts. 1 and 2, Pergamon, Oxford, UK, 1960]. Also, a useful database of activity coefficients is included in the supporting information submitted with the article by M. J. Lazzaroni et al. [*Ind. Eng. Chem. Res.* **44**(11): 4075–4083 (2005)] and available from the publisher. A listing of the original sources is included. Additional sources of data are discussed by A. Skrzecz [*Pure Appl. Chem.* (IUPAC), **69**(5): 943–950 (1997)].

**TABLE 15-1 Selected Partition Ratio Data**

Partition ratios are listed in units of weight percent solute in the extract divided by weight percent solute in the raffinate, generally for the lowest solute concentrations given in the cited reference. The partition ratio tends to be greatest at low solute concentrations. Consult the original references for more information about a specific system.

| Solute | Feed solvent | Extraction solvent | Temp. (°C) | *K* (wt % basis) | Reference |
|---|---|---|---|---|---|
| Ethanol | Cyclohexane | Ethanolamine | 25 | 2.79 | 1 |
| Acetone | Ethylene glycol | Amyl acetate | 31 | 1.84 | 2 |
| Acetone | Ethylene glycol | Ethyl acetate | 31 | 1.85 | 2 |

### RECOMMENDED MODEL SYSTEMS

To facilitate the study and comparison of various types of extraction equipment, H.-J. Bart et al. [chap. 3 in J. C. Godfrey and M. J. Slater, *Liquid-Liquid Extraction Equipment*, Wiley, New York, 1994] recommend several model systems. These include (1) water + acetone + toluene (high interfacial tension); (2) water + acetone + butyl acetate (moderate interfacial tension); and (3) water + succinic acid + *n*-butanol (low interfacial tension). All have solute partition ratios near $K = 1.0$. T. Mišek, R. Berger, and J. Schröter [*Standard Test Systems for Liquid Extraction*, The Instn. of Chemical Engineers, London, 1985] summarize phase equilibrium, viscosities, densities, diffusion coefficients, and interfacial tensions for these systems. Note that methyl isobutyl ketone + acetic acid + water was replaced with the water + acetone + butyl acetate system because of concerns over acetic acid dimerization and Marangoni instabilities. (See the subsection Liquid-Liquid Dispersion Fundamentals.) For test systems with a partition ratio near $K = 10$, Bart et al. recommend (1) water + methyl isopropyl ketone + toluene (high interfacial tension) and (2) water + methyl isopropyl ketone + butyl acetate (medium interfacial tension) and give references to data sources. Bart et al. also recommend a number of systems involving reactive extractants.

## SOLVENT SCREENING METHODS

A variety of methods may be used to estimate solvent properties as an aid to identifying useful solvents for a new application. Many of these methods focus on thermodynamic properties; a favorable partition ratio and low mutual solubility often are necessary for an economical extraction process, so ranking candidates according to thermodynamic properties provides a useful initial screen of the more promising candidates. Keep in mind, however, that other factors also must be taken into account when selecting a solvent, as discussed in Desirable Solvent Properties under Introduction and Overview. When using the following methods, also note that the level of uncertainty may be fairly high. The uncertainty depends upon how closely the chemical system of interest resembles the systems used to develop the method. See Sec. 4 for more discussion of the thermodynamic basis of these methods.

### USE OF ACTIVITY COEFFICIENTS AND RELATED DATA

Compilations of infinite-dilution activity coefficients, when available for the solute of interest, may be used to rank candidate solvents. Partition ratios at finite concentrations can be estimated from these data by extrapolation from infinite dilution using a suitable correlation equation such as NRTL. Examples of these kinds of calculations are given by S. M. Walas [*Phase Equilibria in Chemical Engineering*, Butterworth-Heinemann, Oxford, UK, 1985]. Most activity coefficients available in the literature are for small organic molecules and are derived from vapor-liquid equilibrium measurements or azeotropic composition data.

Partition ratios at infinite dilution can be calculated directly from the ratio of infinite-dilution activity coefficients for solute dissolved in the extraction solvent and in the feed solution, often providing a reasonable estimate of the partition ratio for dilute concentrations. Infinite-dilution activity coefficients may be reported in terms of a van Laar binary interaction parameter

$$\ln \gamma_{i,j}^{\infty} = \frac{A_{i,j}}{RT} \tag{15-25}$$

$$K_i^o = \frac{\gamma_i^{\infty}}{\gamma_i^{*,\infty}} = \frac{\exp(A^{i,j}/RT)}{\exp(A^{*i,j}/RT)} \tag{15-26}$$

where * denotes the extraction solvent phase [Smallwood, *Solvent Recovery Handbook*, 2d ed., Blackwell, 2002]. For example, the partition ratio for transferring acetone from water into benzene at 25°C and dilute conditions may be estimated as follows: For acetone dissolved in benzene $A_{ij}/RT = 0.47$, and for acetone dissolved in water $A_{ij}/RT = 2.29$. Then $K_i^o = e^{2.29}/e^{0.47} = 9.87/1.6 = 6.17$ (mol/mol) ≡ 1.4 (wt/wt). S. W. Briggs and E. W. Comings [*Ind. Eng. Chem.* **35**(4): 411–417 (1943)] report experimental values that range between 1.06 and 1.39 (wt/wt).

For screening candidate solvents, comparing the magnitude of the activity coefficient for the solute of interest dissolved in the solvent phase often is a good way to rank solvents. A smaller value of $\gamma_{i,\text{solvent}}$ indicates a higher $K$ value. Solubility data available for a given solute dissolved in a range of solvents also can be used to rank solvents; higher solubility in a candidate solvent indicates a more attractive interaction (a lower activity coefficient) and therefore a higher partition ratio.

### ROBBINS' CHART OF SOLUTE-SOLVENT INTERACTIONS

When available data are not sufficient (the most common situation), Robbins' chart of functional group interactions (Table 15-2) is a useful guide to ranking general classes of solvents. It is based on an evaluation of hydrogen bonding and electron donor-acceptor interactions for 900 binary systems [Robbins, L. A., *Chem. Eng. Prog.* **76**(10): 58–61 (1980)]. The chart includes 12 general classes of functional groups, divided into three main types: hydrogen-bond donors, hydrogen-bond acceptors, and non-hydrogen-bonding groups. Compounds representative of each class include (1) phenol, (2) acetic acid, (3) pentanol, (4) dichloromethane, (5) methyl isobutyl ketone, (6) triethylamine, (7) diethylamine, (8) *n*-propylamine, (9) ethyl ether, (10) ethyl acetate, (11) toluene, and (12) hexane. Robbins' chart is applicable to any process where liquid-phase activity coefficients are important, including liquid-liquid extraction, extractive distillation, azeotropic distillation, and crystallization from solution. The activity coefficient in the liquid phase is common to all these separation processes.

Here we discuss Robbins' original method. A modified version is given in Sec. 4, Thermodynamics. Robbins' chart predicts positive, negative, or zero deviations from ideal behavior for functional group interactions. For example, consider an application involving extraction of acetone from water into chloroform solvent. Acetone contains a ketone carbonyl group which is a hydrogen acceptor and a member of solute class 5 according to Table 15-2. Chloroform contains a hydrogen donor group (solvent class 4). The solute class 5 and solvent class 4 interaction in Table 15-2 is shown to give a negative deviation from ideal behavior. This indicates an attractive interaction which enhances the liquid-liquid partition ratio. Other classes of solvents shown in Table 15-2 that yield a negative deviation with a ketone (class 5) are classes 1 and 2 (phenolics and acids). Other ketones (solvent class 5) are shown to be compatible with acetone (solute class 5) and tend to give activity coefficients near 1.0, that is, nearly ideal behavior. The solvent classes 6 through 12 tend to provide repulsive interactions between these groups and acetone, and so they are not likely to exhibit partition ratios for ketones as high as the other solvent groups do.

Most of the classes in Table 15-2 are self-explanatory, but some can use additional definition. Class 4 includes halogenated solvents that have highly active hydrogens as described by R. H. Ewell, Harrison, and Berg [*Ind. Eng. Chem.* **36**(10): 871–875 (1944)]. These are molecules that have two or three halogen atoms on the same carbon as a hydrogen atom, such as dichloromethane, trichloromethane, 1,1-dichloroethane, and 1,1,2,2-tetrachloroethane. Class 4 also includes molecules that have one halogen on the same carbon atom as a hydrogen atom and one or more halogen atoms on an adjacent carbon atom, such as 1,2-dichloroethane and 1,1,2-trichloroethane. Apparently, the halogens interact intramolecularly to leave the hydrogen atom highly active. Monohalogen paraffins such as methyl chloride and ethyl chloride are in class 11 along with multihalogen paraffins and olefins without active hydrogen, such as carbon tetrachloride and perchloroethylene. Chlorinated benzenes are also in class 11 because they do not have halogens on the same carbon as a hydrogen atom. Intramolecular bonding on aromatics is another fascinating interaction which gives a net result that behaves much as does an ester group, class 10. Examples of this include *o*-nitrophenol and *o*-hydroxybenzaldehyde (salicylaldehyde). The intramolecular hydrogen bonding is so strong between the hydrogen donor group (phenol) and the hydrogen acceptor group (nitrate or aldehyde) that the molecule acts as an ester. One result is its low solubility in hot water. By contrast, the *para* derivative is highly soluble in hot water.

### ACTIVITY COEFFICIENT PREDICTION METHODS

Robbins' chart provides a useful qualitative indication of interactions between classes of compounds but does not give quantitative differences within each class. For this, methods designed to calculate activity coefficients or related properties are used. The thermodynamic basis for these methods is discussed in Sec. 4, Thermodynamics. Perhaps the most widely used method is the group contribution method known by the name universal quasichemical functional group activity coefficients (UNIFAC). For a review of its current status, see J. Gmehling, D. Constantinescu, and B. Schmid, *Ann. Rev. Chem. Biomol. Eng.* **6:** 267–292 (2015). The use of UNIFAC

for estimating LLE is discussed by J. Gmehling and A. Schedemann [*Ind. Eng. Chem. Res.* **53**(45): 17794-17805 (2014)], P. A. Gupte and R. P. Danner [*Ind. Eng. Chem. Res.* **26**(10): 2036–2042 (1987)] and by H. H. Hooper, S. Michel, and J. M. Prausnitz [*Ind. Eng. Chem. Res.* **27**(11): 2182–2187 (1988)]. S. D. Birajdar et al. [*J. Chem. Eng. Data* **59**(8): 2456–2463 (2014)] discuss the use of UNIFAC for screening candidate solvents, and G. R. Vakili-Nezhand, H. Modarress, and G. A. Mansoori [*Chem. Eng. Technol.* **22**(10): 847–852 (1999)] discuss its use for representing a complex feed containing a large number of components for which available LLE data are incomplete.

Methods based on regular solution theory include the Hansen solubility parameter model [C. M. Hansen, *Hansen Solubility Parameters: A User's Handbook,* 2d ed., CRC Press, Boca Raton, Fla., 2007] and the modified separation of cohesive energy density (MOSCED) model [E. R. Thomas and C. A. Eckert, *Ind. Eng. Chem. Proc. Des. Dev*. **23**(2): 194–209 (1984); and M. J. Lazzaroni et al., *Ind. Eng. Chem. Res*. **44**(11): 4075–4083 (2005)]. Unlike Hansen's model, MOSCED includes two parameters to represent hydrogen bonding ( for both proton donor and acceptor capabilities). Example applications of these models to calculate activity coefficients for the purpose of screening candidate solvents are given by T. C. Frank et al. [*Chem. Eng. Prog.* **95**(12): 41–61 (1999)] for the Hansen model, and by I. Escudero, J. L. Cabezas, and J. Coca [*Chem. Eng. Comm*. **173**(1): 135–146 (1999)] and T. C. Frank et al. [*Ind. Eng. Chem. Res*. **46**(13): 4621–4625 (2007)] for MOSCED. In practice, these methods normally involve regression of some phase equilibrium data to determine parameter values, although estimates can be made. For example, Hansen describes methods for estimating Hansen solubility parameters [C. M. Hansen, ibid.], and R. T. Ley et al. [*Ind. Eng. Chem. Res.* **55**(18): 5415–5430 (2016)] discuss methods for calculating MOSCED parameters in the absence of data.

A method that is used in a fashion similar to how the Hansen and MOSCED models are applied is based on a modified NRTL framework and called NRTL-SAC ( for segment activity coefficient). See C.-C. Chen and Y. Song, *Ind. Eng. Chem. Res.* **43**(26): 8354–8362 (2004); **44**(23): 8909–8921 (2005); and E. Sheikholeslamzadeh and S. Rohani, *Ind. Eng. Chem. Res.* **55**(18): 464–473 (2012). A method developed by P. Meyer and G. Maurer [*Ind. Eng. Chem. Res.* **34**(1): 373–381 (1995)] uses the linear solvation energy relationships (LSER) model and Kamlet-Taft solvatochromic parameters [Taft, R. W., et al., *Nature* **313:** 384 (1985); and R. W. Taft et al., *J. Pharma Sci*. **74:** 807–814 (1985)] to estimate infinite-dilution partition ratios. The SPACE model employs LSER concepts to calculate infinite-dilution activity coefficients [Hait, M. J., et al., *Ind. Eng. Chem. Res.* **32**(11): 2905–2914 (1993)]. For a discussion of LSER methods and molecular descriptors in general, see M. H. Abraham, A. Ibrahim, and A. M. Zissimos, *J. Chromatogr. A,* **1037:** 29–47 (2004).

The conductor-like screening model (COSMO) introduced by A. Klamt is based on calculation of molecular electron density profiles [Klamt, *From Quantum Chemistry to Fluid Phase Thermodynamics and Drug Design,* Elsevier, Amsterdam, 2005; and Klamt et al., *Annu. Rev. Chem. Biomol. Eng.* **1:** 101–122 (2010)]. The Klamt model is called COSMO-RS ( for realistic solvation). A similar model is COSMO-SAC (segment activity coefficient) published by S. T. Lin and S. I. Sandler [*Ind. Eng. Chem. Res*. **41**(5): 899–913, 2332 (2002)]. Databases of electron density profiles (called sigma profiles) have been developed. For example, see E. Mullins et al., *Ind. Eng. Chem. Res*. **45**(12): 4389–4415 (2006), and E. Paulechka et al., *J. Chem. Eng. Data* **60**(12): 3554–3561 (2015). The application of COSMOS-RS to predict liquid-liquid equilibria is discussed by T. Banerjee et al. [*Ind. Eng. Chem. Res*. **46**(4): 1292–1304 (2007)], by L.-Y. Garcia-Chavez et al. [*Sep. Purif. Technol.* **97:** 2–10 (2012)], and by S. D. Birajdar et al. [*J. Chem. Eng. Data* **59**(8): 2456–2463 (2014)].

## METHODS USED TO ASSESS LIQUID-LIQUID MISCIBILITY

In evaluating potential solvents, it is important to determine whether a given candidate will exhibit sufficiently limited miscibility with the feed liquid. Mutual solubility data for organic-solvent + water mixtures often are listed somewhere in the literature and can be obtained through a literature search. (See the subsection Phase Equilibrium Data Sources under Thermodynamic Basis for Liquid-Liquid Extraction.) However, data often are not available for pairs of organic solvents and for multicomponent mixtures showing the effect of dissolved solutes. In these cases, estimates can provide useful guidance. Note, however, that the available estimation methods normally provide limited accuracy, so it is best to measure these properties for the more promising candidates.

Phase splitting behavior can be inferred from activity coefficients. In general, partial miscibility will not occur whenever the infinite-dilution activity coefficients of the components in solution are less than 7. This is a reliable rule, but it depends upon the quality of the activity coefficient data or estimates. If $\gamma^{\infty}$ for any one of the components is greater than 7, then partial miscibility may occur at some finite composition. The criterion $\gamma_i^{\infty} > 7$ often is cited as a general rule indicating a partially miscible system, but there are many exceptions. For detailed discussion, see J. M. Prausnitz, R. N. Lichtenthaler, and E. Gomez de Azevedo, *Molecular Thermodynamics of Fluid-Phase Equilibria*, 3d ed., Prentice-Hall, Upper Saddle River, NJ, 1999. Solubility parameters also can be used to assess miscibility [*Handbook of Solubility Parameters and Other Cohesion Parameters,* 2d ed., ed. A. M. F. Barton, CRC, Boca Raton, Fla., 1991].

As a complementary alternative, N. B. Godfrey's data-based method [*Chemtech* **2**(6): 359–363 (1972)] provides a quick way of qualitatively assessing whether an organic-solvent pair of interest is likely to exhibit partial miscibility at near-ambient temperatures. Godfrey assigned miscibility numbers to approximately 400 organic solvents (Table 15-3) by observing their miscibility in a series of 31 standard solvents (Table 15-4). He then showed that the general miscibility behavior of a given solvent pair can be

predicted by comparing their miscibility numbers. Godfrey's rules, slightly modified, are summarized as follows:

1. If $\Delta \le 12$, where $\Delta$ is the difference in miscibility numbers, the solvents are likely to be miscible in all proportions at 25°C.
2. If $13 \le \Delta \le 15$, the solvents may be only partially miscible with an upper critical solution temperature (UCST) between 25 and 50°C. This is a borderline case. If the binary mixture is miscible, then adding a relatively small amount of water likely will induce phase splitting.
3. If $\Delta = 16$, the solvents are likely to exhibit a UCST between 25 and 75°C.
4. If $\Delta \ge 17$, the solvents are likely to exhibit a UCST above 75°C.

About 15 percent of the solvents in Table 15-3 have dual miscibility numbers $A$ and $B$ because the appropriate difference in miscibility numbers depends upon which end of the hydrophobic-lipophilic scale is being considered. If one of the solvents has dual miscibility numbers $A$ and $B$ and the other has a single miscibility number $C$, then $\Delta$ should be calculated as follows:

5. If $C > B$, then the solvent having miscibility number $C$ is somewhat more lipophilic than the solvent having numbers $A$ and $B$. At this end of the lipophilicity scale, the number $A$ characterizes the solvent's miscibility behavior. Apply rules 1 through 3, using $\Delta = C - A$.
6. If $C < A$, then the solvent having miscibility number $C$ is somewhat less lipophilic than the solvent with numbers $A$ and $B$. At this end of the lipophilicity scale, the number $B$ characterizes the solvent's miscibility behavior. Apply rules 1 through 3, using $\Delta = B - C$.

**TABLE 15-4 Godfrey Standard Solvents**

| Miscibility number | Solvent | |
|---|---|---|
| 1 | Glycerol ("glycerin") | Hydrophilic end of scale |
| 2 | 1,2-Ethanediol ("ethylene glycol") | |
| 3 | 1,4-Butanediol | |
| 4 | 2,2′-Thiodiethanol | |
| 5 | Diethylene glycol | |
| 6 | Triethylene glycol | (decreasing hydrophilicity) |
| 7 | Tetraethylene glycol | (increasing lipophilicity) |
| 8 | Methoxyacetic acid | |
| 9 | Dimethylsulfoxide | |
| 10 | *N*-Formylmorpholine | |
| 11 | Furfuryl alcohol | |
| 12 | 2-(2-Methoxyethoxy) ethanol ("diethylene glycol methyl ether") | |
| 13 | 2-Methoxyethanol ("ethylene glycol methyl ether") | |
| 14 | 2-Ethoxyethanol ("ethylene glycol ethyl ether") | |
| 15 | 2-(2-Butoxyethoxy) ethanol ("diethylene glycol *n*-butyl ether") | |
| 16 | 2-Butoxyethanol ("ethylene glycol *n*-butyl ether") | |
| 17 | 1,4-Dioxane | |
| 18 | 3-Pentanone | |
| 19 | 1,1,2,2-Tetrachloroethane | |
| 20 | 1,2-Dichloroethane | |
| 21 | Chlorobenzene | |

| 27 | 1-Methylcyclohexene | |
| 28 | Cyclohexane | |
| 29 | Heptane | |
| 30 | Tetradecane | |
| 31 | Petrolatum ($C_{14}$–$C_{16}$ alkanes) | Lipophilic end of scale |

Reprinted from N. B. Godfrey, *CHEMTECH*, **2**(6), pp. 359–363 (June, 1972), with permission. Published 1972 by the American Chemical Society.

7. If $A \le C \le B$, then evaluate $\Delta = C - A$ and $\Delta = B - C$ and use the larger of the $D$ values in applying rules 1 through 3. Such a mixture is likely to be miscible in all proportions at 25°C.

8. If both members of a solvent pair have dual miscibility numbers, then the pair is likely to be miscible in all proportions at 25°C.

If a compound of interest is not listed in Table 15-3 or 15-4, a compound of the same type or class may help to gauge its miscibility behavior. In cases where Godfrey's rules indicate that partial miscibility is likely, whether phase splitting actually occurs depends upon the composition of the mixture and the temperature. The composition may be close to but still outside the two-liquid-phase region on a temperature-composition diagram.

Godfrey's method is a useful guide for compounds that exhibit behavior similar to the 31 standard solvents used to define miscibility numbers. The method deals with the common situation in which a mixture exhibits a UCST; that is, solubility tends to increase with increasing temperature. Exceptions to Godfrey's rules include binary mixtures that form unusually strong hydrogen-bonding interactions. Normally, mixtures of this type are completely miscible, or they exhibit a lower critical solution temperature (LCST). Examples include ethylene glycol + triethylamine (Fig. 15-16) and glycerin + ethylbenzylamine (UCST = 280°C and LCST = 49°C) [Sørenson, J. M., and W. Arlt, *Liquid-Liquid Equilibrium Data Collection*, vol. V, pt. 1, DECHEMA, Frankfurt, 1979]. As mentioned earlier, it is not unusual for mixtures of water and amines or water and glycol ethers to exhibit LCST behavior. (See the subsection Phase Diagrams under Thermodynamic Basis for Liquid-Liquid Extraction.) This is a reason why Godfrey's method does not include water.

Sometimes the mutual solubility of a solvent pair of interest can easily be decreased by adding a third component. For example, it is common practice to add water to a solvent system containing a water-miscible organic solvent (the polar phase) and a hydrophobic organic solvent (the nonpolar phase). A typical example is the solvent system (methanol + water) + dichloromethane. An anhydrous mixture of methanol and dichloromethane is completely miscible, but adding water causes phase splitting. Adjusting the amount of water added to the polar phase also may be used to alter the $K$ values for the extraction, density difference, and interfacial tension. Table 15-5 lists some common examples of solvent systems of this type. These systems are common candidates for fractional extractions.

## COMPUTER-AIDED MOLECULAR DESIGN

Many specialized computer programs have been written specifically to identify candidate solvents with properties that best match those needed for a particular application by weighing various considerations of the kind outlined in the subsection Desirable Solvent Properties in addition to the partition ratio. The goal is to determine the optimal solvent structure that best meets the specified set of performance factors [Brignole, E. A., S. Botini, and R. Gani, *Fluid Phase Equilibr.* **29:** 125–132 (1986); and K. G. Joback and G. Stephanopoulos, *Proc. FOCAPD* **11:** 631 (1989)]. Recent studies that include reviews of previous work are given by N. D. Austin, N. V. Sahinidis, and D. W. Trahan [*Chem. Eng. Sci.* **159:** 93–105 (2017) and

**TABLE 15-5 Common Solvent Systems Involving a Water-Miscible Organic Solvent and Addition of Water to Control Properties**

| Polar component | Nonpolar component |
|---|---|
| Methanol | *n*-Hexane, *n*-heptane, other alkanes, dichloromethane |
| Acetonitrile | *n*-Hexane, *n*-heptane, other alkanes, dichloromethane |
| Ethylene glycol, diethylene glycol, triethylene glycol, tetraethylene glycol, and propylene glycol analogs | *n*-Hexane, *n*-heptane, other alkanes, dichloromethane, amyl acetate, toluene, xylene |
| Ethylene glycol mono methyl ether and other glycol ethers | *n*-Hexane, *n*-heptane, other alkanes, and dichloromethane |

*Chem. Eng. Res. Des.* **116:** 2–26 (2016)]; A. I. Papadopoulos and P. Linke [*AIChE J.* **52**(3): 1057–1070 (2006)]; A. T. Karunanithi, L. E. K. Achenie, and R. Gani [*Ind. Eng. Chem. Res.* **44**(13): 4785–4797 (2005)]; and M. Cismondi and E. A. Brignole [*Ind. Eng. Chem. Res.* **43**(3): 784–790 (2004)]. A variety of creative search strategies have been employed, including the use of stochastic algorithms to account for uncertainty [Kim, K.-J., and U. M. Diwekar, *Ind. Eng. Chem. Res.* **41**(5): 1285–1296 (2002)], the use of quantum chemistry methods for property estimation [A. Lehnamm and C. D. Maranas, *Ind. Eng. Chem. Res.* **43**(13): 3419–3432 (2004)], and the application of a genetic theory of evolution (survival of the fittest) [Nieuwoudt, I., Paper No. 233a, AIChE National Meeting, Austin, 2004; and Van Dyk, B., and I. Nieuwoudt, *Ind. Eng. Chem. Res.* **39**(5): 1423–1429 (2000)]. Similar programs have been written to facilitate the identification of alternative solvents or solvent blends as replacements for a given solvent, by attempting to identify compounds that match the physical properties of the solvent the user wishes to replace. An example is the PARIS program developed by the U.S. Environmental Protection Agency [Cabezas, H., P. F. Harten, and M. R. Green, *Chem. Eng. Magazine* **107**(3): 109 (March 2000).

### HIGH-THROUGHPUT EXPERIMENTAL METHODS

In addition to the methods already described, solvents and extraction conditions may be screened by using rapid automated experimental methods and automated sample analysis. High-throughput liquid-liquid extraction methods are reviewed by D. A. Wells [*Progress in Pharmaceutical and Biomedical Analysis*, vol. 5, Elsevier, Amsterdam, 2003]. An example involving automated liquid chromatography is described by R. D. Bolden et al. [*J. Chromatogr. B.* **772:** 1–10 (2002)]. A gas chromatography method that includes automated calculation of partition ratios and mutual solubility, plus automated correlation of data with thermodynamic models, is described by D. Dechambre et al. [*Fluid Phase Equilibr.* **362:** 328–334 (2014)]. Another approach called single-drop microextraction is reviewed by Y. Yan et al. [*J. Chromatogr. A.* **1368:** 1–17 (2014)]. For a review of high-throughput methods in general, see K. Murray, ed., *Principles and Practice of High Throughput Screening*, Blackwell, Oxford, UK, 2005. The automated methods described in the subsection Liquid-Liquid Equilibrium Experimental Methods under Thermodynamic Basis for Liquid-Liquid Extraction also may be useful for screening solvents.

## LIQUID DENSITY, VISCOSITY, AND INTERFACIAL TENSION

**General References:** See Sec. 2, Physical and Chemical Data; Rosen, M. J., *Surfactants and Interfacial Phenomena*, 4th ed., Wiley, New York, 2012; Hartland, S., *Surface and Interfacial Tension: Measurement, Theory, and Applications*, Marcel Dekker, New York, 2004; and Poling, B. E., J. M. Prausnitz, and J. P. O'Connell, *The Properties of Gases and Liquids*, 5th ed., McGraw-Hill, New York, 2000.

The utility of liquid-liquid extraction as a separation tool depends upon both phase equilibria and transport properties. The most important physical properties that influence transport properties are liquid-liquid interfacial tension, liquid density, and viscosity. These properties influence solute diffusion and the formation and coalescence of drops, and so are critical factors affecting the performance of liquid-liquid contactors and phase separators.

### DENSITY AND VISCOSITY

Many handbooks contain an extensive compilation of liquid density data. These same sources often include liquid viscosity data, although fewer experimental data may be available for a particular compound. Available data compilations include those by G. Wypych, *Handbook of Solvents*, ChemTec, Toronto, 2014; A. Wypych and G. Wypych, *Solvents Database*, CD-ROM, ChemTec, Toronto, 2014; C. L. Yaws, *Thermodynamic and Physical Property Data*, 2d ed., Gulf, Houston, 1998; and E. W. Flick, *Industrial Solvents Handbook*, 5th ed., Noyes, Westwood, NJ, 1998. In addition, viscosity data for $C_1$–$C_{28}$ organic compounds have been compiled by C. L. Yaws in *Handbook of Viscosity*, vols. 1–3, Elsevier, Amsterdam, 1994. Density and viscosity data also are available from the Thermodynamics Research Center at the National Institute of Standards and Technology (Boulder, Colo.) and from the DIPPR physical property databank of AIChE.

Methods for estimating density and viscosity are reviewed by B. E. Poling, J. M. Prausnitz, and J. P. O'Connell [*The Properties of Gases and Liquids*, 5th ed., McGraw-Hill, New York, 2000]. However, it is best to measure density and viscosity in the laboratory whenever possible. The methods used to measure viscosity are described in numerous books, including *Measurement of Transport Properties of Fluids*, vol. 3, ed. W. A. Wakeham, A. Nagashima, and J. V. Sengers, Blackwell, Oxford, UK, 1991; and G. E. Leblanc, R. A. Secco, and M. Kostic, "Viscosity Measurement," chap. 30 in *Measurement, Instrumentation, and Sensors Handbook*, ed. Webster, CRC Press, Boca Raton, Fla., 1999. The Stabinger method allows simultaneous measurement of viscosity and density [American Society for Testing and Materials, ASTM D7042-04 (2005)].

### INTERFACIAL TENSION

Typical values of interfacial tension are listed in Tables 15-6 and 15-7. Refer to the references listed in these tables for the full data sets and for data on other mixtures. Table 15-6 shows typical values for organic + water binary mixtures. Table 15-7 shows the strong effect of the addition of a third component. Also, R. E. Treybal's classic plot of interfacial tension versus mutual solubility is given in Fig. 15-21. This information can be helpful in assessing whether interfacial tension is likely to be low, moderate, or high for a new application. However, for design purposes, interfacial tension should be measured by using representative feed and solvent because even small amounts of surface-active impurities can significantly impact the result.

Methods used to measure interfacial tension are reviewed by J. Drelich, Ch. Fang, and C. L. White ["Measurement of Interfacial Tension in Fluid-Fluid Systems," in *Encyclopedia of Surface and Colloid Science*, Marcel Dekker, New York, 2002, pp. 3152–3166]. Also see D. Megias-Alguacil, P. Fischer, and E. J. Windhab, *Chem. Eng. Sci.* **61:** 1386–1394 (2006). One class of methods derives interfacial tension values from measurement of the shape, contact angle, or volume of a drop suspended in a second liquid. These methods include the pendant drop method (a drop of heavy liquid hangs from a vertically mounted capillary tube immersed in the light liquid), the sessile drop method (a drop of heavy liquid lies on a plate immersed in the light liquid), and the spinning drop method (a drop of one liquid is suspended in a rotating tube filled with the second liquid). The sessile drop method is particularly useful for following the change in interfacial tension when surfactants or macromolecules accumulate at the surface of the drop. The spinning drop method is well suited to measuring low interfacial tensions. Another class of methods derives interfacial tension values from measurement of the force required to detach a ring of wire (Du Noüy's method), or a plate of glass or platinum foil (the Wilhelmy method), from the liquid-liquid interface. The ring or plate must be extremely clean. For the commonly used ring-pull method, the wire is usually flamed before the experiment and must be kept very horizontal and located exactly at the interface of the two liquids.

**TABLE 15-6 Typical Interfacial Tensions for Different Classes of Organic + Water Binary Mixtures at 20 to 25°C**

| Class of organic compounds | Interfacial tension, dyn/cm |
|---|---|
| Alkanes ($C_5$–$C_{12}$) | 45–53 |
| Halogenated alkanes ($C_1$–$C_4$) | 30–40 |
| Halogenated aromatics (single ring) | 35–40 |
| Aromatics (single ring) | 30–40 |
| Mononitro aromatics (single ring) | 25–28 |
| Ethers ($C_4$–$C_6$) | 10–30 |
| Esters ($C_4$–$C_6$) | 10–20 |
| Ketones ($C_4$–$C_8$) | 5–15 |
| Organic acids ($C_5$–$C_{12}$) | 3–15 |
| Aniline | 6–7 |
| Alcohols ($C_4$–$C_8$) | 2–8 |

For an initial assessment, an approximate value for the interfacial tension may be obtained, at least in principle, from knowledge of the maximum size of drops that can persist in a dispersion at equilibrium and without agitation. For example, if it is possible to determine drop size from a photograph of the dispersion of interest at quiescent conditions, then an estimate of interfacial tension may be obtained from the balance between interfacial tension and buoyancy forces

$$\sigma \approx d_{\max}^2 \, \Delta \rho g \tag{15-27}$$

where $d_{\max}$ is the maximum drop diameter. Antonov's rule states that interfacial tension between two liquids is approximately equal to the difference in their liquid-air surface tensions measured at the same conditions. For an organic + water system,

$$\sigma \approx \left| \sigma_{w(o)} - \sigma_{o(w)} \right| \tag{15-28}$$

where $\sigma_{w(o)}$ represents the surface tension of the water saturated with the organic and $\sigma_{o(w)}$ represents the surface tension of organic saturated with water.

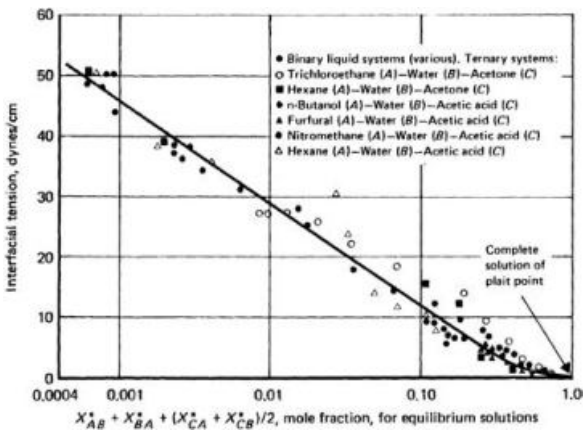

**FIG. 15-21** Correlation of interfacial tension with mutual solubility for binary and ternary two-liquid-phase mixtures. [*Reprinted from Treybal,* Liquid Extraction, *2d ed., McGraw-Hill, New York, 1963. Copyright 1963 McGraw-Hill, Inc.*]

Measurements of interfacial tension are not always feasible, and calculation methods are sometimes used. The results are least reliable for interfacial tensions below about 10 dyn/cm ($10^{-2}$ N/m). A commonly used empirical correlation of interfacial tension and mutual solubilities is given by D. J. Donahue and F. E. Bartell [*J. Phys. Chem.* **56:** 480–484 (1952)]:

$$\sigma = -3.33 - 7.21 \ln (x_1'' + x_2') \tag{15-29}$$

where $\sigma$ = interfacial tension, dyn/cm ($10^{-3}$ N/m)
$x_1''$ = mole fraction solubility of organic in aqueous phase
$x_2'$ = mole fraction solubility of water in organic phase

R. E. Treybal [*Liquid Extraction*, 2d ed., McGraw-Hill, New York, 1963] modified Eq. (15-29) to expand its application to ternary systems:

$$\sigma = -5.0 - 7.355 \ln [x_1'' + x_2' + 0.5 (x_3' + x_3'')] \tag{15-30}$$

where $\sigma$ = interfacial tension, dyn/cm ($10^{-3}$ N/m)
$x_3''$ = mole fraction solute in aqueous phase
$x_3'$ = mole fraction solute in organic phase

The results are plotted in Fig. 15-21. Also, J. Fu, B. Li, and C. Wang [*Chem. Eng. Sci.* **41**(10): 2673–2679 (1986)] derived a relationship for ternary mixtures:

$$\sigma = \frac{0.9414 RTz}{(A_o \exp z)(x_1'' q_1 + x_2' q_2 + x_{3r} q_3)} \tag{15-31}$$

$$z = -\ln (x_1'' + x_2' + x_{3r}) \tag{15-32}$$

where $\sigma$ = interfacial tension, dyn/cm ($10^{-3}$ N/m)
$R$ = ideal gas law constant ($8.314 \times 10^7$ dyn cm/gmol-K)
$T$ = absolute temperature (K)
$x_2''$ = solubility of extract phase in raffinate phase (mole fraction)
$x_2'$ = solubility of raffinate phase in extract phase (mole fraction)
$x_{3r}$ = mole fraction of solute 3 in bulk phase richest in solute 3
$A_o$ = van der Waals area of standard segment ($2.5 \times 10^9$ cm$^2$/gmol)
$q_i$ = van der Waals surface area ratio, usually calculated from UNIQUAC

Newer methods involve modeling of fundamental intermolecular interactions underlying both mutual solubility and interfacial tension. See the methods of B. Li and J. Fu [*Fluid Phase Equilibr.* **81:** 129–152 (1992)]; P. Wang and A. Anderko [*Ind. Eng. Chem. Res.* **52**(20): 6822–6840 (2013)]; and M. P. Andersson et al. [*J. Chem. Theory Comput.* **10**(8): 3401–3408 (2014)].

## HOLDUP, SAUTER MEAN DIAMETER, AND INTERFACIAL AREA

Most liquid-liquid extractors are designed to generate drops of one liquid suspended in the other rather than liquid films. The volume fraction of the dispersed phase (or holdup) within the extractor is defined as

$$\phi_d = \frac{\text{volume of dispersed phase}}{\text{total contacting volume}} \tag{15-33}$$

where the total contacting volume is the volume within the extractor minus the volume of any internals such as impellers, packing, or trays. A distribution of drop sizes will be present. The Sauter mean drop diameter $d_{32}$ represents a volume to surface-area average diameter

$$d_{32} = \frac{\sum_{i=1}^{n} N_i d_i^3}{\sum_{i=1}^{n} N_i d_i^2} \tag{15-34}$$

where $N_i$ is the number of drops with diameter $d_i$. The Sauter mean diameter often is used in the analysis and modeling of extractor performance because it is directly related to holdup and interfacial area (assuming spherical drops). It is calculated from the total dispersed volume divided by total interfacial area, and often it is expressed in the form

$$d_{32} = \frac{6\varepsilon\phi_d}{a} \tag{15-35}$$

where $a$ is interfacial area per unit volume and ε is the void fraction within the extractor, that is, the fraction of internal volume not occupied by any packing, trays, and so on. In the remainder of Sec. 15, the Sauter mean diameter is denoted simply by $d_p$. In the design of extraction equipment, Eq. (15-35) often is used to calculate interfacial area from estimates of drop size and holdup.

Much less is known about the actual distribution of drop sizes existing within liquid-liquid extractors, particularly at high holdup and as a function of agitation intensity (if agitation is used) and location within the extractor. For a review, see A. Kumar and S. Hartland, chap. 17 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994. Experimental methods used to measure drop size distribution include the use of a high-speed video camera [Ribeiro, M. M. M., et al., *Chem. Eng. J.* **97:** 173–182 (2004)], real-time optical measurements [Ritter, J., and M. Kraume, *Chem. Eng. Technol.* **23**(7): 579–581 (2000)], and phase-Doppler anemometry [Lohner, H., K. Bauckhage, and E. H. Schombacher, *Chem. Eng. Technol.* **21**(4): 337–341 (1998); and Willie, M., G. Langer, and U. Werner, *Chem. Eng. Technol.* **24**(5): 475–479 (2001)].

## FACTORS AFFECTING WHICH PHASE IS DISPERSED

Consider mixing a batch of two liquid phases in a stirred tank. The minority phase generally will be the dispersed phase whenever the ratio of minority to majority volume fractions, or phase ratio, is less than about 0.5 (equivalent to a dispersed-phase volume fraction or holdup less than 0.33). For phase ratios between 0.5 and about 2, a region called the ambivalent range, the phase that becomes dispersed is determined in large part by the protocol used to create the dispersion. For example, pouring liquid A into a stirred tank already containing liquid B will tend to create a dispersion of A suspended in B, as long as agitation is maintained. When more of the dispersed-phase material is added to the system, the population density of dispersed drops will increase and eventually reach a point where the drops are so close together they coalesce and the phases become inverted, that is, the formerly dispersed phase becomes the continuous phase. In the ambivalent range, a sudden increase in the agitation intensity also can trigger phase inversion by increasing the number of drop-to-drop collisions. Once phase inversion occurs, it is not easily reversed because the new condition corresponds to a more stable configuration.

This phase behavior may be roughly correlated in terms of light and heavy phase properties including relative density and viscosity as follows:

$$\chi = \frac{\phi_L}{\phi_H}\left(\frac{\rho_L\mu_H}{\rho_H\mu_L}\right)^{0.3} = \frac{\phi_L}{1-\phi_L}\left(\frac{\rho_L\mu_H}{\rho_H\mu_L}\right)^{0.3} \tag{15-36}$$

where $\chi < 0.3$ light phase always dispersed
$\chi = 0.3$–$0.5$ light phase probably dispersed
$\chi = 0.5$–$2.0$ either phase can be dispersed, and phase inversion may occur
$\chi = 2.0$–$3.3$ heavy phase probably dispersed
$\chi > 3.3$ heavy phase always dispersed

The symbol ϕ denotes the volume fraction of light ($L$) and heavy ($H$) phases existing within the vessel. Equation (15-36) is taken from the expression recommended by W. B. Hooper [Sec. 1.11 in *Handbook of Separation Techniques for Chemical Engineers,* 3d ed., ed. P. A. Schweitzer, McGraw-Hill, New York, 1997] and L. J. Jacobs and W. R. Penney [chap. 3 in *Handbook of Separation Process Technology*, ed. R. W. Rousseau, Wiley, New York, 1987] for design of continuous decanters. It is based on the dispersed-phase data of A. H. Selker and C. A. Sleicher [*Can. J. Chem. Eng.* **43:** 298–301 (1965)].

Equation (15-36) should apply to continuously fed extraction columns and other continuous extractors as well as batch vessels. The equation is expressed here in terms of volume fractions $\phi_L/\phi_H$ existing within the vessel, not volumetric flow rates of each phase entering the vessel $Q_L/Q_H$. The ratio of volume fractions within a continuously fed vessel can be very different from $Q_L/Q_H$—primarily because buoyancy allows the dispersed-phase drops to travel rapidly through the continuous phase relative to the average dispersed-phase superficial velocity. For example, a continuously fed extraction column can be designed to operate with either phase being the dispersed phase, with the main liquid-liquid interface controlled at the top of the column (for a light-phase dispersed system) or at the bottom (for a heavy-phase dispersed system). As the dispersed-to-continuous phase ratio within the column is increased, through either changes in operating variables or changes in the design of the internals, a point may be reached where the population density or holdup of dispersed drops is too large and phase inversion occurs. In the absence of stabilizing surfactants, the point of phase inversion should correspond roughly to the same general phase-ratio rules given in Eq. (15-36), with the exact conditions at which phase inversion occurs depending upon agitation intensity (if used) and the geometry of any internals (baffles, packing, trays, and so on). Certain extractors such as sieve tray columns often are designed to disperse the majority flowing phase. In extreme cases, the ratio $Q_d/Q_c$ (where $d$ and $c$ represent dispersed and continuous phases) may be as high as 50, and the continuous phase may be nearly stagnant with a superficial velocity as low as 0.02 cm/s; yet the phase ratio within the extractor can be controlled within the guidelines needed to avoid phase inversion [approximated by Eq. (15-36)].

Dispersion stability also can be affected by the presence of fine solids or gas bubbles as well as surfactants. For additional discussion of factors affecting which phase is dispersed, see M. A. Norato, L. L. Tsouris, and C. Tavlarides, *Can. J. Chem. Eng.* **76:** 486–494 (1998); and A. W. Pacek et al., *AIChE J.* **40**(12): 1940–1949 (1994). For a given application, the precise conditions that lead to phase inversion must be determined by experiment. For organic + water dispersions, experimental determination may be facilitated by measuring the conductivity of the mixture. Conductivity normally will be significantly higher when water is in the continuous phase [Gilchrist, A., et al., *Chem. Eng. Sci.* **44**(10): 2381–2384 (1989)]. Another method involves monitoring the dynamics of phase inversion by using a stereo microscope and video camera [Pacek, A. W., et al., *AIChE J.* **40**(12): 1940–1949 (1994)].

## SIZE OF DISPERSED DROPS

In nonagitated (static) extractors, drops are formed by flow through small holes in sieve plates or inlet distributor pipes. The maximum size of drops issuing from the holes is determined not by the hole size but primarily by the balance between buoyancy and interfacial tension forces acting on

the stream or jet emerging from the hole. Neglecting any viscosity effects (i.e., assuming low dispersed-phase viscosity), the maximum drop size is proportional to the square root of interfacial tension σ divided by density difference Δρ:

$$d_{\max} = (\text{const})\sqrt{\frac{\sigma}{\Delta\rho\, g}} \quad \text{for static extractors} \tag{15-37}$$

The proportionality constant typically is close to unity [Seibert, A. F., and J. R. Fair, *Ind. Eng. Chem. Res.* **27**(3): 470–481 (1988)]. Note that Eq. (15-37) indicates the maximum stable drop diameter and not the Sauter mean diameter, although the two are proportionally related and may be close in value. Smaller drops may be formed at the distributor due to jetting of the inlet liquid through the distributor holes or by mechanical pulsation of the liquid inside the distributor [Koch, J., and A. Vogelpohl, *Chem. Eng. Technol.* **24**(12): 1245–1248 (2001)]. In static extractors, hydrodynamic stresses within the main body of the extractor away from the distributor are small and normally not sufficient to cause significant drop breakage as drops flow through the extractor, although small drops may collide and coalesce into larger drops. Some authors report a small amount of drop breakage in packed columns due to collisions with packing materials [Mao, Z.-Q., J. C. Godfrey, and M. J. Slater, *Chem. Eng. Technol.* **18:** 33–40 (1995)]. Additional discussion is given in the subsection Static Extraction Columns under Liquid-Liquid Extraction Equipment.

In agitated extractors, drop size is determined by the equilibrium established between drop breakage and coalescence rates occurring within the extractor. Breakage is due to turbulent stresses caused by the agitator, so it is mainly confined to the vicinity of the agitator. Drop coalescence, however, can happen anywhere in the vessel where drops can come into close proximity with one another. Dispersed drops will begin to break into smaller droplets when turbulent stresses exceed the stabilizing forces of interfacial tension and liquid viscosity. A. N. Kolmogorov [*Dokl. Akad. Nauk* **66:** 825–828 (1949)] and J. O. Hinze [*AIChE J.* **1**(3): 289–295 (1955)] developed expressions for the maximum size of drops in an agitated liquid-liquid dispersion. Their results can be expressed as follows:

$$d_{\max} = (\text{const})\left(\frac{\sigma}{\rho_c}\right)^{3/5}\left(\frac{P}{\mathcal{V}}\right)^{-2/5} \quad \text{for agitated extractors} \tag{15-38}$$

where $P/\mathcal{V}$ is the rate of mechanical energy dissipation (or power $P$) input to the dispersion per unit volume $\mathcal{V}$. Equation (15-38) assumes dispersed-phase holdup is low. It also assumes viscous forces that resist breakage can be neglected, a valid assumption for water and typical low- to moderate-viscosity organic solvents. Wang and Calabrese discuss how to determine when viscous resistance to breakage becomes important and show that this depends upon interfacial tension as well as dispersed-phase viscosity [Wang, C. Y., and R. V. Calabrese, *AIChE J.* **32**(4): 667–676 (1986)]. Equation (15-38) can be restated as

$$\frac{d_{\max}}{D_i} \propto \text{We}^{-3/5} \tag{15-39}$$

where We is a dimensionless Weber number (disruptive shear stress/cohesive interfacial tension) and $D_i$ is a characteristic diameter. For applications involving the use of rotating impellers, $D_i$ is the impeller diameter and the appropriate Weber number is $\text{We} = \rho_c\omega^2 D_i^3/\sigma$, where ω is the impeller speed (in rotations per unit time). For static mixers, $D_i = D_{sm}$ and $\text{We} = \rho_c V_{sm}^2 D_{sm}/\sigma$, where $D_{sm}$ is the static mixer pipe diameter and $V_{sm}$ is the superficial liquid velocity (entrance velocity). A variety of drop size models derived for various mixers and operating conditions have been tabulated by D. E. Leng and R. V. Calabrese [chap. 12 in *Handbook of Industrial Mixing*, ed. E. L. Paul, V. A. Atiemo-Obeng, and S. M. Kresta, Wiley, New York, 2004, pp. 669–675]. Also see additional discussion by Leng and Calabrese ["Immiscible Liquid-Liquid Systems," chap. 12 in *Advances in Industrial Mixing*, ed. S. M. Kresta et al., Wiley, New York, 2015] and by M. I. I. Z. Abidin, A. A. A. Raman, and M. I. M. Nor [*AIChE J.* **61**(4): 1129–1145 (2015)].

Equation (15-39) represents a limiting operating regime where the rate of drop breakage dominates performance and the coalescence rate can be neglected. Drop coalescence requires that two drops collide, and the coalescence rate increases with increasing holdup due to greater opportunity for drop-drop collisions. For agitated systems with fast coalescence at high holdup, that is, when drop coalescence dominates, drop size appears best correlated by an expression of the form $d_p/D \propto \text{We}^{-n}$, where $n$ varies between 0.35 and 0.45 [A. W. Pacek, C. C. Man, and A. W. Nienow, *Chem. Eng. Sci.* **53**(11): 2005–2011 (1998); and M. Kraume, A. Gabler, and K. Schulze, *Chem. Eng. Technol.* **27**(3): 330–334 (2004)].

When two drops first come into contact in the process of coalescing, a film of continuous phase becomes trapped between them. The film is compressed at the point of encounter until it drains away and the two drops can merge. Decreasing the viscosity of the continuous phase, by heating or by addition of a low-viscosity diluent, may promote drop coalescence by increasing the rate of film drainage. Surface-active impurities or surfactants, when present, also can affect the coalescence rate by accumulating at the surface of the drop. Surfactants tend to stabilize the film and reduce coalescence rates. Fine solid particles that are wetted by the continuous phase tend to slow film drainage, also reducing the rate of drop coalescence.

A number of semiempirical drop size data correlations have been developed for different types of extractors (static and agitated), including a term for holdup. See A. Kumar and S. Hartland, *Ind. Eng. Chem. Res.* **35**(8): 2682–2695 (1996); and A. Kumar and S. Hartland, chap. 17 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994. These equations predict a characteristic drop size. They do not provide information about the drop size distribution or the minimum drop size. For discussion of minimum drop size, see G. Zhou and S. M. Kresta, *Chem. Eng. Sci.* **53**(11): 2063–2079 (1998).

## STABILITY OF LIQUID-LIQUID DISPERSIONS

In designing a liquid-liquid extraction process, normally the goal is to generate an unstable dispersion that provides reasonably high interfacial area for good mass transfer during extraction and yet is easily broken to allow rapid liquid-liquid phase separation after extraction. Given enough time, most dispersions will break on standing. Often this process occurs in two distinct periods. The first is a relatively short initial period or primary break during which an interface forms between two liquid layers, one or both of which remain cloudy or turbid. This is followed by a longer period or secondary break during which the liquid layers become clarified. During the primary break, the larger drops migrate to the interface where they accumulate and begin to coalesce. If the coalescence rate is relatively slow compared to the rate at which drops rise or fall to the interface, then a layer of coalescing drops or *dispersion band* will form at the interface. The initial interface can form within a few minutes or less for drop sizes on the order of 100 to 1000 μm (0.1 to 1 mm), as in a water + toluene system, for example. When the drop size distribution in the feed dispersion is wide, smaller droplets remain suspended in one or both phases. Longer residence times are then required to break this secondary dispersion. In extreme cases, the secondary dispersion can take days or even longer to break.

When a dispersion requires a long time to break, the presence of surfactant-like impurities may be a contributing factor. Surfactants are molecules with a hydrophobic end (such as a long hydrocarbon chain) and a hydrophilic end (such as an ionic group or oxygen-containing short chain). Surfactants stabilize droplets by forming an adsorbed film at the interface and by introducing electrical repulsions between drops [Tcholakova, S., N. D. Denkov, and T. Danner, *Langmuir* **20**(18): 7444–7458 (2004)]. Both effects can interfere with drop coalescence. Surfactants also decrease the interfacial tension of the system. As more surfactant is introduced into a solution, the concentration of free surfactant molecules in the bulk liquid increases and reaches a plateau called the critical micelle concentration. At this point, any excess molecules begin forming aggregates with other surfactant molecules at the interface of the two liquids to minimize interaction with the continuous phase. The dispersed phase is then trapped inside the micelles. As more surfactant is added to the mixture, more micelles can form, and in most cases the droplets become smaller to maximize interfacial area. In theory, the maximum volume fraction of the dispersed phase should be limited to 0.74 due to the close packing density of spheres; but in practice much higher values are possible when the micelles change to other structures of different geometries such as a mix of small drops among larger ones and nonspherical shapes.

Emulsions are broken by changing conditions to promote drop coalescence, either by disrupting the film formed at the interface between adjacent drops or by interfering with the electrical forces that stabilize the drops. Water droplets usually are positively charged while oil droplets are negatively charged. Physical techniques used to break emulsions include heating (including application of microwave radiation), freezing and thawing, adsorption of surface-active compounds, filtration of fine particles that stabilize films between drops, and application of an electric field. Heating can be particularly effective for nonionic surfactants, because heating disrupts hydrogen bonding interactions that contribute to micelle stability. Chemical techniques include adding a salt to alter the charges around drops, changing the pH of the system, and adding a de-emulsifier compound (or even another type of surfactant) to interact with and alter the surfactant layer. Ionic surfactants are particularly sensitive to change in pH. Additives include bases and acids, aluminum or ferric salts, chelating agents, charged polymers (polyamines or polyacrylates), polyalcohols,

silicone oils, various fatty acid esters and fatty alcohols, as well as adsorbents such as clay and lime. For further discussion, see V. N. Rajaković and D. Skala, *Sep. Purif. Technol.* **49**(2): 192–196 (2006); and G. R. Alther, *Chem. Eng. Magazine* **104**(3): 82–88 (1998). Chemical additives need to be used in sufficiently small concentrations so as not to interfere with other operations in the overall process or product quality. General information is available in L. L. Schramm, *Emulsions, Foams, and Suspensions*, Wiley-VCH, New York, 2005; P. Becher, *Emulsions: Theory and Practice*, 3d ed., American Chemical Society, Washington, DC, 2001; and B. P. Binks, *Modern Aspects of Emulsion Science*, Royal Society of Chemistry, London, 1998.

### EFFECT OF SOLID-SURFACE WETTABILITY

The stability of a dispersion also may depend upon the surface properties of the container or equipment used to process the dispersion, because the walls of the vessel, or more importantly, the surfaces of any internal structures, may promote drop coalescence. In a liquid-liquid extractor or a liquid-liquid phase separator, the wetting of a solid surface by a liquid is a function of the interfacial tensions of both the liquid-solid and the liquid-liquid interfaces. For dispersed drops with low liquid-solid interfacial tension, the drops tend to spread out into films when in contact with the solid surface. In general, an aqueous liquid will tend to wet a metal or ceramic surface better than an organic liquid will, and an organic liquid will tend to wet a polymer surface better than an aqueous liquid will. However, there are many exceptions. R. F. Strigle [*Packed Tower Design and Applications*, 2d ed., chap. 11, Gulf, Houston, 1994] indicates that for packed extractors, metal packings may be wetted by either an aqueous or an organic solvent depending upon the initial exposure of the metal surface (whether the unit is started up filled with the aqueous phase or the organic phase). In general, however, metals tend to be preferentially wetted by an aqueous phase. Also, it is not uncommon for materials of construction to acquire different surface properties after aging in service due to adsorption of impurities, corrosion, or fouling. This aging effect often is observed for polymer materials. Small-scale lab tests are recommended to determine these wetting effects. For detailed discussion of wettability and its characterization, see *Contact Angle, Wettability, and Adhesion*, vols. 1–3, ed. K. L. Mittal, Wiley, New York, 2013; and J. C. Berg, ed., *Wettability*, Marcel Dekker, New York, 1993. Recently, new experimental polymer materials having specific surface roughness characteristics that allow design of specific wettability characteristics have been reported [Kota, A. K., et al., *Nat. Commun.* **3**(8): 1025 (2012); and G. Kwon et al., *MRS Commun.* **5**(3): 475–494 (2015)]. In any new application, the potential for change in wettability due to aging or fouling in service will need careful evaluation.

In liquid-liquid extraction equipment, the internals generally should be preferentially wetted by the continuous phase in order to maintain dispersed-phase drops with a high population density (high holdup). If the dispersed phase preferentially wets the internals, then drops may coalescence on contact with these surfaces, and this can result in loss of interfacial area for mass transfer and even in the formation of rivulets that flow along the internals. In an agitated extractor, this tendency may be mitigated somewhat, if needed, by increasing the agitation intensity.

### MARANGONI INSTABILITIES

Numerous studies have shown that mass transfer of solute from one phase to the other can alter the behavior of a liquid-liquid dispersion because of interfacial tension gradients that form along the surface of a dispersed drop. These gradients can induce interfacial turbulence and circulation within drops, resulting in enhanced mass-transfer rates. For background on these phenomena, known as Maranoni instabilities, see C. V. Sternling and L. E. Scriven, *AIChE J.* **5**(4): 514–523 (1959); L. E. Scriven and C. V. Sternling, *Nature* **187:** 186–188 (1960); and Z.-S. Mao and J. Chen, *Chem. Eng. Sci.* **59:** 1815–1828 (2004).

The direction of mass transfer can alter the magnitude of Marangoni instabilities, affecting the rate of drop-drop coalescence and the resulting drop size. For example, A. F. Seibert and J. R. Fair [*Ind. Eng. Chem. Res.* **27**(3): 470–481 (1988)] showed that mass transfer out of a drop into the continuous phase can promote coalescence and production of larger dispersed drops. A. Kumar and S. Hartland [*Ind. Eng. Chem. Res.* **35**(8): 2682–2695 (1996)] suggest that transfer of solute from the dispersed to the continuous phase ($d \rightarrow c$) tends to produce larger drops because the concentration of transferring solute in the draining film between two approaching drops is higher than that in the surrounding continuous liquid. This lowers the local interfacial tension and accelerates drainage, thus promoting drop coalescence. For mass transfer in the opposite direction ($c \rightarrow d$), smaller drops tend to form because the solute concentration in the draining film between drops is relatively low. The magnitude of these effects depends upon system properties, the surface activity of the transferring solute, and the degree of mass transfer. Unless the solute is unusually surface-active, the effect will be small. For more information, see C. Gourdon, G. Casamatta, and G. Muratet, chap. 7 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994; E. S. Perez de Oritz, chap. 3, "Marangoni Phenomena," in *Science and Practice of Liquid-Liquid Extraction,* vol. 1, ed. J. D. Thornton, Oxford University Press, Oxford, UK, 1992; and A. Grahn, *Chem. Eng. Sci.* **61:** 3586–3592 (2006).

## PROCESS FUNDAMENTALS AND BASIC CALCULATION METHODS

**General References:** See Sec. 5, Heat and Mass Transfer, as well as J. D. Seader, E. J. Henley, and D. K. Roper, *Separation Process Principles with Applications Using Process Simulators*, 4th ed., Wiley, New York, 2016; Wankat, P. C., *Separation Process Engineering,* 3d ed., Prentice-Hall, Upper Saddle River, NJ, 2012; Godfrey, J. C., and M. J. Slater, *Liquid-Liquid Extraction Equipment*, Wiley, New York, 1994; Thornton, J. D., ed., *Science and Practice of Liquid-Liquid Extraction*, vol. 1, Oxford University Press, Oxford, UK, 1992; Wankat, P. Baird, and C. Hanson, eds., *Handbook of Solvent Extraction*, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991; King, C. J., *Separation Processes*, 2d ed., McGraw-Hill, New York, 1980, and Dover, 2013; Brian, P. L. T., *Staged Cascades in Chemical Processing*, Prentice-Hall, Englewood Cliffs, NJ, 1972; Geankoplis, C. J., *Mass Transport Phenomena*, Holt, Rinehart and Winston, New York, 1972; and Treybal, R. E., *Liquid Extraction*, 2d ed., McGraw-Hill, New York, 1963.

The fundamental mechanisms for solute mass transfer in liquid-liquid extraction involve molecular diffusion from one liquid to the other driven by a deviation from equilibrium plus convective (or advective) mass transfer due to bulk flow of the two liquids. When a liquid feed is contacted with a liquid solvent, solute transfers from the interior of the feed across a liquid-liquid interface into the interior of the solvent. This occurs while solute moves with the bulk flow of the two liquids. Given sufficient contacting time, transfer of solute from one liquid to the other will continue until the solute's chemical potential is the same in both liquids and equilibrium is achieved. The bulk flow of liquids determines residence time in the equipment and thus the amount of time available for solute diffusion. It also can affect properties of the dispersion that impact mass-transfer resistance (including drop size distribution, population density or holdup, and interfacial area).

The calculation methods used to quantify extraction processes generally involve either the calculation of the number of theoretical stages, with the application of an operating efficiency to reflect mass-transfer resistance, or calculations based on consideration of mass-transfer rates using expressions related in some way to molecular diffusion, interfacial area, and bulk flow rates. One must carefully consider flow rates, even when using the theoretical stage approach, because flow rates can have a dramatic impact on efficiency (by affecting residence time, etc.). Theoretical-stage calculations commonly are used to characterize separation difficulty regardless of the type of extractor to be used. They are also used for extractor design purposes, although for this purpose they generally should be reserved for single-stage contactors or mixer-settler cascades involving discrete stages, or for other equipment where discrete contacting zones exist, such as in a sieve tray column. Rate-based models most often are applied to differential-type contactors that lack discrete contacting stages, to staged contactors with low stage efficiencies, or to processes with extraction factors greater than about 3, indicating a mass-transfer-limited operating regime. Differential-type contactors operating at extraction factors less than 3 also may be adequately modeled with theoretical stages because these contactors operate reasonably close to equilibrium.

With either theoretical stage models or rate-based models, appropriate values for model parameters typically are determined by fitting data generated by using laboratory or pilot-plant experiments, or by analysis of the

performance of large-scale commercial units. In certain cases, parameter values have been correlated as a function of physical properties and operating conditions for specific types of equipment using model systems. The reliability of the resulting correlations is generally limited to applications very similar to those used to develop the correlations. Also, most calculation methods have been developed for continuous steady-state operation. The dynamic modeling of extraction processes is discussed elsewhere [Mohanty, S., *Rev. Chem. Eng.* **16**(3): 199 (2000); Weinstein, O., R. Semiat, and D. R. Lewin, *Chem. Eng. Sci.* **53**(2): 325–339 (1998); and Steiner, L., and S. Hartland, chap. 7 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991].

The calculation methods used for designing standard extraction operations are analogous in many respects to methods used to design absorbers and strippers in vapor-liquid and gas-liquid contacting such as those described by J. R. Ortiz-Del Castillo, et al. [*Ind. Eng. Chem. Res.* **39**(3): 731–739 (2000)] and by A. L. Kohl ["Absorption and Stripping," chap. 6 in *Handbook of Separation Process Technology*, ed. R. W. Rousseau, Wiley-Interscience, New York, 1987]. Unlike in stripping and absorption, however, liquid-liquid extraction always deals with highly nonideal systems; otherwise, only one liquid phase would exist. This nonideality contributes to difficulties in modeling and predicting phase equilibria, liquid-liquid phase behavior (hydraulics), and thus mass transfer. Also, the mass-transfer efficiency of an extractor generally is much less than that observed in distillation, stripping, or absorption equipment. For example, an overall sieve tray efficiency of 70 percent is common in distillation, but it is rare when a sieve tray extractor achieves an overall efficiency greater than 30 percent. The difference arises in part because generation of interfacial area, normally by dispersing drops of one phase in the other, generally is more difficult in liquid-liquid contactors. Unlike in distillation, the formation of liquid films often is purposely avoided; generation of dispersed droplets provides greater interfacial area for mass transfer per unit volume of extractor. (Film formation may be important in extraction applications involving centrifugal contactors or baffle tray extractors, but this is not generally the case.) In certain cases, mass-transfer rates also may be slower compared to those of gas-liquid contactors because the second phase is a liquid instead of a gas, and transport properties in that phase are less favorable. Although mass-transfer efficiency generally is lower, the specific throughput of liquid-liquid extraction equipment (in kilograms of feed processed per hour per unit volume) can be higher than is typical of vapor-liquid contactors, simply because liquids are much denser than vapors.

## THEORETICAL (EQUILIBRIUM) STAGE CALCULATIONS

Calculating the number of theoretical stages is a convenient method used by process designers to evaluate separation difficulty and assess the compromise between the required equipment size (column height or the number of actual stages) and the ratio of solvent rate to feed rate required to achieve the desired separation. In any mass-transfer process, there can be an infinite number of combinations of flow rates, number of stages, and degrees of solute transfer. The optimum is governed by economic considerations. The cost of using a high solvent rate with relatively few stages should be carefully compared with the cost of using taller extraction equipment (or more equipment) capable of achieving more theoretical stages at a reduced solvent rate and operating cost. While the operating cost of an extractor is generally quite low, the operating cost for a solvent recovery distillation tower can be quite high. Another common objective for calculating the number of countercurrent theoretical stages is to evaluate the performance of liquid-liquid extraction test equipment in a pilot plant or to evaluate production equipment in an industrial plant. As mentioned earlier, most liquid-liquid extraction equipment in common use can be designed to achieve the equivalent of 1 to 8 theoretical countercurrent stages, with some designed to achieve 10 to 12 stages.

**McCabe-Thiele Type of Graphical Method** Graphical methods may be used to determine theoretical stages for a ternary system (solute plus feed solvent and extraction solvent) or for a pseudo-ternary with the focus placed on a key solute of interest. Although developed long ago, graphical methods are still valuable today because they help visualize the problem, clearly illustrating pinch points and other design issues not readily apparent by using other techniques. Even with computer simulations, often it is useful to plot the results for a key solute as an aid to analyzing the design. This section briefly reviews the commonly used McCabe-Thiele type of graphical method. More detailed discussions of this and other graphical methods are available elsewhere. For example, see A. F. Seibert, "Extraction and Leaching," chap. 14 in *Chemical Process Equipment: Selection and Design*, 3d ed., ed. J. R. Couper et al., Butterworth-Heinemann, Oxford, UK, 2012; P. C. Wankat, *Separation Process Engineering*, Prentice-Hall, Upper Saddle River, NJ, 2012; and C. J. King, *Separation Processes*, 2d ed., McGraw-Hill, New York, 1980, and Dover, 2013, among others. Also see instructional materials available on the Internet, such as those from the University of Colorado's LearnChemE web site. An example is the discussion of the Hunter-Nash graphical method used for liquid-liquid extractor design (www.colorado.edu/learncheme/separations/HunterHashMethodLLE.html, accessed January 15, 2018).

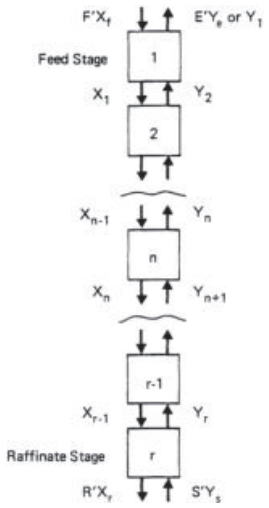

**FIG. 15-22** Countercurrent extraction cascade.

In distillation calculations, the McCabe-Thiele graphical method assumes constant molar vapor and liquid flow rates and allows convenient stepwise calculation with straight operating lines and a curved equilibrium line. A similar concept can be achieved in liquid-liquid extraction by using Bancroft coordinates and expressing flow rates on a solute-free basis, that is, a constant flow rate of feed solvent $F'$ and a constant flow rate of extraction solvent $S'$ through the extractor [T. W. Evans, *Ind. Eng. Chem.* **26**(8): 860–864 (1934)]. The solute concentrations are then given as the mass ratio of solute to feed solvent $X'$ and the mass ratio of solute to extraction solvent $Y'$. These concentrations and coordinates give a straight operating line on an $X'$–$Y'$ diagram for stages 2 through $r - 1$ in Fig. 15-22. The ratio of solute-free extraction solvent to solute-free feed solvent will be constant within the extractor except at the outer stages where unsaturated feed and extraction solvent enter the process. Equilibrium data using these mass ratios have been shown to follow straight-line segments on a log-log plot (see Fig. 15-20), and they will be approximately linear over some composition range on an $X'$–$Y'$ plot. When expressed in terms of Bancroft coordinates, the equilibrium line typically will curve upward at high solute concentrations, as shown in Fig. 15-23.

To illustrate the McCabe-Thiele method, consider the simplified case where feed and extraction solvents are immiscible; that is, mutual solubility is nil. Then the rate of feed solvent alone in the feed stream $F'$ is the same

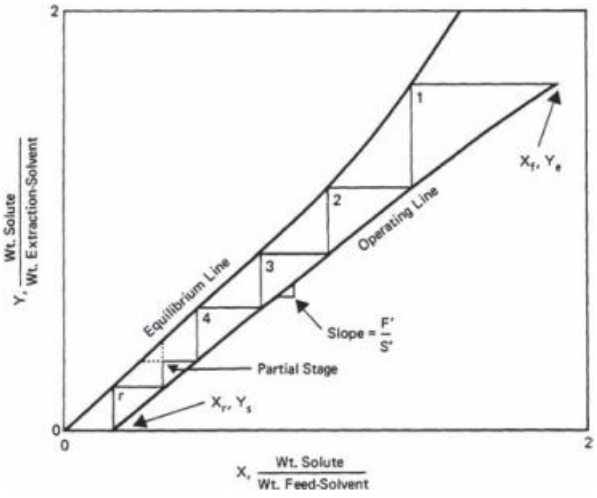

**FIG. 15-23** McCabe-Thiele type of graphical stage calculation using Bancroft coordinates.

as the rate of feed solvent alone in the raffinate stream $R'$. In like manner, the rate of extraction solvent alone is the same in the entering stream $S'$ as in the leaving extract stream $E'$. The ratio of extraction-solvent to feed-solvent flow rates is therefore $S'/F' = E'/R'$. A material balance can be written around the feed end of the extractor down to any stage $n$ (as shown in Fig. 15-22) and then rearranged to a McCabe-Thiele type of operating line with a slope of $F'/S'$:

$$Y'_{n+1} = \frac{F'}{S'} X'_n + \frac{E'Y'_e - F'X'_f}{S'} \tag{15-40}$$

Similarly, the same operating line can be derived from a material balance around the raffinate end of the extractor up to stage $n$:

$$Y'_n = \frac{F'}{S'} X'_{n-1} + \frac{S'Y'_s - R'X'_r}{S'} \tag{15-41}$$

The overall extractor material balance is given by

$$Y'_e = \frac{F'X'_f + S'Y'_s - R'X'_r}{E'} \tag{15-42}$$

The endpoints of the operating line on an $X'$–$Y'$ plot (Fig. 15-23) are the points ($X'_f$, $Y'_s$) and ($X'_f$, $Y'_e$) where $X'$ and $Y'$ are the mass ratios for solute in the feed phase and extract phase, respectively, and subscripts $f$, $r$, $s$, and $e$ denote the feed, raffinate, entering extraction solvent, and leaving extract streams. The number of theoretical stages can then be stepped off graphically as illustrated in Fig. 15-23.

**Kremser-Souders-Brown Theoretical Stage Equation** The Kremser-Souders-Brown (KSB) equation [A. Kremser, *Natl. Petrol. News* **22**(21): 43–49 (1930); and M. Souders and G. G. Brown, *Ind. Eng. Chem.* **24**(5): 519–522 (1932)] provides a way of calculating performance equivalent to that of a McCabe-Thiele type of graphical calculation with straight equilibrium and operating lines. In terms of Bancroft coordinates, the KSB equation may be written

$$N = \frac{\ln\left[\left(\frac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'}\right)\left(1 - \frac{1}{\mathcal{E}}\right) + \frac{1}{\mathcal{E}}\right]}{\ln \mathcal{E}} \qquad \mathcal{E} = m'\frac{S'}{F'}, \mathcal{E} \neq 1 \tag{15-43}$$

where $N$ = number of theoretical stages
$X'_f$ = mass ratio solute to feed solvent in feed entering process (Bancroft coordinates)
$X'_r$ = mass ratio solute to feed solvent in raffinate leaving process
$Y'_s$ = mass ratio solute to extraction solvent in extraction solvent entering process
$\mathcal{E}$ = extraction factor
$m' = dY'/dX'$, local slope of equilibrium line in Bancroft coordinates
$S'$ = mass flow rate of extraction solvent (solute-free basis)
$F'$ = mass flow rate of feed solvent (solute-free units)

Solutions to Eq. (15-43) are shown graphically in Fig. 15-24. The concentration of solute in the extract leaving the process $Y'_e$ is determined from the material balance, as in Eq. (15-42). (Note that other systems of units also may be used here, as long as they are consistently applied.)

Rearranging Eq. (15-43) yields another common form of the KSB equation:

$$\frac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'} = \frac{\mathcal{E}^N - 1/\mathcal{E}}{1 - 1/\mathcal{E}} \qquad \mathcal{E} \neq 1 \tag{15-44}$$

Equations (15-43) and (15-44) can be used whenever $\mathcal{E} > 1$ or $\mathcal{E} < 1$. They cannot be used when $\mathcal{E}$ is exactly equal to unity because this would involve division by zero. When $\mathcal{E} = 1$, the number of theoretical stages is given by

$$N = \frac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'} - 1 \quad \text{for } \mathcal{E} = 1 \tag{15-45}$$

Equation (15-45) may be rewritten

$$\frac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'} = N + 1 \quad \text{for } \mathcal{E} = 1 \tag{15-46}$$

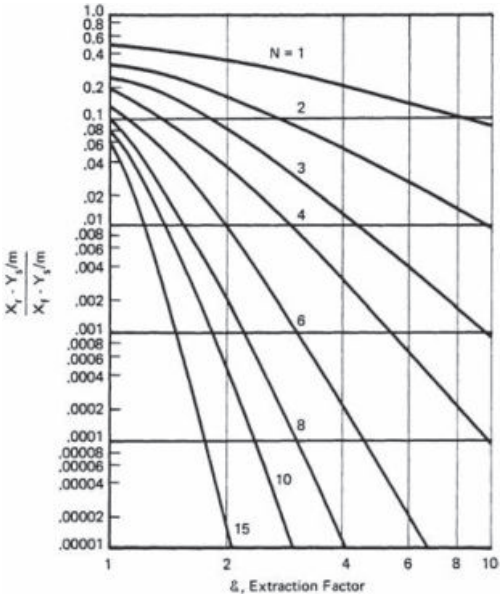

**FIG. 15-24** Graphical solutions to the KSB equation [(Eq. 15-43)].

In the special case where $\mathcal{E} < 1$, the *maximum* performance potential is represented by

$$\left(\frac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'}\right)_{\max} \approx \frac{1}{1 - \mathcal{E}} \quad \text{for } \mathcal{E} < 1 \text{ and large } N \tag{15-47}$$

Equation (15-47) reflects the fact that the carrying capacity of the extract stream limits performance at $\mathcal{E} < 1$, as noted in earlier discussions.

In general, Eqs. (15-43) through (15-47) (and Fig. 15-24) are valid for any concentration range in which equilibrium can be represented by a linear relationship $Y = mX + b$ (written here in general form for any system of units). For applications that involve dilute feeds, the section of the equilibrium line of interest is a straight line that extends through the origin where $Y_i = 0$ at $X_i = 0$. In this case, $b = 0$ and the slope of the equilibrium line is equal to the partition ratio ($m = K$). The KSB equation also may be used to represent a linear segment of the equilibrium curve at higher solute concentrations. In this case, the linear segment is represented by a straight line that does not extend through the origin, and $m$ is the local slope of the equilibrium line, so $b \neq 0$ and $m \neq K$. Furthermore, a series of KSB equations may be used to model a highly curved equilibrium line by dividing the analysis into linear segments and matching concentrations where the segments meet. For equilibrium lines with moderate curvature, an approximate average slope of the equilibrium line may be obtained from the geometric mean of the slopes at low and high solute concentrations:

$$m_{\text{average}} \approx m_{\text{geometric mean}} = \sqrt{m_{\text{low}} m_{\text{high}}} \tag{15-48}$$

As we have noted, other systems of units such as mass fraction and mass flow rates or mole fraction and molar flow rates also may be used with the KSB equation; however, Bancroft coordinates and solute-free mass flow rates are recommended because then the operating line must be linear, and this normally extends the concentration range over which the KSB analysis may be used. It is important to check whether equilibrium can be adequately represented by a straight line over the concentration range of interest. The application of the KSB equation is discussed in the subsection Shortcut Calculations under Calculation Procedures. Additional discussion is given by P. C. Wankat [*Equilibrium Staged Separations*, Prentice-Hall, Englewood Cliffs, NJ, 1988] and by C. J. King [*Separation Processes*, 2d ed., McGraw-Hill, New York, 1980]. To facilitate the use of the KSB equation in computer calculations where the singularity around $\mathcal{E} = 1$ can present difficulties, U. V. Shenoy and D. M. Fraser have proposed an alternative form of the equation [*Chem. Eng. Sci.* **58**(22): 5121–5124 (2003)].

**Stage Efficiency** For a multistage process, the overall stage efficiency is simply the number of theoretical stages divided by the number of actual stages times 100:

$$\xi_o(\%) = \frac{\text{theoretical stages}}{\text{actual stages}} \times 100 \tag{15-49}$$

The fundamental stage efficiency is referred to as the Murphree stage efficiency $\xi_m$. The Murphree efficiency based on the dispersed phase is defined as

$$\xi_{\text{md}} = \frac{C_{d,n+1} - C_{d,n}}{C_{d,n+1} - C_d^*} \tag{15-50}$$

where $C_{d,n+1}$ = concentration of solute $i$ in dispersed phase at stage $n+1$
$C_{d,n}$ = concentration of solute $i$ in dispersed phase at stage $n$
$C_d^*$ = concentration of solute $i$ in dispersed phase, at equilibrium

The overall stage efficiency is related to the Murphree stage efficiency and the extraction factor:

$$\xi_o(\%) = \frac{\ln[1 + \xi_{\text{md}}(\mathcal{E} - 1)]}{\ln \mathcal{E}} \times 100 \tag{15-51}$$

For applications involving extraction of multiple solutes, sometimes the extraction rate and mass-transfer efficiency for each solute are significantly different. In these cases, individual efficiencies will need to be determined for each solute.

Stage efficiencies normally are determined by running miniplant tests to measure performance as a function of process variables such as feed rates, operating temperature, physical properties, impurities, and agitation (if used). A number of data correlations have been developed for various types of mixing equipment. In principle, these can be used in the estimation of mass-transfer rates and stage efficiencies, but in practice reliable design generally requires generation of miniplant data and application of mixing scale-up methods. (See the subsection Mixer-Settler Equipment under Liquid-Liquid Extraction Equipment.)

The overall efficiency of an extraction column also can be expressed as the height equivalent to a theoretical stage (HETS). This is simply the total contacting height $Z_t$ divided by the number of theoretical stages achieved.

$$\text{HETS} = \frac{Z_t}{N} \tag{15-52}$$

The HETS often is used to compare staged contactors with differential contactors.

## RATE-BASED CALCULATIONS

This subsection reviews the basics of Fickian diffusion, the mass-transfer coefficient, and mass-transfer unit approaches to modeling extraction performance. These methods have been used for many years and continue to provide a useful basis for the design of extractors and extraction processes. Additional discussions of these and other rate-based methods are given in the books edited by J. C. Godfrey and M. J. Slater [*Liquid-Liquid Extraction Equipment*, Wiley, New York, 1994] and by J. D. Thornton [*Science and Practice of Liquid-Liquid Extraction*, vol. 1, Oxford University Press, Oxford, UK, 1992]. See R. Taylor and R. Krishna, *Multicomponent Mass Transfer*, Wiley, New York, 1993; and R. Krishna, *Ind. Eng. Chem. Res.* **55**(4): 1053–1063 (2016), for discussion of the Maxwell-Stefan approach to modeling multicomponent diffusion. For discussions of drop breakage and coalescence rates, drop size distributions, and drop population balances, see D. E. Leng and R. V. Calabrese, "Immiscible Liquid-Liquid Systems," chap. 12 in *Advances in Industrial Mixing*, ed. S. M. Kresta et al., Wiley, New York, 2015, and chap. 12 in *Handbook of Industrial Mixing*, ed. E. L. Paul, V. A. Atiemo-Obeng, and S. M. Kresta, Wiley, New York, 2004; and M. I. I. Z. Abidin, A. A. A. Raman, and M. I. H. Nor, *AIChE J.* **61**(4): 1129–1145 (2015). Also see the discussion of general approaches to analyzing dispersed-phase systems given by D. Ramkrishna, A. Sathyagal, and G. Narsimhan [*AIChE J.* **41**(1): 35–44 (1995)]. For discussions of the effect of contaminants on mass-transfer rates, see J. Saien et al., *Ind. Eng. Chem. Res.* **45**(4): 1434–1440 (2006); and A. M. Dehkordi et al., *Ind. Eng. Chem. Res.* **46**(5): 1563–1571 (2007).

**Solute Diffusion and Mass-Transfer Coefficients** For a binary system consisting of components $A$ and $B$, the overall rate of mass transfer of component $A$ with respect to a fixed coordinate is the sum of the rates due to diffusion and bulk flow:

$$N_A = -\mathcal{D}_{AB}\frac{\partial C_A}{\partial z} + N_A\frac{C_A}{C} \tag{15-53}$$

where $N_A$ = flux for component $A$ (moles per unit area per unit time)
$\mathcal{D}_{AB}$ = mutual diffusion coefficient of $A$ into $B$ (area/unit time)
$z$ = dimension or direction of mass transfer (length)
$C$ = total concentration of $A$ and $B$ (mass or mole per unit volume)
$C_A$ = concentration of $A$ (mass or mole per unit volume)

Equation (15-53) is written for steady-state unidirectional diffusion in a quiescent liquid, assuming that the net transfer of component $B$ is negligible. For transfer of component $A$ across an interface or film between two liquids, it may be rewritten in the form

$$N_A = \frac{\mathcal{D}_{AB}}{\Delta z\,(1 - x_A)_m}\left(C_A - C_A^i\right) \tag{15-54}$$

where $(1 - x_A)_m$ = mean mole fraction of component $B$
$C_A^i$ = concentration of component $A$ at interface
$C_A$ = concentration of component $A$ in bulk

For steady-state counter diffusion where $N_A + N_B = 0$, the flux equation simplifies to

$$N_A = \frac{\mathcal{D}_{AB}}{\Delta z}\left(C_A - C_A^i\right) \tag{15-55}$$

The flux also may be written in terms of an individual mass-transfer coefficient $k$

$$N_A = k(C_A - C_A^i) \tag{15-56}$$

where

$$k = \frac{\mathcal{D}_{AB}}{\Delta z(1 - x_A)_m} \tag{15-57}$$

In Eqs. (15-53) to (15-57), the flux is expressed in terms of mass or moles per unit area per unit time, and the concentration driving force is defined in terms of mass or moles per unit volume. The units of the mass-transfer coefficients are then length per unit time. Whenever mass-transfer coefficients are reported, it is important to check how they have been defined (which may vary from our example) and how they were determined; they need to be used in the same way in any subsequent calculations. Additional discussion of mass-transfer coefficients and mass-transfer rate expressions is given in Sec. 5. Also see G. S. Laddha and T. E. Degaleesan, chap. 3 in *Transport Phenomena in Liquid Extraction*, McGraw-Hill, New York, 1978; A. H. P. Skelland, *Diffusional Mass Transfer*, Krieger, Huntington, NY, 1985; A. H. P. Skelland and D. W. Tedder, chap. 7 in *Handbook of Separation Process Technology*, ed. R. W. Rousseau, Wiley, New York, 1987; R. B. Bird, W. E. Stewart, and E. N. Lightfoot, *Transport Phenomena*, 2d ed., Wiley, New York, 2002; and E. L. Cussler, *Diffusion: Mass Transfer in Fluid Systems*, 3d ed., Cambridge, 2009. Available correlations of molecular diffusion coefficients (diffusivities) are discussed in Sec. 5 and in B. E. Poling, J. M. Prausnitz, and J. P. O'Connell, *The Properties of Gases and Liquids*, 5th ed., McGraw-Hill, New York, 2000.

**Mass-Transfer Rate and Overall Mass-Transfer Coefficients** In transferring from one phase to the other, a solute must overcome certain resistances: (1) movement from the bulk of the feed phase to the interface; (2) movement across the interface; and (3) movement from the interface to the bulk of the extract phase, as illustrated in Fig. 15-25. The two-film theory first used to model this process [Lewis, W. K. and W. G. Whitman, *Ind. Eng. Chem.* **16:** 1215–1220 (1924)] assumes that motion in the two phases is negligible near the interface such that the entire resistance to transfer is contained within two laminar films on each side of the interface, and mass transfer occurs by molecular diffusion through these films. The theory further invokes the following simplifying assumptions: (1) The rate of mass transfer within each phase is proportional to the difference in concentration in the bulk liquid and the interface; (2) mass-transfer resistance across the interface itself is negligible, and the phases are in equilibrium at the interface; and (3) steady-state diffusion occurs with negligible holdup of diffusing solute at the interface. Within a liquid-liquid extractor, the rate of steady-state mass transfer between the dispersed phase and the continuous phase (mass or moles per unit time per unit volume of extractor) is then expressed as

$$R_A = \frac{dC}{dt} = k_d a(C_{d,i} - C_d) = k_c a(C_c - C_{c,i}) \tag{15-58}$$

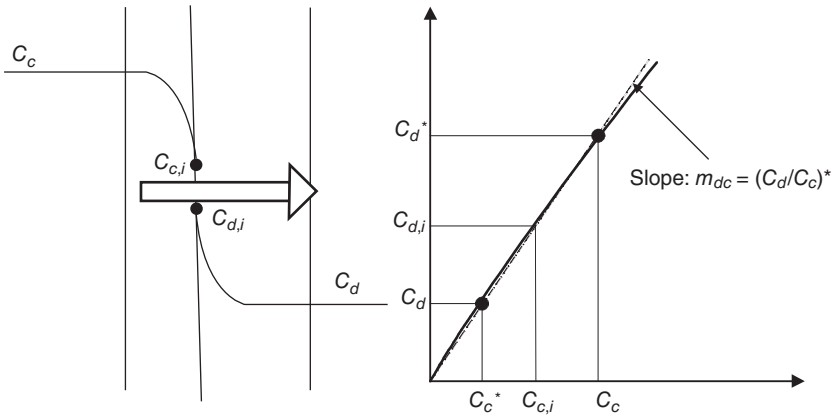

**FIG. 15-25** Two-film mass transfer.

where $C_i$ = concentration at interface (mass or moles per unit volume)
$C$ = concentration in bulk liquid (mass or moles per unit volume)
$k_c$ = continuous-phase mass-transfer coefficient (length per unit time)
$k_d$ = dispersed-phase film mass-transfer coefficient (length per unit time)
$a$ = interfacial area for mass transfer per unit volume of extractor (length$^{-1}$)

Subscripts $d$ and $c$ denote the dispersed and continuous phases. The concentrations at the interface normally are not known, so the rate expression is written in terms of equilibrium concentrations assuming that the rate is proportional to the deviation from equilibrium:

$$R_A = \frac{dC}{dt} = k_{\text{od}} a (C_d^* - C_d) = k_{\text{oc}} a (C_c - C_c^*) \tag{15-59}$$

where the superscript $*$ denotes equilibrium, and $k_{\text{oc}}$ is an overall mass-transfer coefficient given by

$$\frac{1}{k_{\text{oc}}} = \underbrace{\frac{1}{k_c}}_{\substack{\text{Continuous} \\ \text{phase resistance}}} + \underbrace{\frac{1}{m_{\text{dc}}^{\text{vol}} k_d}}_{\substack{\text{Dispersed} \\ \text{phase resistance}}} \tag{15-60}$$

Similarly, the overall mass-transfer coefficient based on the dispersed phase is given by

$$\frac{1}{k_{\text{od}}} = \underbrace{\frac{1}{k_d}}_{\substack{\text{Dispersed} \\ \text{phase resistance}}} + \underbrace{\frac{m_{\text{dc}}^{\text{vol}}}{k_c}}_{\substack{\text{Continuous} \\ \text{phase resistance}}} \tag{15-61}$$

Assuming mass-transfer coefficients are constant over the range of conditions of interest, Eq. (15-59) may be integrated to give

$$\frac{C_c - C_c^*}{C_{c,\text{initial}} - C_c^*} = \exp(-k_{\text{oc}} a \theta) \approx \frac{C_c}{C_{c,\text{initial}}} \tag{15-62}$$

where θ is the contact time. In general, the application of mass-transfer coefficients for extractor design requires knowledge of interfacial area, normally obtained from estimates of average drop size and dispersed-phase holdup, as well as information related to contact time, normally expressed in terms of maximum phase velocities limited by flooding behavior. As we discuss later, a correction for the effect of axial mixing on scale-up also is needed for column extractors.

In Eqs. (15-60) and (15-61), $m_{\text{dc}}^{\text{vol}} = dC_d/dC_c$ is the local slope of the equilibrium line, with the equilibrium concentration of solute in the dispersed phase plotted on the ordinate ($y$ axis), and the equilibrium concentration of solute in the continuous phase plotted on the abscissa ($x$ axis). Note that $m_{\text{dc}}^{\text{vol}}$ is expressed on a volumetric basis (denoted by superscript *vol*), that is, in terms of mass or mole per unit volume, because of the way the mass-transfer coefficients are defined. The mass-transfer coefficients will not necessarily be the same for each solute being extracted, so depending upon the application, mass-transfer coefficients may need to be determined for a range of different solutes. As noted earlier, other systems of units also may be used as long as they are consistently applied.

The mass-transfer coefficient in each film is expected to depend upon molecular diffusivity, and this behavior often is represented by a power-law function $k \propto \mathcal{D}^n$. For two-film theory, $n = 1$ as discussed previously [(Eq. (15-57)]. Subsequent theories introduced by R. W. Higbie [*Trans. AIChE* **31:** 365 (1935)] and by P. V. Dankwerts [*Ind. Eng. Chem.* **43:** 1460–1467 (1951)] allow for surface renewal or penetration of the stagnant film. These theories indicate a 0.5 power-law relationship. Numerous models have been developed since then, where $0.5 < n < 1.0$. The results depend upon such things as whether the dispersed drop is treated as a rigid sphere, as a sphere with internal circulation, or as oscillating drops. These theories are discussed by A. H. P. Skelland ["Interphase Mass Transfer," chap. 2 in *Science and Practice of Liquid-Liquid Extraction*, vol. 1, ed. J. D. Thornton, Oxford University Press, Oxford, UK, 1992].

Mass-transfer coefficients are functions of bulk fluid flow (convective mass transfer), as well as molecular diffusion. In the design of extraction equipment with complex flows, mass-transfer coefficients are determined by experiment and then correlated as a function of flow rates, molecular diffusivity, physical properties, and specific equipment factors such as the geometry of equipment internals and agitation intensity, if mechanical agitation is used. The application of mass-transfer coefficients also requires calculation of interfacial area, or values of $k \times a$ are correlated together. The available theories provide an approximate framework for the data. In most cases, the dominant mass-transfer resistance resides in the feed (raffinate) phase, as the slope of the equilibrium line usually is greater than unity. In that case, the overall mass-transfer coefficient based on the raffinate phase may be written

$$\frac{1}{k_{\text{or}}} = \frac{1}{k_r} + \frac{1}{m_{\text{er}}^{\text{vol}} k_e} \approx \frac{1}{k_r} \quad \text{for large } m_{\text{er}}^{\text{vol}} \tag{15-63}$$

where $m_{\text{er}}^{\text{vol}}$ is defined by the usual convention in terms of concentration in the extract phase over that in the raffinate phase, $m_{\text{dc}}^{\text{vol}} = dC_{i,\text{extract}}/dC_{i,\text{raffinate}}$. This approximation is particularly useful when the extraction solvent is significantly less viscous than the feed liquid, so the solute diffusivity and mass-transfer coefficient in the extract phase are relatively large. For detailed discussion of mass-transfer coefficients, see A. Kumar and S. Hartland, *Trans. Inst. Chem. Eng.* Part A, **77:** 372–384 (1999).

**Mass-Transfer Units** The mass-transfer unit concept follows directly from mass-transfer coefficients. The choice of one or the other as a basis for analyzing a given application often is one of preference. A. P. Colburn [*Ind. Eng. Chem.* **33**(4): 450–467 (1941)] provides an early review of the relationship between the height of a transfer unit and volumetric mass-transfer coefficients ($k_{\text{or}}a$). From a differential material balance and application of the flux equations, the required contacting height of an extraction column $Z_t$ is related to the height of a transfer unit $H_{\text{or}}$ and the number of transfer units $N_{\text{or}}$

$$Z_t = \left( \frac{V_r}{k_{\text{or}} a} \right) \int_{X_{\text{out}}}^{X_{\text{in}}} \frac{dX}{X - X^*} = H_{\text{or}} \times N_{\text{or}} \tag{15-64}$$

where $V_r$ is the velocity of the raffinate phase, $a$ is the interfacial area per unit volume, and the superscript $*$ denotes the equilibrium concentration. Equation (15-64) is written in terms of an overall mass-transfer coefficient based on the raffinate phase for the usual case in which the main resistance

to mass transfer is in the raffinate. The transfer unit model has proved to be a convenient framework for characterizing mass-transfer performance. An advantage of this model compared to the theoretical stage model is the observation that the height of a transfer unit, $H_{or}$, given by the quantity $V_r/k_{or}a$, normally is less affected by changes in process operating variables compared to the height equivalent to a theoretical stage (HETS).

Thus, mass-transfer units are defined as the integral of the differential change in solute concentration divided by the deviation from equilibrium, between the limits of inlet and outlet solute concentrations:

$$N_{or} = \int_{X_{out}}^{X_{in}} \frac{dX}{X - X^*} \tag{15-65}$$

When equilibrium and operating lines are linear, Eq. (15-65) can be expressed as

$$N_{or} = \frac{\ln\left[\left(\frac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'}\right)\left(1 - \frac{1}{\mathcal{E}}\right) + \frac{1}{\mathcal{E}}\right]}{1 - \frac{1}{\mathcal{E}}} \quad \mathcal{E} = m'\frac{S'}{F'}, \mathcal{E} \neq 1 \tag{15-66}$$

where $N_{or}$ is the number of overall mass-transfer units based on the raffinate phase. The units are the same as those used previously for the KSB equation, Eq. (15-43). Rearranging Eq. (15-66) gives

$$\frac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'} = \frac{\exp[N_{or}(1 - 1/\mathcal{E})] - 1/\mathcal{E}}{1 - 1/\mathcal{E}} \tag{15-67}$$

Note that Eq. (15-66) is the same as Eq. (15-43) except in the denominator. Comparing these equations shows that the number of overall raffinate phase transfer units is related to the number of theoretical stages by

$$N_{or} = N \times \frac{\ln \mathcal{E}}{1 - 1/\mathcal{E}} \tag{15-68}$$

The difference becomes pronounced when values of the extraction factor are high. When $\mathcal{E} = 1$, the number of mass-transfer units and number of theoretical stages are the same:

$$N_{or} = N = \frac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'} - 1 \qquad \text{for } \mathcal{E} = 1 \tag{15-69}$$

As with the KSB equation, in the special case where $\mathcal{E} < 1$, the maximum performance potential is represented by

$$\left(\frac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'}\right)_{max} \approx \frac{1}{1 - \mathcal{E}} \quad \text{for } \mathcal{E} < 1 \text{ and large } N_{or} \tag{15-70}$$

Equation (15-66) often is referred to as the Colburn equation. Although commonly used to represent the performance of a differential contactor, it models any steady-state, diffusion-controlled process with straight equilibrium and operating lines. As with the KSB equation, the operating line is straight even when solute concentration changes significantly as long as Bancroft coordinates are used, and both the KSB and Colburn equations can be used to model applications involving a highly curved equilibrium line by dividing the analysis into linear segments. With these approaches, these equations often can be used for applications involving high concentrations of solute.

Solutions to the Colburn equation are shown graphically in Fig. 15-26. Note the contrast to the KSB equation solutions shown in Fig. 15-24. The KSB equations are best used to model countercurrent contact devices where the separation is primarily governed by equilibrium limitations, such as extractors involving discrete stages with high stage efficiencies. The Colburn equation, on the other hand, better represents the performance of a diffusion rate-controlled contactor because performance approaches a definite limit as the extraction factor increases beyond $\mathcal{E} = 10$ or so, corresponding to a diffusion rate limitation where addition of extra solvent has little or no effect. Note that in the Colburn equation, Eq. (15-66), the extraction factor always appears as $1/\mathcal{E}$, and this is how a finite diffusion rate is taken into account. The KSB equation, Eq. (15-43), can be misleading in this regard because it predicts continued improvement as the extraction factor increases without limit.

In summary, the key relationships employed when applying the mass transfer unit model to the design of an extraction column can be expressed as follows:

$$H_{or} = \frac{V_r}{k_{or}a} = \frac{Z_t}{N_{or}} \tag{15-71}$$

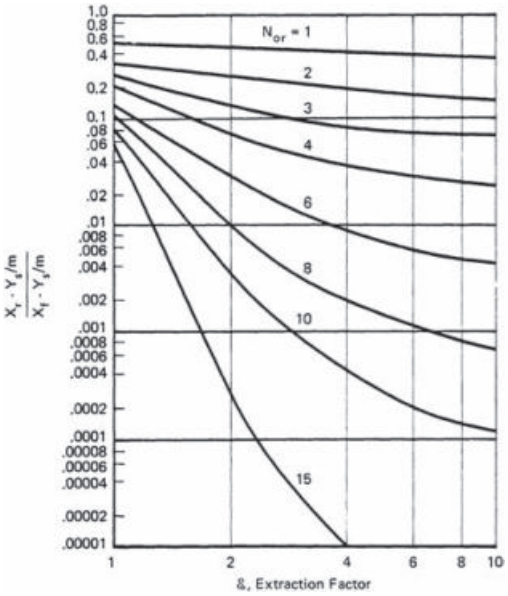

**FIG. 15-26** Graphical solutions to the Colburn equation [Eq. (15-66)].

The value of $H_{or}$ is the sum of contributions from the resistance to mass transfer in the raffinate phase ($H_r$) plus resistance to mass transfer in the extract phase ($H_e$) divided by the extraction factor $\mathcal{E}$:

$$H_{or} = H_r + \frac{H_e}{\mathcal{E}} \tag{15-72}$$

The individual transfer unit heights are given by

$$H_r = \frac{Q_r}{A_{col}\, k_r a} \tag{15-73}$$

$$H_e = \frac{Q_e}{A_{col}\, k_e a} \tag{15-74}$$

where $Q$ = volumetric flow rate
$A_{col}$ = column cross-sectional area
$k$ = film mass-transfer coefficient (length per unit time)
$a$ = interfacial mass-transfer area per unit volume of extractor

and subscripts $r$ and $e$ denote the raffinate and extract phases, respectively. As discussed earlier, the main resistance to mass transfer generally resides in the feed (raffinate) phase.

The lumped parameter $H_{or}$ characterizes the efficiency of the differential contactor; higher contacting efficiency is reflected in a lower value of $H_{or}$. It deals directly with the ultimate design criterion, the height of the column, and reliable values often can be obtained from miniplant experiments and experience with commercial units. For processes with discrete contacting stages, mass-transfer efficiency may be expressed as the number of transfer units achieved per actual stage. For applications involving transfer of multiple solutes, the value of $H_{or}$ or $N_{or}$ per actual stage may differ for each solute, as discussed earlier with regard to stage efficiencies and mass-transfer coefficients.

## EXTRACTION FACTOR AND GENERAL PERFORMANCE TRENDS

Because of their simplicity, the KSB equation [Eq. (15-43)] and the Colburn equation [Eq. (15-66)] are useful for illustrating a number of general trends in mass-transfer performance, in particular, helping to show how the extraction factor is related to process performance for different process configurations. For illustration, consider a simple dilute system involving immiscible liquids and zero solute concentration in the entering extraction solvent. The resulting expressions that follow are written in a general form without regard to a specific set of units.

For a single-stage batch process or a continuous extraction process that achieves one theoretical stage, the change in solute concentration expressed in terms of a solute reduction factor is

$$F_R = \frac{X_{\text{in}}}{X_{\text{out}}} = \frac{\mathcal{E} - 1/\mathcal{E}}{1 - 1/\mathcal{E}} \qquad \text{for } N = 1 \tag{15-75}$$

The required solvent-to-feed ratio is then approximated by

$$\frac{S}{F} = \frac{F_R - 1}{K} \qquad \text{for } N = 1 \tag{15-76}$$

After extraction, the concentration of solute in the extract, no matter what the extraction configuration, is given by

$$Y_{\text{out}} = \frac{X_{\text{in}}}{S/F}\left(1 - \frac{1}{F_R}\right) \qquad \text{for } Y_{\text{in}} = 0 \tag{15-77}$$

Equation (15-77) follows from Eq. (15-42).

If the performance of a single-stage extraction is not adequate, repeated cross-current extractions can be carried out to increase solute recovery or removal. For this configuration, the reduction factor is given by

$$F_R = \left(1 + \frac{\mathcal{E}}{N}\right)^{\xi_o N} \qquad \text{for cross-current operation} \tag{15-78}$$

where $N$ is the number of repeated extractions or stages employing equal amounts of solvent, $\xi_o$ is overall stage efficiency, and the extraction factor is expressed in terms of the total amount of solvent used by the process. Although high solute recoveries can be obtained by using cross-current processing, the required solvent usage will be high, as indicated by

$$\frac{S}{F} = \frac{N}{K}\left(F_R^{1/(\xi_o N)} - 1\right) \qquad \text{for cross-current operation} \tag{15-79}$$

where $S$ is the total amount of solvent. The concentration of solute in the combined extract will be low, as calculated by using Eq. (15-77). Comparing the results of Eqs. (15-75) and (15-76) with Eqs. (15-78) and (15-79) will show that multistage cross-current extraction yields improved performance relative to using single-stage extraction with the same total amount of solvent, but at the cost of additional contacting steps.

Compared to single-stage or cross-current processing, multistage, countercurrent processing allows a significant reduction in solvent use or an increase in separation performance. For this type of process, the reduction factor is approximated by

$$F_R = \frac{\mathcal{E}^{\xi_o N} - 1/\mathcal{E}}{1 - 1/\mathcal{E}} \qquad \text{for countercurrent operation} \tag{15-80}$$

Inspection of Eqs. (15-75) and (15-80) will show how the addition of countercurrent stages magnifies the effect of the extraction factor on performance. Note that Eq. (15-80) predicts that performance will continue to improve as the value of $\mathcal{E}$ increases, approaching $F_R = \mathcal{E}^{\xi_o N}$ at high values of $\mathcal{E}$. However, stage efficiency must remain high, and this likely will require a change in some operating variable such as residence time per stage.

Multistage countercurrent processing may be practiced batchwise as well as in a continuous cascade. A batchwise countercurrent operation involves first treating a batch with extract solution as the extract leaves the process, and the last treatment is carried out by using fresh solvent as it enters the process (as in Figs. 15-6 and 15-22). A multistage, countercurrent process with discrete contacting stages (practiced either batchwise or using a continuous cascade) is well suited to applications with fairly slow rates of mass transfer because liquid-liquid contacting is carried out stagewise in separate vessels or compartments, and long residence times can be designed into each stage.

For a countercurrent extraction column with no discrete stages (or for processes operated within a diffusion-controlled regime far from equilibrium), performance is well modeled by the Colburn equation, where

$$F_R = \frac{\exp[N_{\text{or}}(1 - 1/\mathcal{E})] - 1/\mathcal{E}}{1 - 1/\mathcal{E}} \qquad \text{for countercurrent operation} \tag{15-81}$$

and

$$Z_t = N_{\text{or}} \times H_{\text{or}} \tag{15-82}$$

Extraction columns are most attractive for applications with fairly fast mass transfer because residence time in the column is limited. Performance becomes mass-transfer-limited at high values of $\mathcal{E}$, approaching $F_R = \exp N_{\text{or}}$. At this point, a significant increase in performance can be achieved only by adding transfer units (column height), which corresponds to an increase in residence time for solute mass transfer.

With countercurrent processing, carried out using either a multistage cascade or an extraction column, the required solvent-to-feed ratio generally can be reduced by adding more and more stages or transfer units. As discussed in Minimum and Maximum Solvent-to-Feed Ratios, the minimum practical solvent-to-feed ratio is approximated by

$$\left(\frac{S}{F}\right)_{\min} \approx \frac{1.3}{K} \qquad \text{for countercurrent processing} \tag{15-83}$$

Below this value, the required number of stages or transfer units increases rapidly. At $\mathcal{E} = 1$, the number of theoretical stages and number of transfer units are equal, and

$$F_R = N + 1 = N_{\text{or}} + 1 \quad \text{for } \mathcal{E} = 1 \tag{15-84}$$

For $\mathcal{E} < 1$, the fraction of solute removed from the feed $\theta_i$ will approach a value equal to the extraction factor. In this case,

$$(F_R)_{\max} = \frac{1}{1 - \mathcal{E}} \qquad \text{for } \mathcal{E} < 1 \tag{15-85}$$

## POTENTIAL FOR SOLUTE PURIFICATION USING STANDARD EXTRACTION

As noted earlier, the ability of a standard extraction process to isolate a desired solute from other solutes is limited. This can be illustrated by using the KSB equation [Eq. (15-43)] to calculate solute transfer for a dilute feed containing a desired solute $i$ and an impurity solute $j$. On a solvent-free basis, the purity of solute $i$ in the feed is given by

$$P_{i,\text{feed}}\ (\text{in units of wt \%}) = 100\left(\frac{X''_{i,\text{feed}}}{X''_{i,\text{feed}} + X''_{j,\text{feed}}}\right) \tag{15-86}$$

Similarly, the purity of solute $i$ in the extract is given by

$$P_{i,\text{extract}}\ (\text{wt \%}) = 100\left(\frac{\theta_i X''_{i,\text{feed}}}{\theta_i X''_{i,\text{feed}} + \theta_j X''_{j,\text{feed}}}\right) \tag{15-87}$$

where $\theta_i$ is the fraction of solute extracted from the feed into the extract. By using the KSB equation to estimate $\theta$ for solutes $i$ and $j$, the following expression is derived:

$$\begin{aligned} P_{i,\text{extract}}\ (\text{wt \%}) &= \frac{100}{1 + \left(\dfrac{\theta_j}{\theta_i}\right)\left(\dfrac{X''_{j,\text{feed}}}{X''_{i,\text{feed}}}\right)} \\ &= \frac{100}{1 + \left(\dfrac{\mathcal{E}_j^N - 1}{\mathcal{E}_i^N - 1}\right)\left(\dfrac{\mathcal{E}_i^N - 1/\mathcal{E}_i}{\mathcal{E}_j^N - 1/\mathcal{E}_j}\right)\left(\dfrac{X''_{j,\text{feed}}}{X''_{i,\text{feed}}}\right)} \qquad \text{for } \mathcal{E} \neq 1.0 \end{aligned} \tag{15-88}$$

Equation (15-88) assumes that no solute enters the process with the extraction solvent and that $\mathcal{E}_i$ and $\mathcal{E}_j$ are constant. An alternative expression can be written in terms of transfer units; however, the calculated results are essentially the same as a function of the number of stages or the number of transfer units because the models assume that both solute $i$ and solute $j$ experience the same mass-transfer resistance. Example results obtained by using Eq. (15-88) are shown in Fig. 15-27. Note that performance is not uniquely determined by a given value of $\alpha_{ij} = K_i/K_j = \mathcal{E}_i/\mathcal{E}_j$, but depends upon the absolute value of $\mathcal{E}_i$, as well. In principle, the purity of solute $i$ in the extract will approach a maximum value as the number of stages or transfer units approaches infinity:

$$\text{Maximum } P_{i,\text{extract}}(\%) = 100 \div \left[1 + \frac{1}{\alpha_{i,j}}\left(\frac{X''_{j,\text{feed}}}{X''_{i,\text{feed}}}\right)\right] \qquad \text{in limit as } N \to \infty \tag{15-89}$$

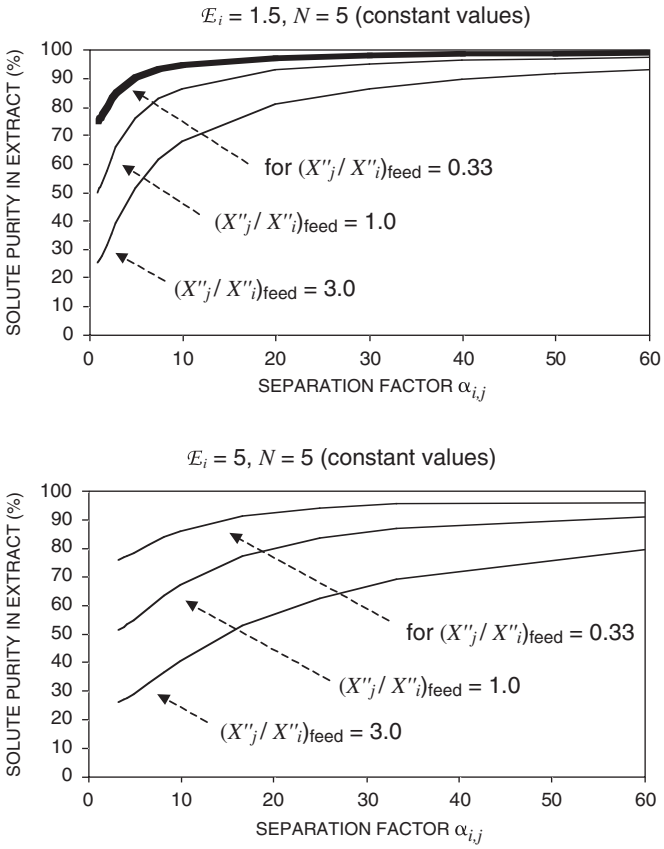

**FIG. 15-27** Approximate purity of solute $i$ in the extract ($P_{i,extract}$) versus separation factor $\alpha_{i,j}$ for standard extraction involving dilute feeds containing solutes $i$ and $j$. Results obtained by using Eq. (15-88). Concentrations are in mass fraction ($X''$).

Of course, this theoretical maximum can never be attained in practice. Equation (15-89) follows from Eq. (15-88), noting that $\theta_j/\theta_i = 1/\alpha_{ij}$ for $N \to \infty$ as discussed by P. L. T. Brian [*Staged Cascades in Chemical Processing*, Prentice-Hall, Englewood Cliffs, NJ, 1972, p. 50]. As noted earlier, the ability to purify a desired solute is greatly enhanced by using fractional extraction (see the subsection Fractional Extraction Calculations).

# CALCULATION PROCEDURES

## SHORTCUT CALCULATIONS

Shortcut calculations can be quite useful to the process designer or run-plant engineer; they may be used to outline process requirements (stream and equipment sizes) early in a design project, to check the output of a process simulation program for reasonableness, to help analyze or troubleshoot a unit operating in the manufacturing plant or pilot plant, or to help explain performance trends and relationships between key process variables. In some applications involving dilute or even moderately concentrated feeds, they also may be used to specify the final design of an extraction process. In carrying out such calculations, L. A. Robbins [Sec. 1.9 in *Handbook of Separation Techniques for Chemical Engineers*, ed. P. A. Schweitzer, McGraw-Hill, New York, 1997] indicates that most liquid-liquid extraction systems can be treated as having immiscible solvents (case *A*), partially miscible solvents with a low solute concentration in the extract (case *B*), or partially miscible solvents with a high solute concentration in the extract (case *C*). These cases are illustrated in Examples 15-1 through 15-3.

***Example 15-1 Shortcut Calculation, Case A*** Consider a 100-kg/h feed stream containing 20 wt% acetic acid in water that is to be extracted with 200 kg/h of recycle MIBK that contains 0.1 wt% acetic acid and 0.01 wt% water. The aqueous raffinate is to be extracted down to 1 wt% acetic acid. How many theoretical stages will be required and what will the extract composition be? The equilibrium data for this system are listed in Table 15-8 (in units of weight percent). The corresponding Hand plot is shown in Fig. 15-20. The Hand correlation (in mass ratio units) can be expressed as $Y' = 0.930(X')^{1.10}$, for $X'$ between 0.03 and 0.25.

Assuming immiscible solvents, we have

$F' = 100(1 - 0.2) = 80$ kg water/h

$$X'_f = \frac{0.2}{0.8} = 0.25 \text{ kg acetic acid/kg water}$$

$$X'_r = \frac{0.01}{0.99} = 0.01 \text{ kg acetic acid/kg water}$$

$S' = 200(1 - 0.001) = 199.8$ kg MIBK/h

$$Y'_s = \frac{0.2}{199.8} = 0.001 \text{ kg acetic acid/kg MIBK}$$

If we assume $R' = F'$ and $E' = S'$, we can calculate $Y'_e$ from Eq. (15-42):

$$Y'_e = \frac{80(0.25) + 199.8(0.001) - 80(0.01)}{199.8} = 0.097 \frac{\text{kg acetic acid}}{\text{kg MIBK}}$$

Calculate $X'_1 = (0.097/0.930)^{1/1.10} = 0.128$. Then

$$m' = \frac{dY'}{dX'} = (0.930)(1.10)(X')^{0.1} \qquad \text{for } X' \text{ between 0.03 and 0.25}$$

$$m'_1 = 0.833 \qquad \text{at } X' = 0.128$$

$$m'_r = \frac{dY'}{dX'} = K' = 0.656 \qquad \text{for } X' \text{ below 0.03}$$

**TABLE 15-8 Water + Acetic Acid + Methyl Isobutyl Ketone Equilibrium Data at 25°C**

| Weight percent in raffinate | | | $X'$ | Weight percent in extract | | | $Y'$ |
|---|---|---|---|---|---|---|---|
| Water | Acetic acid | MIBK | Acetic acid | Water | Acetic acid | MIBK | Acetic acid |
| 98.45 | 0 | 1.55 | 0 | 2.12 | 0 | 97.88 | 0 |
| 95.46 | 2.85 | 1.7 | 0.0299 | 2.80 | 1.87 | 95.33 | 0.0196 |
| 85.8 | 11.7 | 2.5 | 0.1364 | 5.4 | 8.9 | 85.7 | 0.1039 |
| 75.7 | 20.5 | 3.8 | 0.2708 | 9.2 | 17.3 | 73.5 | 0.2354 |
| 67.8 | 26.2 | 6.0 | 0.3864 | 14.5 | 24.6 | 60.9 | 0.4039 |
| 55.0 | 32.8 | 12.2 | 0.5964 | 22.0 | 30.8 | 47.2 | 0.6525 |
| 42.9 | 34.6 | 22.5 | 0.8065 | 31.0 | 33.6 | 35.4 | 0.9492 |

SOURCE: Sherwood, Evans, and Longcor, *Ind. Eng. Chem.*, **31**(9), pp. 1144–1150 (1939).

$$K'_s = 0.656 \quad \text{at } Y'_s = 0.001$$

$$\mathcal{E} = \sqrt{m'_1 m'_r}\ \frac{S'}{F'} = \frac{0.739(199.8)}{80} = 1.85$$

And $N$ is determined from Fig. 15-24 and Eq. (15-43).

$$N = \frac{\ln\left[\left(\frac{0.25 - 0.001/0.656}{0.01 - 0.001/0.656}\right)\left(1 - \frac{1}{1.85}\right) + \frac{1}{1.85}\right]}{\ln 1.85} = 4.3 \text{ theoretical stages}$$

This result is very close to that obtained by using a McCabe-Thiele diagram (Fig. 15-23). From solubility data at $Y' = 0.1039$ kg acetic acid/kg MIBK (given in Table 15-8), the extract layer contains 5.4/85.7 = 0.0630 kg water/kg MIBK, and $Y''_e = (0.097)/(1 + 0.097 + 0.063) = 0.084$ mass fraction acetic acid in the extract.

For cases *B* and *C*, Robbins developed the concept of pseudosolute concentrations for the feed and solvent streams entering the extractor that will allow the KSB equations to be used. In case *B* the solvents are partially miscible, and the miscibility is nearly constant through the extractor. This frequently occurs when all solute concentrations are relatively low. The feed stream is assumed to dissolve extraction solvent only in the feed stage and to retain the same amount throughout the extractor. Likewise, the extraction solvent is assumed to dissolve feed solvent only in the raffinate stage. With these assumptions the primary extraction solvent rate moving through the extractor is assumed to be $S'$, and the primary feed solvent rate is assumed to be $F'$. The extract rate $E'$ is less than $S'$, and the raffinate rate $R'$ is less than $F'$ because of solvent mutual solubilities.

The slope of the operating line is $F'/S'$, just as in Eqs. (15-40) and (15-41), but only stages 2 through $r - 1$ will fall directly on the operating line. And $X'_1$ must be on the equilibrium line in equilibrium with $Y'_e$ by definition. One can also calculate a pseudofeed concentration $X'^B_f$ that will fall on the operating line at $Y'_{n+1} = Y'_e$ as follows:

$$X'^B_f = X'_f + \frac{S' - E'}{F'} Y'_e \tag{15-90}$$

Likewise, one knows that $Y'_r$ will be on the equilibrium line with $X'_r$. One can therefore calculate a pseudoconcentration of solute in the inlet extraction solvent $Y'^B_s$ that will fall on the operating line where $X'_{n-1} = X'_r$, as follows:

$$Y'^B_s = Y'_s + \frac{F' - R'}{S'} X'_r \tag{15-91}$$

For case *B*, the pseudo inlet concentration $X'^B_f$ can be used in the KSB equation with the actual value of $X'_r$ and $\mathcal{E} = m'S'/F'$ to calculate rapidly the number of theoretical stages required. The graphical stepwise method illustrated in Fig. 15-23 also can be used. The operating line will go through points $(X'_r, Y'^B_s)$ and $(X'^B_f, Y'_e)$ with a slope of $F'/S'$.

***Example 15-2 Shortcut Calculation, Case B*** Let us solve the problem in Example 15-1 by assuming case *B*. The solute (acetic acid) concentration is low enough in the extract that we may assume that the mutual solubilities of the solvents remain nearly constant. The material balance can be calculated by an iterative method.

From equilibrium data (Table 15-8) the extraction solvent (MIBK) loss in the raffinate will be about 0.016/0.984 = 0.0163 kg MIBK/kg water, and the feed solvent (water) loss in the extract will be about 5.4/85.7 = 0.0630 kg water/kg MIBK.

First iteration: Assume $R' = F' = 80$ kg water/h. Then extraction solvent in raffinate = (0.0163)(80) = 1.30 kg MIBK/h. Estimate $E' = 199.8 - 1.3 = 198.5$ kg MIBK/h. Then feed solvent in extract = (0.063)(198.5) = 12.5 kg water/h.

Second iteration: Calculate $R' = 80 - (0.063)(198.7) = 67.5$ kg water/h. And $E' = 199.8 - (0.0163)(67.5) = 198.7$ kg MIBK/h.

Third iteration: Converge $R' = 80 - (0.063)(198.7) = 67.5$ kg water/h. And $Y'_e$ is calculated from the overall extractor material balance [Eq. (15-42)]:

$$Y'_e = \frac{80(0.25) + 199.8(0.001) - (67.5)(0.01)}{198.7} = 0.0983 \frac{\text{kg acetic acid}}{\text{kg MIBK}}$$

$$Y_e = \frac{0.0983}{1 + 0.0983 + 0.0630} = 0.0846 \text{ mass fraction acetic acid in extract}$$

From the Hand correlation of equilibrium data,

$$Y'_e = 0.930(X')^{1.10} \qquad \text{for } X' \text{ between 0.03 and 0.25}$$

The raffinate composition leaving the feed (first stage) is

$$X'_1 = \left(\frac{0.0983}{0.930}\right)^{1/1.10} = 0.130$$

$$m'_1 = \frac{dY}{dX} = (0.930)(1.10)(X')^{0.1}$$

$$m'_r = \frac{dY}{dX} = K' = 0.656$$

$$m'_1 = 0.834 \quad \text{at } X'_1 = 0.13$$

$$m'_r = 0.656 \quad \text{at } X'_r = 0.01$$

$$K'_s = 0.656 \quad \text{at } Y'_s = 0.001$$

$$\mathcal{E} = \sqrt{m'_1 m'_r}\ \frac{S'}{F'} = \frac{(0.740)(199.8)}{80} = 1.85$$

And $X'^B_f$ is calculated from Eq. (15-90)

$$X'^B_f = 0.25 + \frac{(199.8 - 198.7)(0.0983)}{80} = 0.251$$

and $Y'^B_s$ from Eq. (15-91):

$$Y'^B_s = 0.001 + \frac{(80 - 67.5)(0.01)}{199.8} = 0.0016$$

Now $N$ is determined from Fig. 15-24, Eq. (15-43), or the McCabe-Thiele type of plot (Fig. 15-23). For case *B*,

$$N = \frac{\ln\left[\left(\frac{0.251 - 0.0016/0.656}{0.01 - 0.0016/0.656}\right)\left(1 - \frac{1}{1.85}\right) + \frac{1}{1.85}\right]}{\ln 1.85} = 4.5 \text{ theoretical stages}$$

A less frequent situation, case *C*, can occur when the solute concentration in the extract is so high that a large amount of feed solvent is dissolved in the extract stream at the feed end of the process (at the feed stage), but a relatively small amount of feed solvent (say one-tenth as much) is dissolved by the extract stream at the raffinate end of the process (at the raffinate stage). The feed stream is assumed to dissolve the extraction solvent only in the feed stage just as in case *B*. But the extract stream is assumed to dissolve a large amount of feed solvent leaving the feed stage and a negligible amount leaving the raffinate stage. With these assumptions, the primary feed solvent rate is assumed to be $R'$, so the slope of the operating line for case *C* is $R'/S'$. Again the extract rate $E'$ is less than $S'$, and the raffinate rate $R'$ is less than $F'$.

The pseudofeed concentration for case *C*, $X'^C_f$, can be calculated from

$$X'^C_f = \frac{F'}{R'} X'_f + \frac{S' - E'}{R'} Y'_e \tag{15-92}$$

For case *C*, the value of $Y'_s$ will fall on the operating line, and the extraction factor is given by

$$\mathcal{E}^C = \frac{m'S'}{R'} \tag{15-93}$$

On an $X'$–$Y'$ diagram for case *C*, the operating line will go through points $(X'_r, Y'_r)$ and $(X'^C_f, Y'_e)$ with a slope of $R'/S'$ similar to Fig. 15-23. When the KSB equation is used for case *C*, use the pseudofeed concentration $X'^C_f$ from Eq. (15-92) and the extraction factor $\mathcal{E}^C$ from Eq. (15-93). The raffinate concentration $X'_r$ and inlet solvent concentration $Y'_s$ are used without modification. For more detailed discussion, see L. A. Robbins, sec. 1.9 in *Handbook of Separation Techniques for Chemical Engineers*, ed. P. A. Schweitzer, McGraw-Hill, New York, 1997.

***Example 15-3 Number of Transfer Units*** Let us calculate the number of transfer units required to achieve the separation in Example 15-2. The solution to the problem is the same as in Example 15-1 except that the denominator is changed. From Eq. (15-68):

$$N_{or} = 4.5 \frac{\ln 1.85}{1 - 1/1.85} = 6.0 \text{ transfer units}$$

## COMPUTER-AIDED CALCULATIONS (SIMULATIONS)

A number of process simulation programs such as Aspen Plus® and Aspen HYSYS® from AspenTech, ChemCAD® from Chemstations, ProSimPlus from ProSim, and SimSci PRO/II® from Schneider Electric, among others, can facilitate rigorous calculation of the number of theoretical stages required by a given application, provided an accurate liquid-liquid equilibrium model is employed. Some commercially available simulation packages do not include rate-based programs specifically designed for extraction process simulation; however, the equivalent number of transfer units at each stage can be calculated from knowledge of the extraction factor by using Eq. (15-68). Process simulation programs are particularly useful for concentrated systems that exhibit highly nonlinear equilibrium and operating lines, significant change in extract and raffinate flow rates within the process due to transfer of solute from one phase to the other, significant changes in the mutual solubility of the two phases as solute concentration changes, or nonisothermal operation. They also facilitate convenient calculation for complex extraction configurations such as fractional extraction with extract reflux as well as calculations involving more than three components (more than one solute). They can also facilitate process optimization by allowing rapid evaluation of numerous design cases. These programs do not provide information about mass-transfer performance in terms of stage efficiencies or extraction column height requirements, or information about the throughput and flooding characteristics of the equipment; these factors must be determined separately by using other methods. The use of simulation software to analyze extraction processes is illustrated in Examples 15-4 and 15-5.

In using simulation software, it is important to keep in mind that the reliability of the results is highly dependent upon the quality of the liquid-liquid equilibrium (LLE) model programmed into the simulation. In most cases, an experimentally validated model will be needed because UNIFAC and other estimation methods are not sufficiently accurate. It also is important to recognize, as mentioned in earlier discussions, that binary interaction parameters determined by regression of vapor-liquid equilibrium (VLE) data cannot be relied upon to accurately model the LLE behavior for the same system. On the other hand, a set of binary interaction parameters that model LLE behavior properly often will provide a reasonable VLE fit for the same system because pure-component vapor pressures often dominate the calculation of VLE.

Commercially available simulation programs often are used in a fashion similar to the classic graphical methods. When separation of specific solutes is important, the design of a new process generally focuses on determining the optimum solvent rates and number of theoretical stages needed to comply with the separation specifications according to relative $K$ values for solutes of interest. Calculations often are made by focusing on a "soluble" key solute with a relatively high $K$ value, and an "insoluble" key solute, expressing the design specification in terms of the maximum concentration of soluble key left in the raffinate and the maximum concentration of insoluble key contaminating the extract (analogous to "light" and "heavy" key components in distillation design). Then solutes with $K$ values higher than that of the soluble key will go out with the extract to a greater extent, and solutes with $K$ values less than that of the insoluble key will go out with the raffinate. If the desired separation is not feasible using a standard extraction scheme, then fractional extraction schemes should be evaluated.

For rating an existing extractor, the designer must make an estimate of the number of theoretical stages the unit can deliver and then determine the concentrations of key solutes in extract and raffinate streams as a function of the solvent-to-feed ratio, keeping in mind the fact that the number of theoretical stages a unit can deliver can vary depending upon operating conditions.

The use of process simulation software for process design is discussed by W. D. Seider, J. D. Seader, D. R. Lewin, and S. Widagdo [*Product and Process Design Principles: Synthesis, Analysis, and Evaluation*, 3d ed., Wiley, New York, 2009] and by R. Turton, R. C. Bailie, W. B. Whiting, J. A. Shaeiwitz, and D. Bhattacharyya [*Analysis, Synthesis, and Design of Chemical Processes*, 4th ed., Prentice-Hall, Upper Saddle River, NJ, 2012]. Various computational procedures for extraction simulation are discussed by L. Steiner [chap. 6 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994]. In addition, a number of authors have developed specialized methods of analysis. For example, D. Sanpui, M. K. Singh, and A. Khanna [*AIChE J.* **50**(2): 368–381 (2004)] outline a computer-based approach to rate-based, nonisothermal modeling of extraction processes. B. Harjo, K. M. Ng, and C. Wibowo [*Ind. Eng. Chem. Res.* **43**(14): 3566–3576 (2004)] describe methods for visualization of high-dimensional liquid-liquid equilibrium phase diagrams as an aid to process conceptualization. This methodology can help focus the design effort by identifying specific composition regions where the design analysis will be particularly sensitive to uncertainties in the equilibrium behavior. The method of M. Minotti, M. F. Doherty, and M. F. Malone [*Ind. Eng. Chem. Res.* **35**(8): 2672–2681 (1996)] facilitates a feasibility analysis of potential solvents and process options by locating fixed points or pinches in the composition profiles determined by equilibrium and operating constraints. A. Marcilla et al. [*Ind. Eng. Chem. Res.* **38**(8): 3083–3095 (1999)] developed a method involving correlation of tie lines to calculate equilibrium compositions at each stage without iterations. To optimize the design and operating parameters of an extraction cascade, J. A. Reyes-Labarta and I. E. Grossmann [*AIChE J.* **47**(10): 2243–2252 (2001)] have proposed a calculation framework that employs nonlinear programming techniques to systematically evaluate a wide range of potential process configurations and interconnections. Focusing on another aspect of process design, R. Ravi and D. P. Rao [*Ind. Eng. Chem. Res.* **44**(26): 10016–10020 (2005)] provide an analysis of the phase rule (number of degrees of freedom) for liquid-liquid extraction processes.

***Example 15-4 Extraction of Phenol from Wastewater*** The amount of 350 gpm (79.5 $m^3/h$) of wastewater from a coke oven plant contains an average of 700 ppm phenol by weight that needs to be reduced to 1 ppm or less to meet environmental requirements [Karr, A. E., and S. Ramanujam, *St. Louis AIChE Symp.*, March 19, 1987]. The wastewater comes from the bottom of an ammonia stripping tower at 105°C and is to be extracted at 1.7 atm with recycle methylisobutyl ketone (MIBK) containing 5 ppm phenol. The extraction will be carried out by using a reciprocating-plate extractor (Karr column). How many theoretical stages will be required in the extractor at a solvent-to-feed ratio of 1:15, and what is the resulting extract composition?

The Aspen Plus® process simulation program is used in this example, but any of a number of process simulation programs such as those mentioned earlier also may be used for this purpose. In Aspen Plus, the EXTRACT liquid-liquid extraction unit-operation block is used to model the phenol wastewater extraction. As is typical in process simulation programs, the EXTRACT block is fundamentally a rating calculation rather than a design calculation, so the determination of the required number of stages for the separation cannot be made directly. In addition, the EXTRACT block can only handle integral numbers of theoretical stages, so the fractional number of required theoretical stages must be determined by an interpolation method.

The partition ratio for transfer of phenol from water into MIBK at 105°C is $K'' = 34$ on a mass fraction basis [Greminger, D. C., et al., *Ind. Eng. Chem. Proc. Des. Dev.* **21**(1): 51–54 (1982)]. Because the partition ratio is so high, a low solvent-to-feed ratio of 1:15 can be used and still give an extraction factor of about 2. In the EXTRACT block, a property option is available that allows the user to specify liquid-liquid $K$ value correlations (designated as KLL Correlation in Aspen Plus) for the components involved in the extraction rather than a complete set of binary interaction parameters to define the liquid-liquid equilibria. In this example, it is time-consuming to regress a set of liquid-liquid binary interaction parameters that results in representative partition ratios, so the option of simply specifying $K$ values directly is recommended. Because phenol will be relatively dilute in both the raffinate and extract phases, appropriate liquid-liquid $K$ values for distribution of water and MIBK between phases at 105°C can be estimated from water–MIBK liquid-liquid equilibrium data [Řehák, M., et al., *Collect. Czech Chem. Commun.* **65:** 1471–1486 (2000)] to yield $K''_{\text{water}} = 0.0532$ and $K''_{\text{MIBK}} = 53.8$ (mass fraction basis). It is important in Aspen Plus to specify $K$ values for all the components in the extractor in order to properly model the liquid-liquid equilibria with this approach.

The temperatures and compositions of the wastewater and solvent feed streams, as well as the wastewater feed flow rate, are specified in the problem statement. The solvent flow rate is specified as one-fifteenth of the wastewater flow rate as described above. In the EXTRACT block, the number of stages will be manually varied from 2 to 10 to observe the effect on the raffinate and extract concentrations, and it will be specified as operating adiabatically at 1.7 atm. Water is specified as the key component in the first liquid phase, and MIBK is specified as the key component in the second liquid phase. The rest of the block parameters (convergence, report, and miscellaneous block options) are allowed to remain at their default values.

The raffinate and extract concentrations resulting from successive simulation runs for 2 through 10 theoretical stages are given in Table 15-9, and the raffinate phenol concentrations are presented graphically in Fig. 15-28. Examining the results, we can see that the number of theoretical stages required to achieve the 1 ppm phenol discharge limitation falls somewhere between 7 and 8. In addition, we can see from Fig. 15-28 that the dependence of raffinate phenol concentration on the number of stages yields nearly a straight line on a semilog plot. As a result, performing a linear interpolation of the log of the raffinate concentration between 7 and 8 stages yields the number of stages required to achieve 1 ppm phenol in the raffinate:

$$N = 7 + (8-7)\left(\frac{\log 1.48 - \log 1}{\log 1.48 - \log 0.709}\right) = 7.53 \text{ theoretical stages}$$

Examining the extract phenol concentrations in Table 15-9, it is clear that they varied little for five or more stages, as is expected because nearly all the phenol contained in the wastewater feed was extracted in stages 1 through 4. As a result, the extract will contain 1.3 wt% phenol, 5.2 percent water, and 93.5 percent MIBK.

The simulation results can be checked by using a shortcut calculation—to provide confidence that the simulation is delivering a reasonable result. The KSB equation [Eq. (15-43)] can be used for this purpose with values taken from the problem specification and estimates of the phenol $K'$ value (in Bancroft coordinates). Because phenol is always quite dilute in both the extract and raffinate phases, its $K'$ value can be calculated from the component mass fraction $K''$ values according to the following approximation:

$$K'_{\text{PhOH}} \cong K''_{\text{PhOH}}\left[\frac{K''_{\text{MIBK}} - 1}{K''_{\text{MIBK}}(1 - K''_{\text{H}_2\text{O}})}\right] = 34\left[\frac{53.8 - 1}{53.8(1 - 0.0532)}\right] = 35.24$$

**TABLE 15-9 Simulation Results for Extraction of Phenol from Wastewater Using MIBK (Example 15-4)**

| | Raffinate compositions | | | Extract compositions | | |
|---|---|---|---|---|---|---|
| $N$ | $X''_{PhOH}$, pmm | $X''_{H_2O}$, mass fraction | $X''_{MIBK}$, mass fraction | $Y''_{PhOH}$, mass fraction | $Y''_{H_2O}$, mass fraction | $Y''_{MIBK}$, mass fraction |
| 2 | 101 | 0.98235 | 0.01755 | 0.01146 | 0.05226 | 0.93628 |
| 3 | 41.8 | 0.98237 | 0.01759 | 0.01260 | 0.05226 | 0.93514 |
| 4 | 17.7 | 0.98238 | 0.01760 | 0.01307 | 0.05226 | 0.93468 |
| 5 | 7.56 | 0.98238 | 0.01761 | 0.01326 | 0.05226 | 0.93448 |
| 6 | 3.29 | 0.98238 | 0.01761 | 0.01335 | 0.05225 | 0.93440 |
| 7 | 1.48 | 0.98238 | 0.01762 | 0.01338 | 0.05225 | 0.93436 |
| 8 | 0.709 | 0.98238 | 0.01762 | 0.01340 | 0.05226 | 0.93435 |
| 9 | 0.382 | 0.98238 | 0.01762 | 0.01340 | 0.05225 | 0.93434 |
| 10 | 0.242 | 0.98238 | 0.01762 | 0.01341 | 0.05225 | 0.93434 |

This value compares favorably with the value of 35.28 calculated from phenol mass ratios derived from extractor internal mole fraction profile data in the simulation output. The extraction factor [Eq. (15-11)] is then calculated with the dilute system approximation that $m_{PhOH} \cong K_{PhOH}$ and solute-free water and MIBK feed rates of 159,911 and 10,668 lb/h taken from the simulation output:

$$\mathcal{E}_{PhOH} = m_{PhOH}\frac{S}{F} \cong K''_{PhOH}\frac{S''}{F''} = K'_{PhOH}\frac{S'}{F'} = 35.24 \times \frac{10{,}668}{159{,}911} = 2.35$$

It is interesting to note that this value of the extraction factor, 2.35, is the same as those calculated on mole fraction, mass fraction, and Bancroft coordinate bases from extractor internal profile data in the simulation, a confirmation that the extraction factor is indeed independent of units as long as consistent values of $m$, $S$, and $F$ are used. By substituting the above values into Eq. (15-43) along with concentrations taken from the problem statement and Table 15-9, the required number of stages is estimated as

$$N \approx \frac{\ln\left[\dfrac{0.0007/0.9993 - (0.000005)/(0.999995)/35.24}{0.000001/0.9824 - (0.000005)/(0.999995)/35.24}\,1 - 1/2.35 + 1/2.35\right]}{\ln 2.35}$$

$$= 7.18 \text{ theoretical stages}$$

The simulation result of 7.53 theoretical stages is close to this shortcut estimate, indicating that the simulation is indeed delivering reasonable results.

## FRACTIONAL EXTRACTION CALCULATIONS

**Dual-Solvent Fractional Extraction** As discussed in the subsection Commercial Process Schemes, under Introduction and Overview, fractional extraction often may be viewed as combining product purification with product recovery by adding a washing section to the stripping section of a standard extraction process. In the stripping section, the mass transfer we focus on is the transfer of the product solute from the wash solvent into the extraction solvent. If we assume dilute conditions and use shortcut calculations for illustration, the extraction factor is given by

$$\mathcal{E}_s = K'_s\frac{S'_s}{W'_s} \tag{15-94}$$

where $\mathcal{E}_s$ = stripping section extraction factor (dimensionless)
$K'_s$ = stripping section partition ratio, defined as equilibrium concentration of product solute in extraction solvent divided by that in wash solvent (Bancroft coordinates)
$S'_s$ = mass flow rate of extraction solvent within stripping section (solute-free basis)
$W'_s$ = mass flow rate of wash solvent in stripping section (solute-free basis)

The change in the concentration of product dissolved in the wash solvent, within the stripping section, can be calculated by using the KSB equation

$$\left(\frac{X'_{out}}{X'_{in}}\right)_{product} \approx \frac{1 - 1/\mathcal{E}_s}{(\mathcal{E}_s)^{N_S} - 1/\mathcal{E}_s} \tag{15-95}$$

where $N_s$ = number of theoretical stages in stripping section
$X'_{in}$ = concentration of product solute in wash solvent at inlet to stripping section ( feed stage)
$X'_{out}$ = concentration of product solute in wash solvent at outlet from stripping section (raffinate end of overall process)

In the washing section, we focus on transfer of impurity solute from the extraction solvent into the wash solvent. A washing extraction factor can be defined as

$$\mathcal{E}_w = \frac{1}{K'_w}\frac{W'_w}{S'_w} \tag{15-96}$$

where $\mathcal{E}_w$ = washing section extraction factor (dimensionless)
$K'_w$ = washing section partition ratio, defined as equilibrium concentration of impurity solute in extraction solvent divided by that in wash solvent (Bancroft coordinates)
$S'_w$ = mass flow rate of extraction solvent within washing section (solute-free basis)
$W'_w$ = mass flow rate of wash solvent in washing section (solute-free basis)

Then the change in the concentration of impurity solute dissolved in the extraction solvent, within the washing section, is given by

$$\left(\frac{Y'_{out}}{Y'_{in}}\right)_{impurities} \approx \frac{1 - 1/\mathcal{E}_w}{(\mathcal{E}_w)^{N_w} - 1/\mathcal{E}_w} \tag{15-97}$$

where $N_w$ = number of theoretical stages in washing section
$Y'_{in}$ = concentration of impurity solute in extraction solvent at inlet to washing section ( feed stage)
$Y'_{out}$ = concentration of impurity solute in extraction solvent at outlet from washing section (extract end of overall process)

The ratio of extraction solvent to wash solvent in each section will be different if either solvent enters the process with the feed. Note that both $K'_s$ and $K'_w$ are defined as the ratio of the appropriate solute concentration in the *extraction* solvent to that in the *wash* solvent.

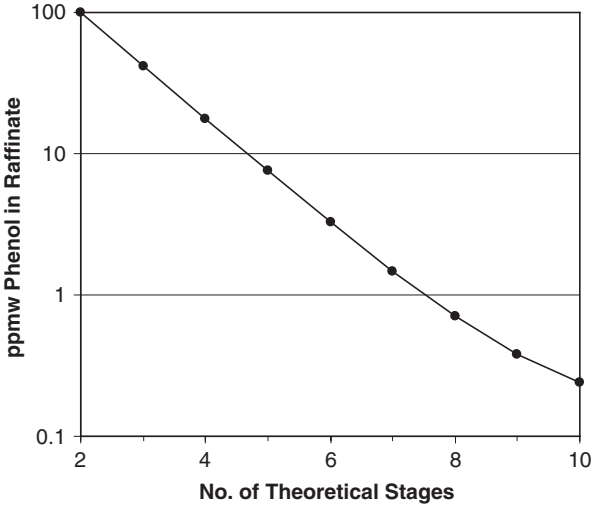

**FIG. 15-28** Simulation results showing phenol concentration in the raffinate versus number of theoretical stages (Example 15-4).

The shortcut calculations just outlined illustrate the general considerations involved in analyzing a fractional extraction process. The analysis requires locating the feed stage and matching the calculations for each section with the material balance at the feed stage, an iterative procedure. B. D. Smith and W. K. Brinkley [*AIChE J.* **6**(3): 446–450 (1960)] discuss the application of the KSB equation to fractional extraction calculations including the use of reflux. Transfer unit calculations also may be used. When equilibrium and operating lines are not linear, more sophisticated calculations will be needed to take this into account. Commercially available simulation software or other computer programs often are used to carry out this procedure (see the subsection Computer-Aided Calculations). Note that with dual-solvent fractional extraction, the total solute concentration always is highest at the feed stage. This can lead to undesired behavior such as tendencies toward emulsion formation or even formation of a single liquid phase at the plait point. The minimum amounts of solvent needed to avoid these effects can be determined in laboratory tests.

Early in a project, it may be useful to consider a simplified case in which the ratio of extraction solvent to wash solvent is constant and is the same in the stripping and washing sections (i.e., the amount of solvent entering with the feed is negligible) and the extraction factors for each section are equal. For this special case, termed a *symmetric separation*, the extraction factors are

$$\mathcal{E}_s = \mathcal{E}_w = \sqrt{\alpha_{i,j}} \tag{15-98}$$

and the ratio of extraction solvent to wash solvent is given by

$$\frac{S}{W} \approx \frac{1}{\sqrt{K_s K_w}} \approx \frac{1}{\sqrt{\alpha_{i,j}} K_w} = \frac{\sqrt{\alpha_{i,j}}}{K_s} \tag{15-99}$$

Using these relationships, we find the number of stages required for the stripping and washing sections will be about the same, and the total number of stages required likely will be close to the minimum number—assuming symmetric separation requirements. The effects of the separation factor and the number of stages on the separation performance can be estimated by using expressions given by P. L. T. Brian [*Staged Cascades in Chemical Processing*, Prentice-Hall, Englewood Cliffs, NJ, 1972]. For a process containing two solutes *i* and *j*, with the feed entering at the middle stage, it follows from Brian's analysis that

$$S_{i,j} = \frac{Y_i}{X_i} \frac{1 - X_i}{1 - Y_i} \approx \alpha_{i,j}^{(N+1)/2} \tag{15-100}$$

where $S_{ij}$ is termed the *separation power* of the process. Equation (15-100) is derived by assuming that the ratio of extract phase to raffinate phase within the process is constant, and that $\alpha_{ij}$ is constant. Interestingly, Eq. (15-100) is very similar in its general form to the equation obtained by using the Fenske equation to calculate fractional distillation performance for a binary feed, assuming that the required number of theoretical stages is twice the minimum number obtained at total reflux. (See Sec. 13, Distillation.)

For a proposed symmetric separation, Eqs. (15-99) and (15-100) can be used to gauge the required flow rates, number of theoretical stages, and separation factor. For example, consider a hypothetical application with the goal of transferring 99 percent of a key solute *i* into the extract and 99 percent of an impurity solute *j* into the raffinate. For illustration, let $K_i = 2.0$ and $K_j = 0.5$, so $\alpha_{ij} = 4$. From Eq. (15-99), the extraction-solvent-to-wash-solvent ratio should be about $S/W = 1.0$ for a symmetric separation. The number of theoretical stages is estimated by using Eq. (15-100): $S_{ij} = 99 \times 99 = 9801$ gives $N \approx 12$ total stages for $\alpha_{ij} = 4$. When one is evaluating candidate solvent pairs for a proposed fractional extraction process, a useful first step is to measure the equilibrium *K* values for product and impurity solutes and then assess process feasibility by using Eqs. (15-99) and (15-100). This can provide a quick way of assessing whether the measured separation factor is sufficiently large to achieve the separation goals, using a reasonable number of stages.

**Single-Solvent Fractional Extraction with Extract Reflux** As discussed earlier, single-solvent fractional extraction with extract reflux is practiced in the petrochemical industry to separate aromatics from crude hydrocarbon feeds. For example, a variety of extraction processes utilizing different high-boiling, polar solvents are used to separate benzene, toluene, and xylene (BTX) from aliphatic hydrocarbons and naphthenes (cycloalkanes), although processes involving extractive distillation are displacing older extraction processes. A typical hydrocarbon feed is a distillation cut containing mostly $C_5$ to $C_9$ components. Commercial extraction processes include the UDEX process (employing mainly diethylene and/or triethylene glycol), the AROSOLVAN process (*N*-methyl-2-pyrrolidone), and the Sulfolane process (2,3,4,5-tetrahydrothiophene-1,1-dioxide), among others. Although the flow diagrams for these processes differ, they all involve the use of a liquid-liquid extractor followed by a top-fed extract stripper or extractive distillation tower. A number of different processing schemes are used to isolate the aromatics and recycle the heavy solvent. Note that only high-boiling solvents are used. This is because a high-boiling (or low-volatility) solvent allows the aromatics to be taken as a distillate product and avoids the increased energy usage of boiling the recycle solvent overhead. For detailed discussion, see T. C. Lo, M. H. I. Baird, and C. Hanson, eds., *Handbook of Solvent Extraction*, chaps. 18.1 to 18.3, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991; A. A. Gaile et al., *Chem. Technol. Fuels Oils* **40**(3): 131–136, and **40**(4): 215–221 (2004); and D. F. Schneider, *Chem. Eng. Prog.* **100**(7): 34–39 (2004).

Consider a process scheme involving a liquid-liquid extractor followed by a top-fed extract stripper and a product recovery distillation tower (as illustrated in Fig. 15-2). In the extractor, the feed is contacted with the polar solvent to transfer aromatics into the solvent phase. Some nonaromatics (NAs) also transfer into the solvent. The stripper is used to remove low-boiling NAs plus some aromatics from the extract to generate a reflux stream. The stripper overheads also contain some high-boiling NAs because their low solubility in the polar solvent boosts their relative volatility in the stripper. In this respect, the stripper functions as an extractive distillation tower with the high-boiling polar solvent serving as the extractive distillation solvent (serving to force high-boiling NAs overhead by increasing their activity coefficients in solution). The stripper bottoms are sent to a product recovery tower where an aromatic product cut is removed overhead and the high-boiling solvent is removed in the bottoms for return to the extractor. The stripper overheads are condensed and returned to the washing section of the extractor (the bottom of the extractor in this case) to provide reflux. As this backwash of reflux passes up through the extractor, the aromatics and a portion of the low-boiling NAs transfer back into the solvent phase, preferentially displacing high-boiling NAs which transfer out of the extract phase because of their lower solubilities in the polar solvent. Without extract reflux, the concentration of higher-boiling NAs in the extract phase would be significantly higher, and they would be difficult to completely remove in the stripper in spite of their low solubilities in the polar solvent. In this manner, low-boiling aromatics and NAs tend to build up in the extract reflux loop to provide a sort of barrier that minimizes the entry of higher-boiling NAs into the extract phase.

The use of simulation software to analyze this type of process is illustrated in Example 15-5, which considers a simplified ternary system for illustration. The simulation of an actual aromatics extraction process is more complex and can exhibit considerable difficulty converging on a solution; however, Example 15-5 illustrates the basic considerations involved in carrying out the calculations.

***Example 15-5 Simplified Sulfolane Process—Extraction of Toluene from n-Heptane*** The amount of 40 metric tons (t) per hour (t/h) of distilled catalytic reformate from petroleum refining, containing 50 percent by weight aromatics, is to be extracted with recovered sulfolane containing 0.4 vol% aromatics in a 10-stage column contactor operating nearly adiabatically at 3 bar (gauge pressure). The extract will be fed to a 10-stage top-fed extract/paraffin stripper operating at 1 bar gauge to recover 98 percent of the aromatics with no more than 500 ppm by weight of nonaromatics. The catalytic reformate at 90°C is fed into the extractor on the fourth stage up from the bottom, and the recovered sulfolane leaving the bottom of a solvent recovery tower at 185°C is cross-exchanged with the extract stream leaving the bottom of the extractor before being fed to the top of the extractor at 105°C. Extract reflux is returned from the paraffin stripper's condenser to the bottom of the extractor with subcooling to 105°C.

1. What solvent flow and stripper reboiler duty are required to achieve the performance specifications, and what are the extract reflux rate and composition?
2. If the required aromatics recovery is increased to 99 percent, what is the effect on solvent flow and stripper reboiler duty?

In real-world commercial catalytic reformate streams, a wide range of aromatic and nonaromatic hydrocarbons must be considered, and the liquid-liquid extraction and distillation simulation becomes quite complicated. In addition, real-world applications of sulfolane extraction normally add a few percent of water to the sulfolane to reduce its pure-component freezing point of 27 to 28°C during shipping and storage [Kosters, W. C. G., chap. 18.2.3 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983; Krieger, Huntington, NY, 1991]. Also, in many processes, steam is injected into the bottom of the solvent recovery tower to help strip the aromatics (i.e., the tower is both steam-stripped and reboiled), allowing operation of the tower at higher pressures without incurring (excessive) solvent thermal degradation. Another issue associated with the solvent recovery tower is the buildup of low-volatility impurities such as tars and waxes in the recycle solvent bottoms returning to the extractor. This requires continuous or periodic purging of some of the recycled solvent to avoid accumulating tars. Furthermore, in a real-world process, water may be used to wash the raffinate to recover solvent. To simplify the problem for this example, however, we model the aromatics as toluene and the NAs as *n*-heptane, consider only sulfolane as the extraction solvent, and do not include water in the calculations—to reduce the problem to a simple ternary system for illustration.

As in Example 15-4, the EXTRACT block in the Aspen Plus process simulation program (Release 27.0) is used to model this problem, but any of a number of process

**TABLE 15-10 NRTL Binary Interaction Parameters for Example 15-5**

| Component $i$ | Component $j$ | $b_{ij}$, K |
|---|---|---|
| *n*-Heptane | Toluene | 23.2040 |
| Toluene | *n*-Heptane | –34.3180 |
| Toluene | Sulfolane | 238.952 |
| Sulfolane | Toluene | 203.243 |
| *n*-Heptane | Sulfolane | 1476.41 |
| Sulfolane | *n*-Heptane | 719.006 |

$\tau_{ij} = b_{ij}/T$ (K); $\alpha_{ij} = 0.2$ for *n*-heptane + sulfolane; $\alpha_{ij} = 0.3$ for toluene + sulfolane and for *n*-heptane + sulfolane. Aspen Plus regression parameters $a_{ij}$, $d_{ij}$, $e_{ij}$, and $f_{ij}$ are set to zero; $c_{ij} = \alpha_{ij}$; $\tau_{ii} = 0$; and $G_{ii} = 1$.

simulation programs such as mentioned earlier may be used for this purpose. The first task is to obtain an accurate fit of some applicable liquid-liquid equilibrium (LLE) data with an appropriate model, realizing that liquid-liquid extraction simulations are very sensitive to the quality of the LLE data fit and that estimation methods such as UNIFAC will often give misleading results for LLE that will give incorrect extractor modeling results. The NRTL liquid activity-coefficient model is utilized for this problem because it can represent a wide range of LLE systems accurately. Model parameters must be determined by regression of experimental data. The regression of the NRTL binary interaction parameters is performed within Aspen Plus in the Properties environment using the Regression run mode to ensure that the resulting parameters are consistent with the form of the NRTL model equations used within Aspen Plus.

Because the extractor operates nearly isothermally, only slightly above and below 100°C, the 100°C data of R. M. De Fre and L. A. Verhoeye [*J. Appl. Chem. Biotechnol.* **26:** 469–487 (1976)] are used as the basis for the toluene + *n*-heptane + sulfolane LLE. And because of the liquid-liquid miscibility gap for the *n*-heptane + sulfolane binary, the NRTL $\alpha_{ij}$ parameter for this pair is given a value of 0.2. The NRTL $\alpha_{ij}$ parameters for toluene + sulfolane and *n*-heptane + toluene are allowed to remain at the Aspen default value of 0.3 because of their low levels of nonideality. The temperature dependence of $\alpha_{ij}$ is set to zero (Aspen Plus parameter $d_{ij} = 0$). In Aspen Plus, the $\tau_{ij}$ parameter may be regressed as a function of temperature by using the expression $\tau_{ij} = a_{ij} + b_{ij}/T + e_{ij} \ln T + f_{ij}T$. In this example, all the regression parameters are set to zero except $b_{ij}$. The component activity coefficients are chosen as the objective function for the regression to obtain a fit that models the liquid-liquid *K* values closely, generally found to be within 5 to 10 percent in this case. The resulting $b_{ij}$ binary parameters given in Table 15-10 are then entered into the properties section of the Aspen Plus flow sheet simulation. Pure-component properties were taken from the standard Aspen Plus pure-component databases supplied with the program.

The major unit operations in the sulfolane process usually include an extractor, paraffin stripper, solvent recovery tower, raffinate wash tower, solvent regenerator, and numerous heat exchangers; but for the purposes of this example, the simulation includes only the extractor, paraffin stripper, and extract/recovered solvent cross-exchanger—the portion of the flow sheet shown in Fig. 15-2 outlined by dotted lines. It should be recognized that the exclusion of the solvent recovery tower ignores the highly interactive behavior of the extractor, stripper, and recovery tower; but this is done here to simplify the analysis for the purposes of illustration. Note that the stripper's condenser is modeled as a separate Aspen Plus HEATER block rather than being included in the stripper block, because the Aspen Plus RADFRAC multistage distillation block used to model the stripper requires some distillate reflux if a condenser is included within the block, and generally none is required for the top-fed stripper in the sulfolane process. As a result, the stripper RADFRAC block is specified with no condenser. Also note that in the sulfolane process, the sulfolane solvent enters the top of the extractor, as it is denser than the catalytic reformate feed stream.

The 40,000 kg/h of catalytic reformate fed to stage 7 (counting from the top according to the convention in the EXTRACT block) is modeled as 50/50 *n*-heptane/toluene on a mass basis, and the residual aromatic content of the recovered sulfolane fed to the top of the extractor is 0.4 vol% toluene as given in the problem statement. As an initial guess, the sulfolane rate to the extractor was set at 120,000 kg/h or a solvent-to-feed ratio of 3.0. Depending on the feedstock, solvent-to-feed ratios can range from about 2.0 to 4.0 [Huggins, R., Paper No. 67c, AIChE Spring Meeting, Houston, March, 1997]. In the EXTRACT block, sulfolane must be specified as the key component in the first liquid phase, and *n*-heptane must be specified as the key component in the second liquid phase, because the EXTRACT block requires that the first liquid be the one exiting the bottom of the extractor. A constant-temperature profile of 105°C in the extractor is entered as an initial estimate. The rest of the block parameters (convergence, report, and miscellaneous block options) are allowed to remain at their default values.

The paraffin stripper RADFRAC block is specified with feed to the first of 10 stages, a reboiler but no condenser, a 1-bar gauge top pressure, no internal pressure drop, and a molar boil-up ratio (boil-up rate/bottoms rate) of 0.2 as an initial guess. An internal RADFRAC design specification is entered to vary the boil-up ratio from 0.10 to 0.30 to achieve a mass purity of 500 ppm *n*-heptane in the stripper bottoms on a sulfolane-free basis. To aid RADFRAC convergence, the standard algorithm was changed to Petroleum/Wide-boiling (Sum-Rates) because of the large volatility difference between the hydrocarbons and the sulfolane solvent.

A separate flow sheet Design Spec block (termed a *controller* block in some other simulators) is entered to vary the solvent feed rate to the extractor to achieve the required 98 percent toluene recovery. In addition, the extract reflux stream is called out as the flow sheet tear stream in a Wegstein convergence block to provide proper block sequencing in the simulation. (This is a numerical technique used to accelerate convergence to a solution.) Because the EXTRACT block will not execute with zero extract reflux flow to the bottom of the extractor, an initial guess is required for that stream: 10,000 kg/h of 50/50 by weight *n*-heptane/toluene at 100°C is chosen.

During simulation execution, we found that reflux tear stream convergence with the default Wegstein parameters is very oscillatory, with no convergence even with maximum iterations raised to 200. As a result, significant damping needs to be provided in the convergence block. We raised the bounds of the Wegstein *q* acceleration parameter to be between 0.75 and 1.0 for nearly full damping, after which flow sheet convergence was achieved in less than 10 iterations of every reflux tear stream loop. We also found that good initial guesses and bounds on variables needed to be set to keep the simulation from converging to an aberrant solution that was not physically valid.

With these modifications, the result is that 125,300 kg/h of sulfolane feed to the extractor is required to recover 98 percent of the toluene in the simplified reformate feed. The stage-by-stage mass fraction profile in the extractor is given in Table 15-11, from which we can see that there is very little change in concentration in either phase

from the feed stage downward. This is so because in our simplified example we have only a single NA hydrocarbon component (*n*-heptane) to deal with, so the benefit of a backwash section in the extractor below the feed is not apparent. In a real-world profile, however, concentrations of higher-boiling NAs would decrease from the feed point to the bottom of the extractor. Also given in Table 15-11 are stage-by-stage $K''$ values and volumetric flows as well as the separation factor (toluene with respect to *n*-heptane) and the extraction factor profiles in the extractor. From these we can see that the separation factor for toluene with respect to *n*-heptane varies from about 6 at the bottom of the extractor to 12 at the top, and that the extraction factor is about 2 above the feed and about 6 below the feed. These separation factors are somewhat higher than the value of 4 or so normally seen in real-world aromatic extraction cases; this, too, is an artifact of the simplified ternary system used to model the process.

Another result of the simulation is that a molar boil-up ratio of 0.14 is required in the stripper to achieve the bottoms mass purity of 500 ppm *n*-heptane considering only the hydrocarbons (solvent-free basis). This boil-up ratio corresponds to a reboiler duty of 3692 kW, or roughly 6700 kg/h of 12-bar gauge steam, and it results in 12,933 kg/h of extract reflux for an extractor reflux-to-feed ratio of 0.323. Compositions and rates of the extract, raffinate, reflux, and stripper bottoms streams are given in Table 15-12.

To determine the solvent flow and other conditions required to achieve 99 percent toluene recovery, we merely need to change the specification of the recovery Design Spec block from 98 to 99 percent and reconverge the simulation. With this change and an additional 180 total reflux tear stream iterations, the result is that 209,300 kg/h of sulfolane feed to the extractor is required, 1.7 times the amount needed for 98 percent toluene recovery. A molar boil-up ratio of 0.178 is required in the stripper to maintain the bottoms mass purity of 500 ppm *n*-heptane on a solvent-free basis, even lower than that for the 98 percent recovery case. Likewise, only a slightly higher extract reflux rate is required, 15,073 kg/h, for an extractor reflux-to-feed ratio of 0.377. However, this boil-up ratio corresponds to a reboiler duty of 7022 kW, or roughly 12,800 kg/h of 12-bar gauge steam, about 90 percent higher than for the 98 percent recovery case. The much higher stripper reboiler duty required for 99 percent recovery results from the significantly greater sulfolane feed rate, indicating that the sizes of the extractor and stripper as well as the energy consumption would need to be significantly greater for that increased recovery, probably making it uneconomical in most applications with a 10-stage extractor and stripper. Compositions and rates of the extract, raffinate, reflux, and stripper bottoms streams for the 99 percent recovery case are also given in Table 15-12.

A recent study by A. F. Seibert, W. E. de Villiers, and J. L. Bravo [Paper No. 401b, AIChE Annual Meeting, San Francisco, 2016] provides experimental data on flooding capacities and mass transfer efficiencies of sieve trays for the extraction of toluene from *n*-heptane with sulfolane in a small-scale (10 cm diameter) continuous extractor at ambient temperature. Applying the performance data from this study, we can estimate preliminary values for extractor diameter, tray count, and overall length for a full-scale sieve plate extractor. A final design would require a more rigorous analysis and consultation with the extractor internals supplier.

Examining the stage-by-stage volumetric flows of the two phases in Table 15-11, we can see that the maximum combined flow occurs in the feed stage, stage 7, at a volumetric sulfolane-to-heptane phase ratio of 2.35. In the Seibert study, the flood point on the sieve trays at a phase ratio of 2.35 was measured at a continuous (heptane) phase velocity of 0.54 cm/s, so a conservative design velocity at 50 percent of that value was chosen, 0.27 cm/s. Referring to a plot of overall tray efficiency versus continuous phase velocity in the study, the average tray efficiency at that velocity is extrapolated to be 10.4 percent, which is in the lower mid-range of the measured tray efficiencies in the small-scale extractor. Applying the design phase velocity of 0.27 cm/s to the maximum volumetric heptane phase flow rate of 61.5 $m^3/h$ in stage 7 yields an extractor cross-sectional area of 6.33 $m^2$ and a diameter of 2.84 m. Applying the design overall tray efficiency of 10.4 percent to the theoretical stage count of 10 results in a projected actual tray count of 96. This is quite a high tray count for a single extractor and is reported here only to illustrate the design method. In real-world applications, the tray count can be much lower because commercial-scale sieve tray extractors are designed with higher tray spacing and are operated at elevated temperatures. As a result, commercial tray efficiencies can be up to 25 percent, which is much higher than the laboratory study used as the basis for our example. (See the subsection Tray Efficiency under Sieve Tray Columns in Static Extraction Columns.)

## EXTRACTOR SELECTION

The common types of commercially available extraction equipment and their general features are outlined in Table 15-13. The choice of extractor type depends upon many factors, including the required number of theoretical stages or transfer units, required residence time (due to slow or fast extraction kinetics or limited solute stability), required production rate, tolerance to fouling, ease of cleaning, and availability of the required materials of construction, as well as the ability to handle high or low interfacial tension, high or low density difference, and high or low viscosities. Other factors that influence the choice of extractor include familiarity and tradition (the preferences among designers and operating companies often differ), confidence in scale-up, height constraints, and, of course, the relative capital and operating costs. The flexibility of the extractor to adjust to changes in feed properties also can be an important consideration. For example, compared to a static extractor, a mechanically agitated extractor typically provides a greater turndown ratio (ability to handle a wider range of flow rates), and agitation intensity can be adjusted in the field as needed to accommodate changes in the feed over time. Other factors that may be important include the ability to operate under pressure, to handle corrosive, highly toxic, or flammable materials, and to meet maintenance requirements, among many other possible considerations. Experience with applications similar to the current application and the use of pilot-plant testing play important roles in equipment selection. Pilot testing can address critical issues including demonstration of separation capabilities and equipment scale-up. The simplest extractor design that can meet the process requirements generally will be selected over other competing designs.

Figure 15-29 outlines the decision process recommended by L. A. Robbins [sec. 1.9 in *Handbook of Separation Techniques for Chemical Engineers*, 3d ed., ed. P. A. Schweitzer, McGraw-Hill, New York, 1997]. As an aid to decision making, Robbins recommends characterizing the feed by measuring

**TABLE 15-13 Common Liquid-Liquid Extraction Equipment and Applications**

| Type of extractor | General features | Fields of industrial application |
|---|---|---|
| Static extraction columns<br>Spray column<br>Baffle column<br>Packed column (random and structured packing)<br>Sieve tray column | Deliver low to medium mass-transfer efficiency, simple construction (no internal moving parts), low capital cost, low operating and maintenance costs, best suited to systems with low to moderate interfacial tension, can handle high production rates | Petrochemical<br>Chemical<br>Food |
| Mixer-settlers<br>Stirred-vessels with integral or external settling zones | Can deliver high stage efficiencies with long residence time, can handle high-viscosity liquids, can be adjusted in the field (good flexibility), with proper mixer-settler design can handle systems with low to high interfacial tension, can handle high production rates | Petrochemical<br>Nuclear<br>Fertilizer<br>Metallurgical |
| Rotary-agitated columns<br>Rotary disc contactor (RDC)<br>Asymmetric rotating disc (ARD) contactor<br>Oldshue-Rushton column<br>Scheibel column<br>Kühni column | Can deliver moderate to high efficiency (many theoretical stages possible in a single column), moderate capital cost, low operating cost, can be adjusted in the field (good flexibility), suited to low to moderate viscosity (up to several hundred centipoise), well suited to systems with moderate to high interfacial tension, can handle moderate production rates | Petrochemical<br>Chemical<br>Pharmaceutical<br>Metallurgical<br>Fertilizer<br>Food |
| Reciprocating-plate column<br>Karr column | Can deliver moderate to high efficiency (many theoretical stages possible in a single column), moderate capital cost, low operating cost, can be adjusted in the field (good flexibility), well suited to systems with low to moderate interfacial tension including mixtures with emulsifying tendencies, can handle moderate production rates | Petrochemical<br>Chemical<br>Pharmaceutical<br>Metallurgical<br>Food |
| Pulsed columns<br>Packed column<br>Sieve tray column | No internal moving parts, can deliver moderate to high efficiency, can handle moderate production rates, well suited to highly corrosive or toxic feeds requiring a hermetically sealed system | Nuclear<br>Petrochemical<br>Metallurgical |
| Centrifugal extractors | Allow short contact time for unstable solutes, minimal space requirements (minimal footprint and height), can handle systems with low density difference or tendency to easily emulsify | Petrochemical<br>Chemical<br>Pharmaceutical<br>Nuclear |

a flooding curve using a 1-in-diameter reciprocating-plate (Karr column) miniplant extractor. This is a plot of maximum specific throughput (close to flooding) versus agitation intensity in the Karr column. The position of the resulting curve may be used to identify the type of extractor best suited for commercial development, as illustrated in Fig. 15-30. The flooding curve reflects the liquid-liquid dispersion behavior of the system, and so it can point to options most in line with those properties. The test typically requires 40 to 200 L of feed materials (10 to 50 gal).

A number of equipment selection guides have been published. H. R. C. Pratt and C. Hanson [chap. 16 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991] provide a detailed comparison chart for 20 equipment types considering 14 characteristics. H. R. C. Pratt and G. W. Stevens [chap. 8 in *Science and Practice of Liquid-Liquid Extraction*, vol. 1, ed. J. D. Thornton, Oxford University Press, Oxford, UK, 1992] modified the Pratt and Hanson selection guide to include solvent volatility and flammability design parameters. J. Stichlmair [*Chem. Ing. Tech.* **52**(3): 253–255 (1980)] and T. L. Holmes, A. E. Karr, and R. W. Cusack [AIChE Summer National Meeting, August, 1987] compared performance characteristics of various equipment designs in the form of a Stichlmair plot. This is a plot of typical mass-transfer efficiency versus characteristic specific throughput ( for combined feed and solvent flows) for various types of extractors. Figure 15-31 represents typical performance data generated by using various small-diameter (2- to 6-in, equal to 5- to 15-cm) extractors. This type of plot is intended for use in comparing the relative performance of different extractor types and can be very helpful in this regard. It should not be used for design purposes.

Volumetric efficiency is another characteristic used to compare the different types of extractors. It can be expressed as the product of specific throughput (including feed and extraction solvent) in total volumetric flow rate per unit area (or a characteristic liquid velocity) times the number of theoretical stages achieved per unit length of extractor. It has the units of stages per unit time, or simply reciprocal time ($h^{-1}$). Thus, volumetric efficiency is inversely proportional to the volume of the column needed to perform a given separation. The Karr reciprocating-plate extractor provides relatively high volumetric efficiency, as it has both a high capacity per unit area and a high number of stages per meter. The Scheibel rotary-impeller column also can provide a high number of stages per meter, but the column throughput typically is less than that of a Karr column, so volumetric efficiency is less. Thus, for a given separation a Scheibel column might be somewhat shorter than a Karr column, but it will need to have a larger diameter to process the same flow rate of feed and extraction solvent. The sieve plate extractor generally exhibits moderate to high throughput, but the number of stages per meter typically is low. The Graesser raining-bucket contactor exhibits low to moderate throughput, but it is reported to have a high separating capability in certain applications.

The ability of an extractor to tolerate the presence of surface-active impurities also may be an important factor in choosing the most appropriate design. A. E. Karr, T. L. Holmes, and R. W. Cusack [*Solvent Extraction and Ion Exchange* **8**(30): 515–528 (1990)] investigated the performance of small-diameter agitated columns and found that the performance of a rotating-disk contactor (RDC) declined faster on addition of trace surface-active impurities compared to the Karr or Scheibel column. The test results indicate that care should be taken when comparing pilot tests of different types of extractors when the data were generated by using high-purity materials. The presence of surface-active impurities can lower column capacity by 20+ percent and efficiency by as much as 60 percent.

Production capacity also may be a deciding factor. Some extractors are available only in small to moderate sizes suitable for low to moderate production rates, as in specialty chemical manufacturing, while others are available in very large sizes designed to handle the very high production rates needed in the petroleum and petrochemical industries. An estimate of relative production rates ( feed plus solvent) for selected extractors is given in Table 15-14. Note that the numbers are intended to represent approximate maximum values for a rough comparison. The actual values likely will vary depending upon the particular application. Keep in mind that the relative mass-transfer performance of the various designs is not represented in Table 15-14, and that very large-diameter columns are limited as to how tall they can be built.

## HYDRODYNAMICS OF COLUMN EXTRACTORS

**Flooding Phenomena** The hydraulic capacity of a countercurrent extractor is constrained by breakthrough of one liquid phase into the discharge stream of the other, a condition called *flooding*. The point at which an extractor floods is a function of the design of the internals (as this affects the pressure drop and holdup characteristics of the extractor), the solvent-to-feed ratio and physical properties (as this affects the liquid-liquid

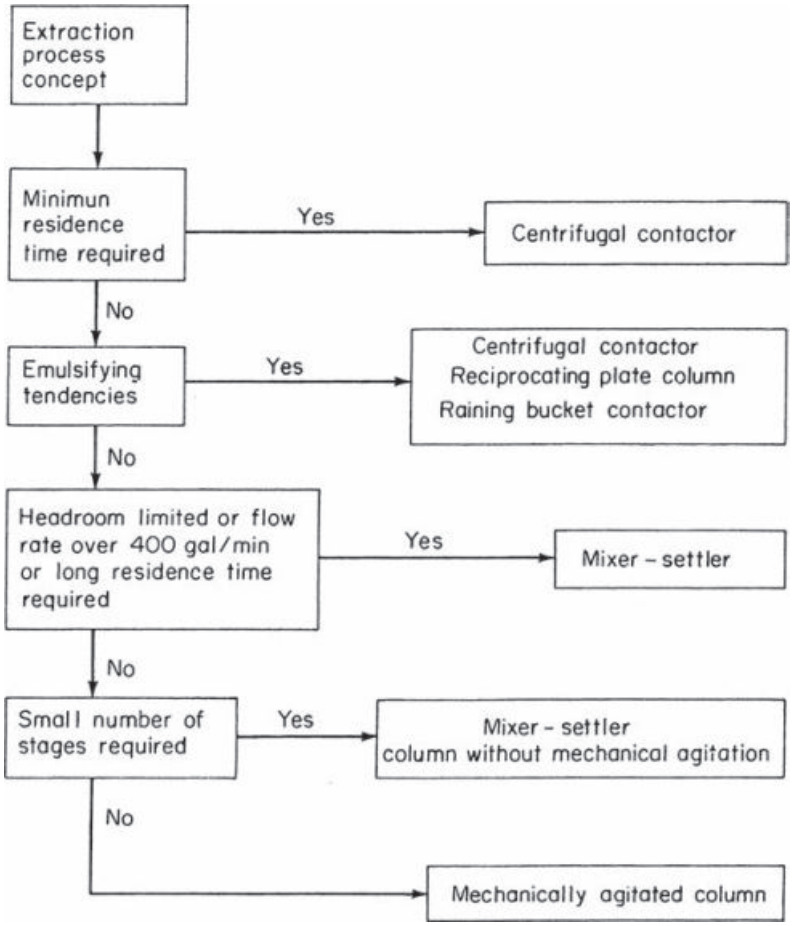

**FIG. 15-29** Decision guide for extractor selection. [*Reprinted from Robbins, Sec. 1.9 in* Handbook of Separation Techniques for Chemical Engineers, *3d ed., Schweitzer, ed., McGraw-Hill, New York, 1997), with permission. Copyright 1997 McGraw-Hill, Inc.*]

dispersion behavior), the agitation intensity (if agitation is used), and the specific throughput. The latter often is expressed in terms of the volumetric flow rate per cross-sectional area; or, equivalently, in terms of liquid velocity. A plot of the maximum throughput that can be sustained just prior to flooding versus a key operating variable is called a flooding curve. Ideally, extractors are designed to operate near flooding to maximize productivity. In practice, however, many new column extractors are designed to operate at 40 to 60 percent of the predicted flood point because of uncertainties in the design, process impurity uncertainties, and to allow for future capacity increases. This practice varies from one type of extractor to another and one designer to another. In a static extraction column, countercurrent flow of the two liquid phases is maintained by virtue of the difference in their densities and the pressure drop through the equipment. Only one of the liquids may be pumped through the equipment at any desired flow rate or velocity; the maximum velocity of the other phase is then fixed by the flood point. If an attempt is made to exceed this hydraulic limit, the extractor will flood.

In extraction equipment, flooding may occur through a variety of mechanisms [Seibert, A. F., J. L. Bravo, and J. R. Fair, *ISEC '02 Proc.* **2:** 1328–1333 (2002)]:

1. Excessive flow rates of either dispersed-phase or continuous-phase, or high agitation intensity, cause dispersed-phase holdup or population density to exceed the volumetric capacity of the equipment.
2. Excessively high continuous-phase flow rate causes excessive entrainment of dispersed phase into the continuous-phase outlet.
3. Inadequate drop coalescence causes the formation of dispersion bands or layers of uncoalesced drops that entrap continuous phase between them. The continuous phase can then be entrained into the wrong outlet.
4. Operation at a high ratio of dispersed phase to continuous phase results in phase inversion. (See the subsection Liquid-Liquid Dispersion Fundamentals.)
5. Operating too close to the liquid-liquid phase boundary causes complete miscibility during an upset. This might be caused by a slight change in solvent or feed rates, by an increase in the concentration of solute in the feed, or by introduction of a surface-active impurity.
6. In sieve tray columns, excessive orifice and/or downcomer pressure drop within the extractor causes the formation of large coalesced layers that back up and overflow the trays. This might be caused by operation outside of the designed flow rates, or by fouling of the internals resulting in increased pressure drop.
7. Poor interface control allows the main liquid-liquid interface to leave the extractor. This may result from inadequate size of interface flow control valves, or operation with internals that provide inverse control responses such as those observed with sieve tray extractors. (See the subsection Process Control Considerations.)
8. Fouling and plugging of internals or the outlet flow control valves.

**Accounting for Axial Mixing** Differential-type column extractors are subject to axial (longitudinal) mixing, also called axial dispersion and generally referred to as backmixing. This condition refers to a departure from uniform plug flow of the swarm of dispersed drops as drops rise or fall in the column, as well as any departure from plug flow of continuous phase in the opposite direction. As a result of axial mixing, the elements of the dispersed phase and the continuous phase exhibit a distribution of residence times within the equipment, and this decreases the effective or overall concentration driving force in the contactor. Because of this effect, the actual column must be taller than simple application of an ideal, plug flow model would indicate. When one is approaching the design of a contactor, factors that may contribute to axial mixing should be considered so that measures might be taken to reduce their effects. This may involve the design of baffles to help direct the liquid traffic within the column. Also, if the transfer of solute occurs such that the continuous phase is significantly denser at the top of an extraction column than at the bottom, this may encourage circulation of continuous phase, and it may be advisable to switch the phase that is dispersed. For more information on this effect, see T. L. Holmes, A. E. Karr,

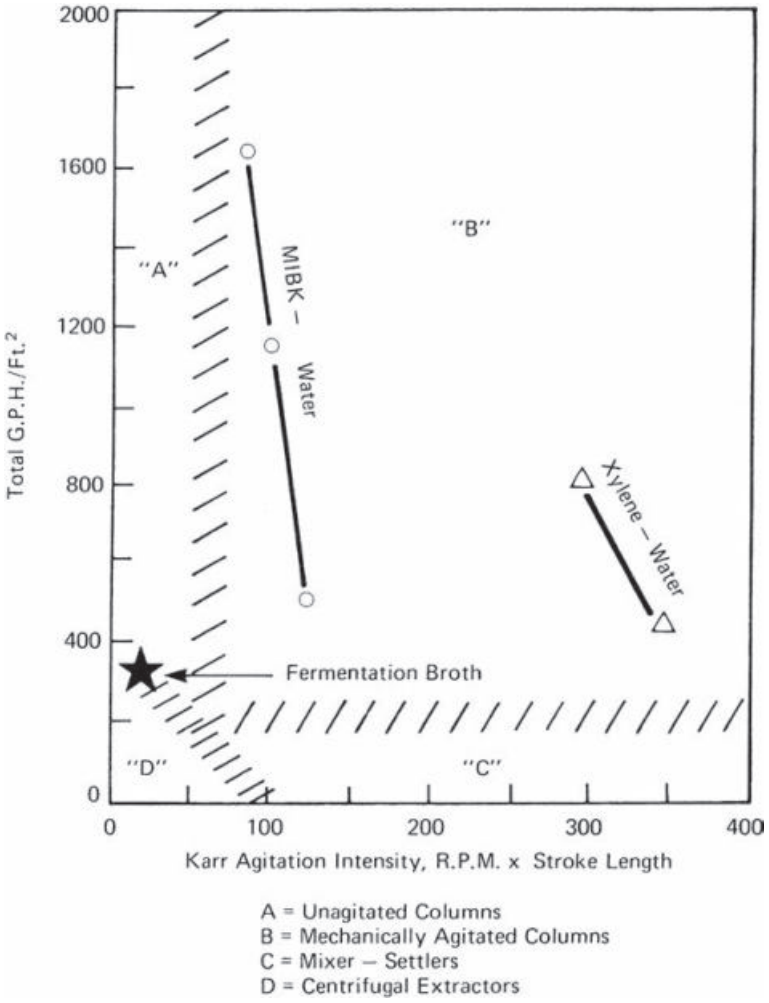

**FIG. 15-30** Typical Karr column flooding characteristics. Example flooding data are shown for two applications involving MIBK + water and xylene + water ( flooding occurs to the right of the indicated flooding curve). A data point for extraction of a fermentation broth is indicated by the star. Results will vary depending upon process variables including solute concentration, the presence of other solutes, and temperature. [*Reprinted from Robbins, Sec. 1.9 in* Handbook of Separation Techniques for Chemical Engineers, *3d ed., Schweitzer, ed., McGraw-Hill, New York, 1997), with permission. Copyright 1997 McGraw-Hill, Inc.*]

and M. H. I. Baird, *AIChE J.* **37**(3): 360–366 (1991); and K. Aravamudan and M. H. I. Baird, *AIChE J.* **42**(8): 2128–2140 (1996).

Axial mixing effects commonly are taken into account by using a diffusion analogy and an axial mixing coefficient $E$, also called the longitudinal dispersion coefficient or eddy diffusivity, to account for the spreading of the concentration profiles. At steady state, the conservation equation has the general form

$$E\frac{\partial^2 C}{\partial z^2}+V\frac{\partial C}{\partial z}+k_o a(C-C^*)=0 \qquad (15\text{-}101)$$

where $V$ is phase velocity, $k_o$ is an overall mass-transfer coefficient, $C$ is solute concentration (mass or moles per unit volume), and the superscript asterisk denotes equilibrium. By using Eq. (15-101) as a foundation, the required height of extractor may be calculated from a simplified plug flow model plus application of a correction factor expressed as a function of $E$ or a Péclet number Pe = $Vb/E$, where $b$ is a characteristic equipment dimension. The required values of $E$ must be determined by experiment. For example, calculations based on the application of mass-transfer coefficients and calculation of interfacial area from drop size and holdup correlations will need to be corrected for axial dispersion as a function of column size. A variety of axial mixing models and data correlations have been developed for various types of column extractors. For detailed discussion, see C. A. Sleicher, *AIChE J.* **5**(2): 145–149 (1959); T. Vermeulen et al., *Chem. Eng. Prog.* **62**(9): 95–102 (1966); and N. N. Li and E. N. Zeigler, *Ind. Eng. Chem.* **59**(3): 30–36 (1967). Also see the detailed discussions in G. S. Laddha and T. E. Degaleesan, *Transport Phenomena in Liquid Extraction*, McGraw-Hill, New York, 1978; H. R. C. Pratt and M. H. I. Baird, chap. 6 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991; and J. C. Godfrey and M. J. Slater, eds., *Liquid-Liquid Extraction Equipment*, Wiley, New York, 1994. The method used by O. Becker [*Chem. Eng. Technol.* **26**(1): 35–41 (2003)] is discussed in the subsection Static Extraction Columns.

Computational fluid dynamics (CFD) simulations are beginning to be developed for certain types of extractors to better understand flow patterns. The simulation of two-liquid-phase flows around complex internals is an active research area. Examples include CFD calculations for a rotating-disk contactor by G. Modes and H.-J. Bart [*Chem. Eng. Technol.* **24**(12): 1242–1244 (2001)] and CFD calculations for a pulsed column extractor by A. Amokrane et al. [*Can. J. Chem. Eng.* **92:** 220–233 (2014)].

**Liquid Distributors and Dispersers** It should be recognized that the performance of a column extractor can be significantly affected by how uniformly the feed and solvent inlet streams are distributed to the cross section of the column. The requirements for distribution and redistribution vary depending upon the type of column internals (packing, trays, agitators, or baffles) and the impact of the internals on the flow of dispersed and continuous phases within the column. Important considerations in specifying a distributor include the number of holes and the hole pattern (geometric layout), hole size, number of downcomers or upcomers (if used) and their placement, the maximum to minimum flow rates the design can

handle (turndown ratio), and resistance to fouling. Various types of liquid distributors are available, including sieve tray dispersers and ladder-type pipe distributors designed to give uniform distribution of drops across the column cross section. (See the subsection Packed Columns and Sieve Tray Columns under Liquid-Liquid Extraction Equipment for more information about these. The height of the coalesced layer on a disperser plate may be calculated by using the method described in Sieve Tray Columns.) Ring-type distributors also are used, primarily for agitated extractors. Equipment vendors should be consulted for additional information.

Typical hole sizes for distributors and dispersers are between 0.05 in (1.3 mm) and 0.25 in (6.4 mm). Small holes should be avoided in applications where the potential for plugging or fouling of the holes is a concern. For plate dispersers, the holes should be spaced no closer than about 3 hole diameters to avoid coalescence of drops emerging from adjacent holes. Design velocities for liquid exiting the holes generally are in the range of 0.5 to 1.0 ft/s (15 to 30 cm/s). Several methods have been proposed for more precisely specifying the design velocities. For detailed discussion, see A. Kumar and S. Hartland, chap. 17 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994, pp. 631–635; K. Ruff, *Chem. Ing. Tech.* **50**(6): 441–443 (1978); and G. S. Laddha and T. E. Degaleesan, chap. 11 in *Transport Phenomena in Liquid Extraction*, McGraw-Hill, New York, 1978, pp. 307–310. These methods are relevant for the design of distributors/dispersers used in all types of column extractors. The liquid should issue from the hole as a jet that breaks up into drops. The jet should yield a drop size distribution that provides good interfacial area, with an average drop size smaller than the maximum given by $d_{\max} = [\sigma/(\Delta\rho g)]^{0.5}$, but without creating small secondary drops that cause entrainment problems or formation of an emulsion. (See the subsection Size of Dispersed Drops in Liquid-Liquid Dispersion Fundamentals.) As a general guideline, the maximum recommended design velocity corresponds to a Weber number of about 12:

$$V_{o,\max} \approx \left(\frac{12\sigma}{d_o \rho_d}\right)^{1/2} \tag{15-102}$$

The minimum Weber number that ensures jetting in all the holes is about 2. It is common practice to specify a Weber number between 8 and 12 for a new design. For a detailed discussion of fundamentals, see S. Homma et al., *Chem. Eng. Sci.* **61**(12): 3986–3996 (2006).

It is well established that the dispersed phase must issue cleanly from the holes. This requires that the material of the pipe or disperser plate be preferentially wetted by the continuous phase (requiring the use of plastics or plastic-coated trays in some instances), or that the dispersed phase issue from nozzles projecting beyond the surface. For plate dispersers, these may be formed by punching the holes and leaving the burr in place [Mayfield, F. D., and W. L. Church, *Ind. Eng. Chem.* **44**(9): 2253–2260 (1952)]. Once the design velocity is set, the number of holes is given by

$$N_{\text{holes}} = \frac{Q_d}{A_o V_o} \tag{15-103}$$

where $Q_d$ is the total volumetric flow rate of dispersed phase and $A_o$ is the cross-sectional area of a single hole.

## STATIC EXTRACTION COLUMNS

**Common Features and Design Concepts** Static extractors include spray-type, packed, and trayed columns often used in the petrochemical industries (Fig. 15-32). They offer the advantages of (1) availability in large diameters for high production rates, (2) simple operation with no moving parts and associated seals, (3) requirement for control of only one operating interface, and (4) relatively small required footprint compared to mixer-settler equipment. Their primary disadvantage usually is lower mass-transfer efficiency compared to that of mechanically agitated extractors. This usually limits applications to those involving low viscosities (less than about 5 cP), low to moderate interfacial tensions (typically 3 to 20 dyn/cm equal to 0.003 to 0.02 N/m), and often no more than four to six equilibrium stages. J. Koch and G. Shiveler [*Chem. Eng. Prog.* **111**(11): 22–30 (2015)] discuss important design principles to keep in mind when translating laboratory results to

*Typical maximum value for dispersed + continuous phase flow rates.
The actual value for a given application will depend upon physical properties and rates of extraction and phase separation and may be much lower.
†Typical value. Larger diameters may be possible.
‡Throughput and equivalent diameter are based on mixer-settler footprint. Estimates based on hydrometallurgical stripping applications.
§Larger diameters possible but not recommended due to severe backmixing.
¶Higher throughput may be achieved by increasing the column open area.

the commercial scale. Although the spray column is the least efficient static extractor in terms of mass-transfer performance, due to considerable backmixing effects, it finds use in processing feeds that would easily foul other equipment. Packed column designs can provide improved mass-transfer performance by limiting backmixing. However, packed column mass transfer can be limited by backmixing, especially with larger diameter columns and high dispersed to continuous phase flow ratios. In contrast, the sieve tray column can be designed to minimize backmixing such that the efficiency scales well with column diameter. It should be noted that mechanically agitated extractors also can experience significant backmixing and a loss of efficiency with larger diameter columns.

An understanding of the general hydraulics of a static contactor is necessary for estimating the diameter and height of the column, as this affects both capacity and mass-transfer efficiency. Accurate evaluations of characteristic drop diameter, dispersed-phase holdup, relative velocity of the two phases (called slip velocity), and flooding velocities usually are necessary. Fortunately, the relative simplicity of these devices facilitates their analysis and the approaches taken to modeling performance.

***Choice of Dispersed Phase*** The great majority of extractor designs function by formation of dispersed drops to maximize contact area and mass transfer. Static extractors generally are designed with the majority phase dispersed in order to maximize dispersed-phase holdup and interfacial area needed for mass transfer; that is, the phase with the greatest flow rate entering the column generally is dispersed. The choice of dispersed phase also depends upon the relative viscosity of the two phases. If one phase is particularly viscous, it may be necessary to disperse that phase. Note that a few extractor designs involve formation of films or rivulets instead of drops for increased capacity and greater tolerance to fouling, but this approach is not common as it normally involves lower mass-transfer capability.

***Drop Size and Dispersed-Phase Holdup*** Various models used to estimate the size of dispersed drops in static extractors are listed in Table 15-15. Also see the subsection Size of Dispersed Drops under Liquid-Liquid Dispersion Fundamentals. Measurements of dispersed-phase holdup within a column-type extractor often are made by stopping all flows in and out of the extractor and measuring the change in the main interface level. This technique can be prone to significant experimental error as a result of end effects, static holdup present in small laboratory packings, inaccurate measurement of the baseline interface level, inability to instantaneously stop both inlet flows and the heavy phase outlet flow, and holdup variations within a column as flooding conditions are approached. Examples of models for prediction of holdup are provided in Table 15-16. Additional models are given in J. C. Godfrey and M. J. Slater, eds., *Liquid-Liquid Extraction Equipment*, Wiley, New York, 1994. In general, an implicit calculation of the dispersed-phase holdup is usually encountered. One must be careful in evaluating the roots of these calculations, especially in the region of high dispersed-phase holdup ($\phi_d > 0.2$).

***Interfacial Area*** The mass-transfer efficiency of most extraction devices is proportional to the area available for mass transfer (neglecting any axial mixing effects). As discussed in the subsection Liquid-Liquid Dispersion Fundamentals, for the general case where the dispersed phase travels through the column as drops, an average liquid-liquid interfacial area can be calculated from the Sauter mean drop diameter and dispersed-phase holdup:

$$a = \frac{6\varepsilon\phi_d}{d_p} \tag{15-104}$$

In most cases, the drop size distribution is not known. Various models are available to estimate the Sauter mean drop diameter and holdup for a variety of extractors (as described above).

***Drop Velocity and Slip Velocity*** The hydraulic characteristics of a static extractor depend upon drop diameter, liquid velocities, and physical properties. The average velocity of a dispersed-phase drop ($V_{\text{drop}}$) and the interstitial velocity of the continuous phase $V_{ic}$ are given by

$$V_{\text{drop}} = \frac{V_d}{\varepsilon\phi_d} \tag{15-105}$$

$$V_{ic} = \frac{V_c}{\varepsilon(1-\phi_d)} \tag{15-106}$$

where $V_d$ = superficial velocity of dispersed phase
$V_c$ = superficial velocity of continuous phase
$\phi_d$ = fraction of void volume occupied by dispersed phase
$\varepsilon$ = void fraction of column ($\varepsilon = 1.0$ for sprays and sieve trays)

The slip velocity is the velocity at which a dispersed drop moves relative to the counter-flowing continuous phase, calculated by adding the magnitudes of the two phase velocities:

$$V_s = \left|V_{\text{drop}}\right| + \left|V_{ic}\right| = \frac{V_d}{\varepsilon\phi_d} + \frac{V_c}{\varepsilon(1-\phi_d)} \tag{15-107}$$

For a dispersed-phase drop of diameter $d_p$, slip velocity can be estimated from a balance of gravitational, buoyancy, and frictional forces:

$$F_{\text{buoyancy}} - F_{\text{gravity}} - F_{\text{drag}} = 0 \tag{15-108}$$

$$F_{\text{buoyancy}} = \rho_c\left(\frac{\pi}{6}d_p^3\right)g \tag{15-109}$$

$$F_{\text{gravity}} = \rho_d\left(\frac{\pi}{6}d_p^3\right)g \tag{15-110}$$

$$F_{\text{drag}} = \frac{1}{2}C_D\rho_c\left(\frac{\pi}{4}d_p^2\right)V_{so}^2 \tag{15-111}$$

where $V_{so}$ is defined as the characteristic slip velocity obtained at low dispersed-phase flow rate. Rearranging Eqs. (15-108) to (15-111) gives

$$V_{so} = \sqrt{\frac{4\Delta\rho g d_p}{3\rho_c C_D}} \tag{15-112}$$

The slip velocity at higher holdup often is estimated from $V_s \approx V_{so}(1-\phi_d)$. Slip velocity is a key concept in various approaches to modeling dispersed-phase holdup, flooding point, and mass transfer.

Equation (15-112) provides the basis for various methods used to predict the characteristic slip velocity. It can be difficult to use for design because of difficulty estimating the drag coefficient $C_D$ and difficulty accounting for packing resistance or drop–drop interactions. The drag coefficient can be affected by internal circulation within the drop. For good mass transfer, it is most desirable to have circulating drops traveling through a relatively nonviscous continuous phase. Particular care should be taken in utilizing models developed primarily from studies involving small laboratory packings, because the packing resistance is particularly significant in that case. Also, many studies do not include low-interfacial tension systems even though most applications of static extractors involve low to moderate interfacial tension. Also note that surface-active impurities can reduce the characteristic drop velocity [Garner, F. H., and A. H. P. Skelland, *Ind. Eng. Chem.* **48**(1): 51–58 (1956); and Skelland, A. H. P., and C. L. Caenepeel, *AIChE J.* **18**(6): 1154–1163 (1972)], which is another reason to approach these models with care. For additional discussion, see T. Míšek, chap. 5 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994.

The following method is recommended for calculating slip velocity in static extractors at low dispersed-phase holdup and very low Reynolds numbers (<2):

$$\text{If } \text{Re}_{\text{Stokes}} = \frac{\rho_c\Delta\rho\, g d_p^3}{18\mu_c^2} < 2, \text{ then } V_{so} = \frac{\Delta\rho\, g d_p^2}{18\mu_c} \quad \text{(Stokes' law)} \tag{15-113}$$

For $\text{Re}_{\text{Stokes}} > 2$, Seibert and coworkers [Seibert, A. F., and J. L. Fair, *Ind. Eng. Chem. Res.* **27**(3): 470–481 (1988); and Seibert, A. F., B. E. Reeves, and J. R. Fair, *Ind. Eng. Chem. Res.* **29**(9): 1901–1907 (1990)] recommend the model of J. R. Grace, T. Wairegi, and T. H. Nguyen [*Trans. Inst. Chem. Eng.* **54:** 167 (1976)]. In this case, the characteristic slip velocity may be calculated from

$$V_{so} = \frac{\text{Re}\,\mu_c}{d_p\rho_c} \tag{15-114}$$

where Re is obtained from the correlation:

$$\frac{\text{Re}}{P^{0.149}} = 0.94H^{0.757} - 0.857 \qquad H \le 59.3 \tag{15-115}$$

$$\frac{\text{Re}}{P^{0.149}} = 3.42H^{0.441} - 0.857 \qquad H > 59.3 \tag{15-116}$$

And $P$ and $H$ are dimensionless groups defined by

$$P = \frac{\rho_c^2\sigma^3}{\mu_c^4 g\Delta\rho} \tag{15-117}$$

$$H = \left(\frac{4d_p^2 g\Delta\rho}{3\sigma}\right)\left(\frac{\mu_w}{\mu_c}\right)^{0.14} P^{0.149} \tag{15-118}$$

and $\mu_w$ is a reference viscosity equal to 0.9 cP ($9\times10^{-4}$ Pa·s). For discussion of methods to correct slip velocity for the effect of high dispersed-phase holdup, see F. Augier, O. Masbernat, and P. Guiraud, *AIChE J.* **49**(9): 2300–2316 (2003).

***Flooding Velocity*** Maximum flow through a countercurrent extractor is limited by the flooding velocity. See the subsection Hydrodynamics of Column Extractors for a general discussion of flooding mechanisms. Examples of published flooding models for static extractors are given in Table 15-17. Because of the many possible causes of flooding, many different approaches to modeling the flooding velocity have been taken. Some of the earlier flooding models were based on the idea that an extractor will enter a flooding condition as the slip velocity goes to zero. However, because flooding can occur in many different ways the results have not always proven reliable, so newer models were developed with other concepts in mind. Also, models developed from small-scale laboratory data can lead to problems when used for design of commercial-scale columns. For example, in packed columns a column-diameter to packing-diameter ratio of at least 8 is recommended to avoid channeling due to wall effects. This means that laboratory studies often utilize small packings with high specific packing surface areas (packing area/contacting volume). The high packing area likely provides significant resistance to drop flow, greater than that encountered in large columns containing large commercial packings. Also, many of the published laboratory data on flooding velocities were generated by using moderate to high-interfacial-tension systems. In this case, the packing surface area resistance can control the flooding mechanism. For these reasons, it is important to understand the background and basis for a given flooding model and assess whether it is appropriate for the given application.

Several published correlations of the flooding velocity (Table 15-17) have elements of the form

$$V_{cf} \propto C_1\frac{C_2}{a_p^n} \qquad 0 < n < 1 \tag{15-119}$$

where $V_{cf}$ is the continuous-phase velocity at which flooding occurs, $a_p$ is the specific packing surface area, and $C_1$ and $C_2$ are empirical constants that depend upon the specific type of packing, fluid physical properties, and flow ratio. While these types of models have excellent reported fits of data, they were primarily developed by using laboratory-scale packings. Furthermore, in the limit as the packing surface area approaches zero, the predicted flooding velocity becomes infinite, an unrealistic result. Care should be taken when extrapolating such models to a larger packing size.

A. F. Seibert, B. E. Reeves, and J. R. Fair [*Ind. Eng. Chem. Res.* **29**(9): 1901–1907 (1990)] have proposed an alternative model that is derived by assuming a tightly packed arrangement of drops at flooding. It has the form

$$V_{cf} = C_1 \Big/ \left[ 1 + \frac{C_2}{C_3 \cos^2(C_4 a_p)} \right] \tag{15-120}$$

where parameters $C_1$, $C_2$, $C_3$, and $C_4$ are functions of system properties and flow ratio (as in Eq. 1 in Table 15-17). An advantage of this flooding model is that as the packing surface area approaches zero, a finite flooding velocity is calculated from $\cos^2(0) = 1$. For this reason, equations in the form of Eq. (15-120) can be used to predict flooding in a spray column and the ultimate capacity of a tray column. Unfortunately, very few flooding data are available for columns greater than 30 cm (12 in) in diameter. Also, many of the available flooding data have been obtained in the absence of mass transfer. With this in mind, for new designs it is recommended that flow velocities be limited to no more than 60 percent of the calculated flooding values. The final design should be refined in miniplant or pilot-plant tests using actual feed materials.

***Drop Coalescence Rate*** The rate of drop coalescence often is assumed to be rapid (not rate-limiting) in the design of static extractors. However, this is not necessarily the case, particularly during operation at high dispersed-phase holdup and high flow ratios of dispersed phase to continuous phase. Under these conditions, a large number of drops flow through a nearly

**TABLE 15-17 Example Flooding Models for Static Extractors**

| Example | Eq. | Comments | Ref. |
|---|---|---|---|
| $V_{cf} = \dfrac{0.178\varepsilon V_{so}}{1 + 0.925(V_{df}/V_{cf})/\cos^2(\pi\zeta/4)} \qquad \zeta = \dfrac{a_p d_p}{2}$ | 1 | Generalized model for spray, packing, and ultimate capacity of sieve tray. $V_{so}$ is calculated by the method of Grace et al. (1976), Eqs. (15-114) to (15-118). | 1,2 |
| $V_{cf} = \dfrac{0.178 V_{so}}{1 + 0.925(V_{df}/V_{cf})}$ | 2 | Spray $V_{so}$ is calculated by the method of Grace et al. (1976), Eqs. (15-114) to (15-118). | 1 |
| $V_{cf} = \varepsilon C \left( \dfrac{4 g \Delta\rho\sigma}{\rho_C^2} \right)^{1/4} (1-\phi_{df})^2 [\exp(-b\phi_{df})](1 - b\phi_{df})$ | 3 | Packing | 3 |

stagnant continuous phase, and these drops must coalesce at the main operating interface located at the top or bottom of the column. A. F. Seibert, J. L. Bravo, and J. R. Fair [*ISEC '02 Proc.* **2:** 1328–1333 (2002)] report that problems with coalescence are most likely when the superficial dispersed-phase velocity $V_{df}$ is greater than about 12 percent of the characteristic slip velocity given by Eqs. (15-113) to (15-118). The rate of coalescence is influenced by the mixture's physical properties and the presence of any surface active contaminants. For these systems, miniplant tests with actual feed chemicals normally are needed to understand the rate of coalescence. If coalescence is slow, design rates will need to be reduced below those predicted by assuming rapid coalescence.

For slowly coalescing systems, the placement of coalescing material within the column at the main interface may significantly improve performance. The height of the uncoalesced layer located at the main operating interface may be reduced by adding a packing type of coalescer that is preferentially wetted by the dispersed phase. The packing may be a structured or mesh type. If plugging or fouling is a concern, a more open (lower-surface-area) structured packing may be preferred. It also may be useful to add a separate liquid-liquid phase separator outside the extractor to clarify the extract or raffinate streams. See the subsection Liquid-Liquid Phase Separation Equipment.

***Mass-Transfer Coefficients*** As discussed in the subsection Rate-Based Calculations, the overall mass-transfer coefficient may be defined based on the dispersed phase or the continuous phase, as follows:

$$\frac{1}{k_{od}} = \frac{1}{k_d} + \frac{m_{dc}^{\text{vol}}}{k_c} \tag{15-121}$$

$$\frac{1}{k_{oc}} = \frac{1}{k_c} + \frac{1}{m_{dc}^{\text{vol}} k_d} \tag{15-122}$$

where the slope of the equilibrium line $m_{dc}^{\text{vol}}$ is expressed in volumetric concentration units. The dispersed-phase and continuous-phase film coefficients $k_d$ and $k_c$ generally are functions of convection and turbulence effects, as well as molecular diffusion and the thicknesses of stagnant films at the interface between drops and the continuous phase. As mentioned earlier, normally the main resistance to mass transfer resides in the feed (raffinate) phase, so often this phase will be chosen as the basis for design calculations, whether it is the dispersed phase or the continuous phase. Examples of mass-transfer coefficient models for static extractors are given in Table 15-18. Also see A. Kumar and S. Hartland, *Trans. Inst. Chem. Eng.*,

**TABLE 15-18 Example Mass-Transfer Coefficient Models**

| Example | Eq. | Comments | Ref. |
|---|---|---|---|
| $k_c = 0.698\left(\frac{\mathcal{D}_c}{d_p}\right)\left(\frac{d_p V_s \rho_c}{\mu_c}\right)\left(\frac{\mu_c}{\rho_c \mathcal{D}_c}\right)^{0.4}(1-\phi_d)$ | 1 | For nonrigid drops. Spray, packing, and sieve trays. | 1 |
| $k_d = 0.023 V_s \sqrt{\frac{\rho_c \mathcal{D}_c}{\mu_c}}$ | 2 | Model of Laddha and Degaleesan. | 2 |
| | | For nonrigid drops. Spray, packing, and sieve trays. | 1 |
| $k_d = \frac{0.00375 V_s}{1+\mu_d/\mu_c}$ | 3 | Model of Handlos and Baron. Approximate solution to series model. Independent of molecular diffusion. Use for large drops. | 3 |
| $\Phi = \frac{\sqrt{\mu_c/\rho_c \mathcal{D}_c}}{1+\mu_d/\mu_c}$ | 4 | Spray, packing, and sieve trays. Use Eq. (3) if $\Phi < 6$. | 1 |
| $k_d = \frac{17.9 \mathcal{D}_d}{d_p}$ | 5 | Laminar circulation within drops. Recommended for long contact times. | 4 |
| | | For Re < 50. | 5 |
| $k_d = 1.14\left(\frac{\mathcal{D}_d}{d_p}\right)\left(\frac{\rho_d d_p^2 \bar{\omega}}{\mu_D}\right)^{0.56}\left(\frac{\mu_d}{\rho_d \mathcal{D}_d}\right)^{0.5}$ | 6 | For oscillating drops. Simplified version for assumption of $\theta = 0.2$. | 6 |
| $\bar{\omega} = \frac{1}{2\pi}\left[\frac{192\sigma b}{d_p^3(3\rho_d + 2\rho_c)}\right]^{0.5} \qquad b = 0.805 d_p^{0.225}, d_p \text{ in cm}$ | 7 | | |
| $k_c = \frac{\mathcal{D}_c}{d_p}\left[2 + 0.95\left(\frac{\rho_c V_s d_p}{\mu_c}\right)^{0.5}\left(\frac{\mu_c}{\rho_c \mathcal{D}_c}\right)^{0.33}\right]$ | 8 | For rigid drops. | 7 |
| $k_c = 0.725\left(\frac{\mathcal{D}_c}{d_p}\right)\left(\frac{\rho_c V_s d_p}{\mu_c}\right)^{0.57}\left(\frac{\mu_c}{\rho_c \mathcal{D}_c}\right)^{0.42}(1-\phi_d)$ | 9 | For circulating drops. Developed from correlation of spray column data. | 8 |
| $k_c = 1.4\left(\frac{\mathcal{D}_d}{d_p}\right)\left(\frac{\rho_c d_p^2 \omega}{\mu_c}\right)^{0.5}\left(\frac{\mu_c}{\rho_c \mathcal{D}_c}\right)^{0.5}$ | 10 | For oscillating drops. | 9 |

Part A, **77:** 372–384 (1999). The application of mass transfer coefficients requires calculation of interfacial area, normally from an estimate of drop size and holdup. See Tables 15-15 and 15-16 and Eq. (15-104). Note that the mass-transfer coefficient does not include the effect of axial mixing. This correction must be applied separately.

***Axial Mixing*** See the subsection Accounting for Axial Mixing under Liquid-Liquid Extraction Equipment. Many approaches have been developed as discussed earlier. Becker recommends the concept of the height of a dispersion unit (HDU) to correct the height of a transfer unit for axial mixing in a spray or packed contactor [Becker, O., *Chem. Eng. Technol.* **26**(1): 35–41 (2003); *Chem. Ing. Tech.* **74:** 59–66 (2002); and Becker, O., and A. F. Seibert, *Chem. Ing. Tech.* **72:** 359–364 (2000)]. The design procedure involves first calculating $k_o a$ and then converting the result to a transfer unit height. This calculated value is then adjusted to take into account the effect of axial mixing, which varies with column diameter and height. The general analysis has the form:

$$\mathrm{HTU} = \mathrm{HTU}|_{\mathrm{plug}} + \mathrm{HDU}_o = (V/k_o a) + \mathrm{HDU}_o \tag{15-123}$$

where

$$\mathrm{HDU}_o = \left( p_0 + \frac{0.8}{Z_t} \frac{\mathcal{E} \ln \mathcal{E}}{\mathcal{E} - 1} \right)^{-1} \tag{15-124}$$

$$p_0 = \frac{0.1 Z_t / HTU_{\mathrm{plug}} + 1}{0.1 Z_t / HTU_{\mathrm{plug}} + p_1/p_2} \cdot p_1 \tag{15-125}$$

$$\frac{1}{p_1} = \frac{1}{\mathcal{E}} \mathrm{HDU}_r + \mathrm{HDU}_e \qquad \frac{1}{p_2} = \mathrm{HDU}_r + \frac{1}{\mathcal{E}} \mathrm{HDU}_e \tag{15-126}$$

HDU is related to the axial mixing coefficient $E$ and superficial phase velocity $V$ by

$$\mathrm{HDU} = \frac{E}{V} \tag{15-127}$$

The parameters HDU, $E$, $V$, and $k_o$ are for either the dispersed phase or the continuous phase, depending on the basis used to define the overall mass transfer coefficient. The subscript $r$ denotes the raffinate phase, subscript $e$ denotes the extract phase, and $Z_t$ is the contacting height. For $E = 1$, the equations reduce to

$$\mathrm{HDU}_o = \left( \frac{1}{\mathrm{HDU}_r + \mathrm{HDU}_e} + \frac{0.8}{Z_t} \right)^{-1} \tag{15-128}$$

The axial mixing coefficient normally is evaluated for the continuous phase. It is correlated by

$$\frac{E_c \rho_c}{\mu_c} = (C_1 \mathrm{Re}_c^a + C_2 \mathrm{Re}_d^b) \left( \frac{D_{\mathrm{col}}}{100} \right)^c \tag{15-129}$$

$D_{\mathrm{col}}$ = column diameter, cm

where

$$\mathrm{Re}_c = \frac{V_{ic} \rho_c}{\mu_c (a_p + a_w)} \tag{15-130}$$

$$a_w = \frac{4}{D_{\mathrm{col}}} \tag{15-131}$$

$$\mathrm{Re}_d = \frac{V_s d_p \rho_c}{\mu_c} \tag{15-132}$$

In Eq. (15-131), $a_w$ is the specific wall surface ($\mathrm{cm}^2/\mathrm{cm}^3$) and $a_p$ is the specific packing surface ($\mathrm{cm}^2/\mathrm{cm}^3$). This term is dropped for a spray column ($C_1 = 0$). The model coefficients are summarized in Table 15-19. Most of the axial mixing data available in the literature are for the continuous phase; dispersed-phase axial mixing data are rare. Becker recommends assuming $\mathrm{HDU}_d = \mathrm{HDU}_c$ when dispersed-phase data are not available. In Fig. 15-33, Becker presents a parity plot of HTU calculated from Eq. (15-123) based on small- and large-scale data for packed and spray columns.

**Spray Columns** The spray column is one of the simplest and oldest types of equipment used to contact two liquid phases in countercurrent flow. Normally it consists of an empty vertical vessel with a distributor located at one end. The distributor disperses one of the liquids into drops. These drops then rise or fall against the flow of the continuous phase, collecting at the other end of the column and finally coalescing to form a layer of clear liquid that is withdrawn from the column. Because spray columns often are used when solids are present, phases often are dispersed through pipe distributors with large holes oriented in the direction of flow. In cases where the ratio of volumetric flow rates entering the column is far from unity, the liquid entering the extractor at the smaller rate generally should be dispersed to avoid excessive backmixing. Sometimes liquid distributors are used at each end to disperse both phases, with the main liquid-liquid interface located in the middle of the column (Fig. 15-34). See the subsection Liquid Distributors and Dispersers under Liquid-Liquid Extraction Equipment.

Spray columns are inexpensive and easy to operate and provide high volumetric throughput. However, because the continuous phase flows freely through the column, backmixing effects generally are severe. As a result, spray columns rarely achieve more than one theoretical stage. Spray columns may be used when only one theoretical stage is required or when solid precipitation is prevalent and no other contacting device can be used because of plugging. Spray columns also are used for direct heat transfer between large immiscible liquid streams.

***Drop Size, Holdup, and Interfacial Area*** Drop size is estimated by using one of the models listed in Table 15-15, and holdup is estimated from expressions given in Table 15-16. Interfacial area is then calculated by using Eq. (15-104).

***Flooding*** Example flooding models are included in Table 15-17. A review is given by A. Kumar and S. Hartland [chap. 17 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994, pp. 680–686].

***Mass-Transfer Efficiency*** See Table 15-18. As mentioned earlier, spray columns rarely develop more than one theoretical stage due to axial mixing within the column. Nevertheless, it is necessary to determine the column height that will give this theoretical stage. S. D. Cavers [chap. 10 in *Handbook of Solvent Extraction,* ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991] recommends the following equation from G. S. Laddha and T. E. Degaleesan [*Transport Phenomena in Liquid Extraction*, McGraw-Hill, New York, 1978, p. 233] to estimate the overall volumetric mass-transfer coefficient:

$$k_{oc} a = m_{dc}^{\mathrm{vol}} k_{od} a = 0.08 \times \frac{\phi_d (1 - \phi_d)(g^3 \Delta\rho^3 / \sigma \rho_c^2)^{1/4}}{(\mu_c / \rho_c \mathcal{D}_c)^{1/2} + (1/m_{dc})(\mu_d / \rho_d \mathcal{D}_d)^{1/2}} \tag{15-133}$$

Here $\mathcal{D}_c$ and $\mathcal{D}_d$ are the solute diffusion coefficients in the continuous and dispersed phases, respectively. The height of a transfer unit can then be estimated from

$$H_{oc} = \frac{V_c}{k_{oc} a} \tag{15-134}$$

**TABLE 15-19 Correlation Constants for the Becker Axial Mixing Model***

| | No. of data points | $C_1$ | $a$ | $C_2$ | $B$ | $c$ | Average relative error, % |

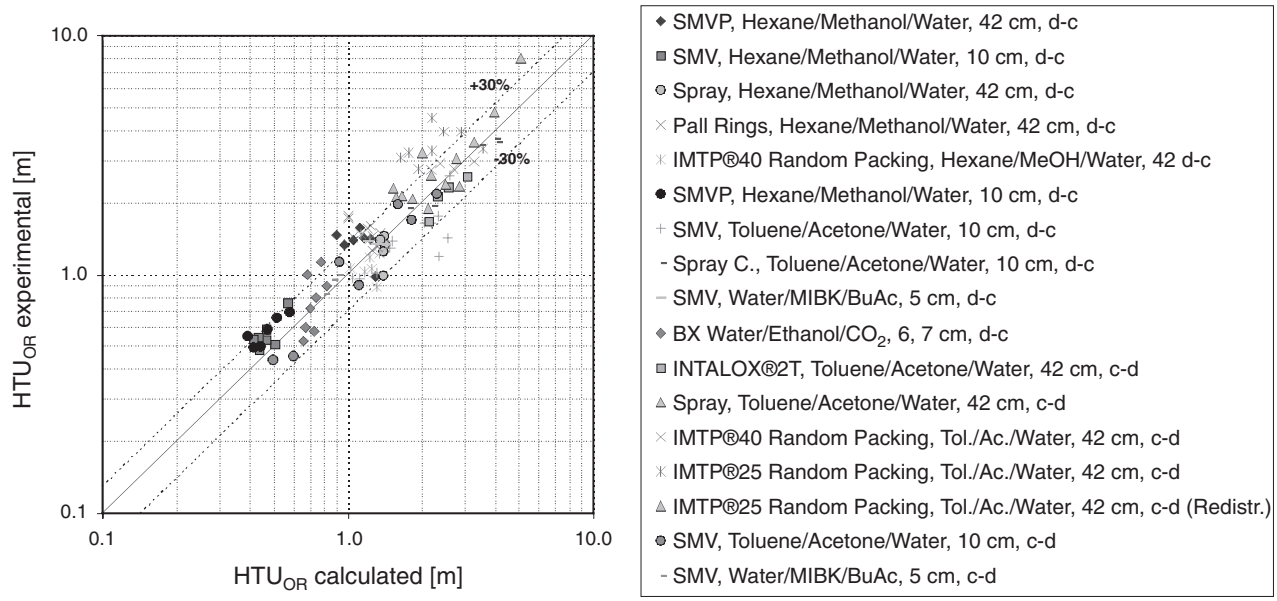

**FIG. 15-33** Parity plot comparing spray and packed column results incorporating axial mixing model. [*Reprinted from Becker,* Chemie Ing. Technik 74*(1–2), pp. 59–66 (2002). Copyright 2002 Wiley-VCH.*]

where $H_{oc}$ is the height of an overall transfer unit based on the continuous phase and $V_c$ is the superficial velocity of the continuous phase. Equation (15-133) provides only a rough approximation. The contacting height is then calculated from the $H_{oc}$ and the required number of transfer units.

**Packed Columns** Packing is used in a column extractor to provide a tortuous path for dispersed drops and to reduce axial mixing (backmixing). Packing affects interfacial area and mass transfer through its impact on the holdup and flow of drops. For further discussion of packed-column extractor design, see R. F. Strigle, chap. 11 in *Packed Tower Design and Applications*, 2d ed., Gulf, Houston, 1994; and G. W. Stevens, chap. 8 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994.

The packings used for liquid-liquid extraction are essentially the same as those used in distillation and absorption service, although the distributors and dispersers and many of the associated internals are not the same. Various examples of commercially available packings used for liquid-liquid extraction service are listed in Table 15-20 ( from Koch-Glitsch, Raschig, and Sulzer). Other manufacturers of packings include AMACS, GTC Technology, Kevin Enterprises, Montz, and RVT, among others. It is a good idea to consult a variety of vendors before making a selection. Illustrations of various types of packings are given in Sec. 14.

Packings are classified as either random or structured. Random packings may be wet-loaded into a column by filling the column with liquid and slowly adding the packing at the liquid surface so the packing pieces gently fall to the surface of the forming bed (typical of ceramic packings); or they may be dry-loaded by transferring them into an empty column through a chute or fabric sock while spreading to maintain uniformity (typical of metal or plastic packings). The familiar ring and saddle packings such as Raschig rings, Berl saddles, Intalox saddles, and Lessing rings are examples of ceramic packings. The more modern random packings such as Pall rings, Hy-Pak®, IMTP®, Raschig Super-Ring, and Intalox® Ultra packings are ring or saddle shapes with internal fingers and slots in the wall. These packings are more open and provide greater access to the interior surfaces for improved capacity and mass-transfer performance. Structured packings are modular assemblies placed inside the column in a specific ordered arrangement. Many are in the form of woven wire mesh or corrugated sheets arranged in layers at specific angles. For packing made from sheets, it is not clear whether surface treatments such as perforations and embossing are important in liquid-liquid extraction, so a number of smooth-surface structured packings are marketed for extraction applications (such as SMV structured packings). For best mass transfer performance, the packing should be preferentially wetted by the continuous phase. (See the subsection Effect of Solid-Surface Wettability under Liquid-Liquid Dispersion Fundamentals.) Many older packed extractors are being refurbished with newer packings and internals to achieve higher throughput while maintaining or improving separation performance. As with any packing and the associated internals, installation procedures recommended by the packing vendor need to be carefully followed to ensure the packing performs as designed. In addition to mass-transfer performance and throughput, another important consideration when choosing metal packing is the packing material and wall thickness relative to corrosion rates. The packing should have sufficient wall thickness for a reasonable service life.

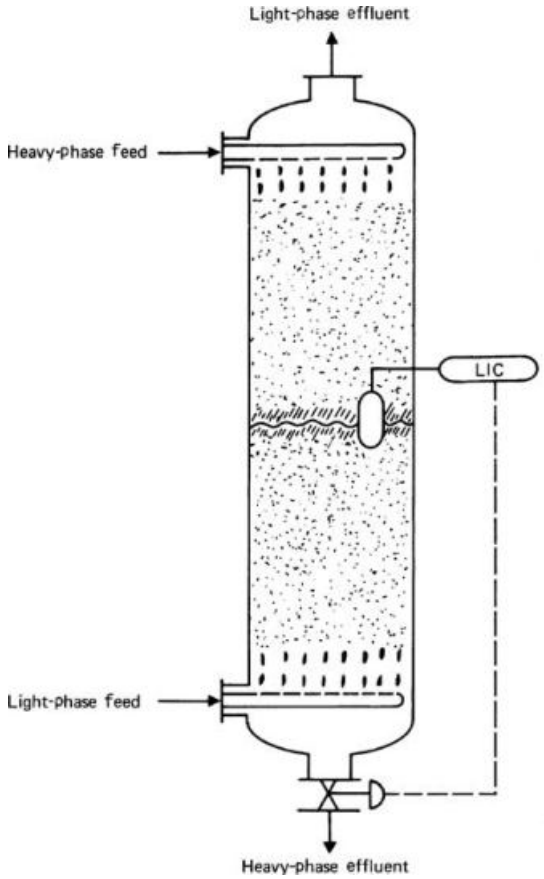

**FIG. 15-34** Spray column with both phases dispersed.

*Polymeric packings also are available and may be appropriate for aqueous dispersed applications, but are less often used in practice.

†Typical value for standard wall thickness. Values will vary depending upon thickness.

‡SMV structured packings are made from smooth corrugated metal sheets. They also are available with horizontal dual-flow perforated plates installed between elements (typically designated SMVP packing). These plates generally reduce backmixing and improve mass-transfer performance at the expense of a reduction in the open cross-sectional area and somewhat reduced capacity.

***Liquid Distribution*** Good initial distribution of the dispersed phase is very important for good performance. R. F. Strigle [*Packed Tower Design and Applications*, 2d ed., chap. 11, Gulf, Houston, 1994] describes typical packed-column internals for liquid-liquid contacting. When the light phase is dispersed, a combination liquid disperser/packing support is preferred because a separate support plate can adversely affect the flow of dispersed drops. An example of a disperser plate is shown in Fig. 15-35. A ladder-type pipe distributor commonly is used to distribute the dispersed-phase feed to the initial disperser plate. Other distributor designs also are available. J. Koch and A. Vogelpohl [*Chem. Eng. Technol.* **24**(7): 695–698; **24**(8): 795–798 (2001)] discuss a sieve plate distributor design that includes a predistributor plate. Many of the concepts concerning geometric uniformity for liquid distribution in packed gas-liquid contactors [Perry, D., D. E. Nutter, and A. Hale, *Chem. Eng. Prog.* **86**(1): 30–35 (1990)] are relevant to liquid-liquid contactors as well. See the subsection Liquid Distributors and Dispersers under Liquid-Liquid Extraction Equipment.

***Redistribution*** A. F. Seibert, B. E. Reeves, and J. R. Fair [*Ind. Eng. Chem. Res.* **29**(9): 1901–1907 (1990)] and R. R. Nemunaitis et al. [*Chem. Eng. Prog.* **67**(11): 60 (1971)] report data showing little benefit from a packed height greater than 10 ft (3 m) and recommend redistributing the dispersed phase about every 5 to 10 ft (1.5 to 3 m) to generate new droplets and constrain backmixing. A packed column often is designed with a redistributor placed between two or more packed sections. In addition, structured packings sometimes are installed with a dual-flow perforated plate (with no downcomer) between elements to reduce backmixing.

***Minimum Packing Size and Drop Size*** For a given application there will be a minimum packing size or dimension below which random packing is too small for good extraction performance [Lewis, J. B., I. Jones, and

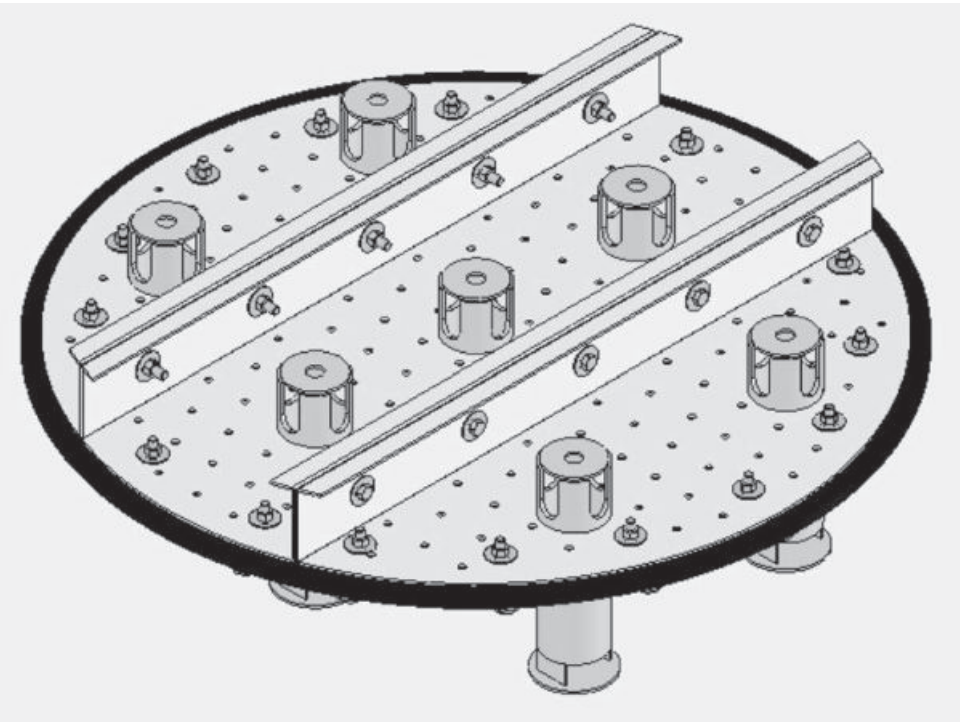

**FIG. 15-35** Example of disperser plate (Sulzer model VSX). (*Courtesy of Sulzer.*)

H. R. C. Pratt, *Trans. Inst. Chem. Eng.* **29:** 126–148 (1951); R. Gayler and H. R. C. Pratt, *Trans. Inst. Chem. Eng.* **31:** 69–77 (1953); and G. S. Laddha and T. E. Degaleesan, chap. 10 in *Transport Phenomena in Liquid Extraction*, McGraw-Hill, New York, 1978, pp. 288–289]. The critical packing dimension or size has been correlated as a multiple of the maximum stable drop size obtained from Eq. (15-37):

$$d_C = 2.4\sqrt{\frac{\sigma}{\Delta\rho g}} \tag{15-135}$$

Below this critical size, the void spaces between packing elements are too small for free flow of dispersed drops. The entry of drops into the packing is severely restricted, often resulting in formation of a coalesced layer at the entrance to the packing and flooding of the column. For packing sizes larger than $d_C$, the characteristic drop diameter is independent of packing size and may be estimated by using the models listed in Table 15-15. The choice of packing size above $d_C$ generally involves a tradeoff; throughput increases with increasing packing size, while mass-transfer performance may decrease with increasing packing size due to an increase in backmixing effects. Typical random packings for commercial-scale columns are in the range of ¾ to 2 in (or about 2 to 5 cm). For small columns, the packing should be no larger than one-eighth of the column diameter to avoid channeling at the wall. This effectively restricts the size of laboratory extractors packed with random packings to no less than 4 in (10 cm) in diameter if they are intended to generate directly scalable data.

***Holdup and Interfacial Area*** The dispersed-phase holdup in a packed-column extractor may be placed into two categories: (1) a small portion that is held in the column for extended periods (essentially permanent) and (2) a larger portion that is free to move through the packing. This is the portion that participates in transfer of solute between phases. The total is $\phi_d$ which here refers to the volume of dispersed phase expressed as a fraction of the void space in the packed section. H. R. C. Pratt and coworkers [*Trans. Inst. Chem. Eng.* **29:** 89–109, 110–125, 126–148 (1951); **31:** 57–68, 69–77, 78–93 (1953)] developed relationships between dispersed-phase velocity and holdup for packed columns. For standard commercial packings of 0.5 in (1.27 cm) and larger, they found that $\phi_d$ varies linearly with $V_d$ up to values of $\phi_d = 0.10$ ( for low values of $V_d$). With further increase of $V_d$, $\phi_d$ increases sharply up to a "lower transition point" resembling loading in gas-liquid contact. At still higher values of $V_d$ an upper transition point occurs, the drops of dispersed phase tend to coalesce, and $V_d$ can increase without a corresponding increase in $\phi_d$. This regime ends in flooding. Below the upper transition point, Pratt and coworkers calculated a value for $\phi_d$ from Eq. (15-107) and the relationship $V_s \approx V_{so}(1-\phi_d)$, such that

$$\frac{V_d}{\phi_d} + \frac{V_c}{1-\phi_d} = \varepsilon V_{so}(1-\phi_d) \tag{15-136}$$

where $V_{so}$ is the characteristic slip velocity at low dispersed-phase flow rate, which can be estimated by using Eqs. (15-113) to (15-118) or alternative methods listed in Table 15-16. Interfacial area is calculated from Eq. (15-104).

***Flooding*** Numerous methods have been proposed for correlating flooding velocities in packed extractors as a function of the packing specific surface area and void volume. Examples are listed in Table 15-17. The earlier methods were developed by using the older-style packings such as Raschig rings and Berl saddles. For example, the well-known flooding correlation $(\sigma/\rho_c)^{0.2}(\mu_c/\Delta\rho)(a_p/\varepsilon)^{1.5}$ versus $(V_c^{1/2}+V_d^{1/2})^2\rho_c/(a_p\mu_c)$ developed by J. W. Crawford and C. R. Wilke [*Chem. Eng. Prog.* **47**(8): 423–431 (1951)] is plotted in Fig. 15-36. This is a dimensional correlation developed by using U.S. Customary System units, so the following units must be used: viscosity in lb/ft/h (equal to 2.42 times the value in cP), density in lb/ft$^3$, interfacial tension in dyn/cm, specific packing surface area in ft$^2$/ft$^3$, and velocities in ft/h based on total column cross section. R. R. Nemunaitis et al. [*Chem. Eng. Prog.* **67**(11): 60–67 (1971)] modified the Crawford-Wilke correlation to include packing factors for specific types of packings (including Raschig rings, Intalox® saddles, and Pall rings). Another correlation that uses packing factors is given by B. C. Sakiadis and A. I. Johnson [*Ind. Eng. Chem.* **46**(6): 1229–1239 (1954)]. See Table 15-17 (equation 6). For this correlation, the units are viscosity in cP, interfacial tension in dyn/cm, and specific packing surface area in ft$^2$/ft$^3$. The generalized flooding model of A. F. Seibert, B. E. Reeves, and J. R. Fair [*Ind. Eng. Chem. Res.* **29**(9): 1901–1907 (1990)] shown in Table 15-17 (equation 1) is based on a mechanistic model validated by data for several types of packing and a range of operating scales, including data from a larger-scale column (42.5-cm inner diameter) using more modern packings: No. 25 IMTP® and No. 40 IMTP® random packings and Intalox® Structured Packing 2T.

Care must be taken in choosing the most appropriate model for a given application and in using the calculated results. A flooding correlation equation can give misleading results when data for the packing of interest was not included in the data used to develop the equation, and this is generally the case for the more modern packings. Because of significant uncertainties in the input physical properties and in the flooding prediction, new designs

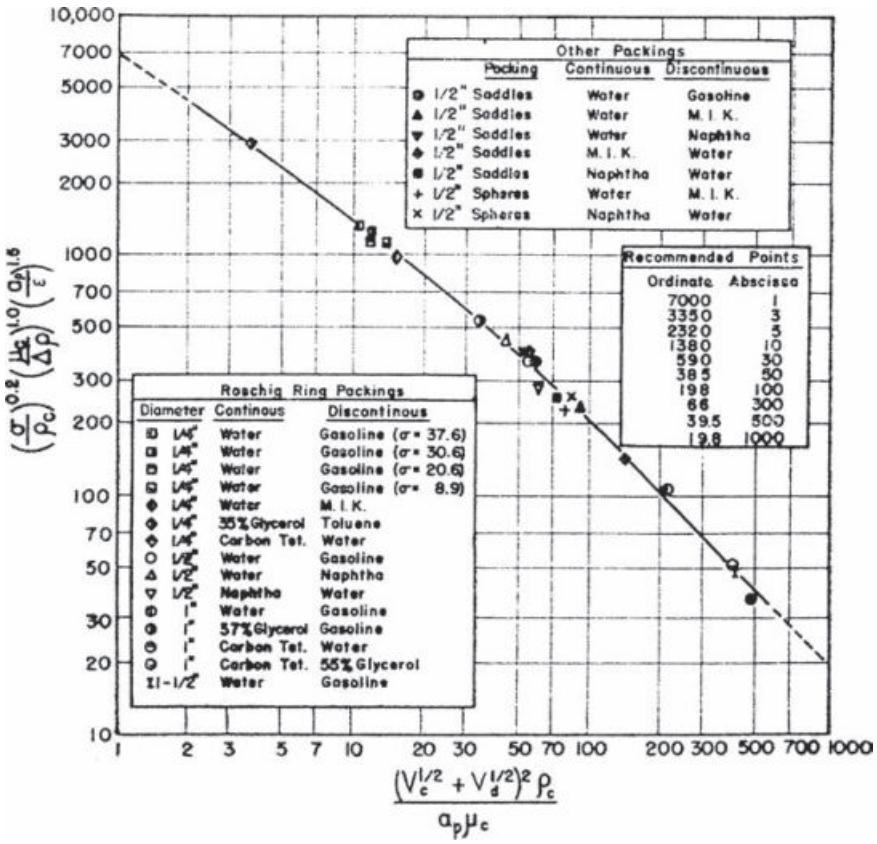

**FIG. 15-36** Crawford-Wilke correlation for flooding in packed columns. Use only the units given in the text. [*Reprinted from Crawford and Wilke*, Chem. Eng. Prog. ***47****(8), pp. 423–431 (1951), with permission.*]

rarely are specified to operate at greater than 60 percent of the calculated flood point. If not already available, some experimental data should be generated for any new design, and in this regard, the flooding correlations may be used to scale up the pilot data to a larger packing size needed for the commercial-scale unit—by calculating the expected percentage change in capacity. This extrapolation approach also may be taken to estimate the improvement that might be achieved by retrofitting an existing commercial unit with a new packing. But again, the results should be used with caution, and consultation with packing vendors is recommended.

***Packing Pressure Drop*** In general, the measured pressure differential across a packed extractor is mostly due to the hydrostatic head pressure. The resistance to flow caused by the packing itself normally is negligible because typical packings are large, and flooding velocities are much lower than those that would be needed to develop significant $\Delta P$ from resistance to flow between the packing elements. In some applications, solids may accumulate in the region of the packing support over time, and this may cause added pressure drop and premature flooding. For additional discussion, see G. S. Laddha and T. E. Degaleesan, chap. 10 in *Transport Phenomena in Liquid Extraction*, McGraw-Hill, New York, 1978, pp. 271–273.

***Mass Transfer*** Table 15-21 lists typical mass-transfer performance for various packing sizes, as given by R. F. Strigle [chap. 11 in *Packed Tower Design and Applications*, 2d ed., Gulf, Houston, 1994]. The data are typical in that as the size of the packing decreases, mass-transfer performance is shown to improve (the required bed depth or packing height decreases). At the same time, the hydraulic capacity decreases, so the design problem involves finding the economic optimum for the given production rate. These guidelines are based on experience with organic aqueous systems and the use of metal slotted-ring or ceramic saddle packings, using high-performance dispersion plates for liquid distribution and redistribution between packed sections. In addition, various mass transfer coefficient models used for estimating packed column performance are included in Table 15-18. Newer methods include the calculation procedure outlined by A. F. Seibert, B. E. Reeves, and J. R. Fair [*Ind. Eng. Chem. Res.* **29**(9): 1901–1907 (1990)] and corrected for axial mixing [as in Eqs. (15-127) to (15-136)], and methods incorporating both axial mixing and dynamic behavior [Morales, C., et al., *Comput. Chem. Eng.* **31:** 1694–1701 (2007)]. While these guidelines and calculation procedures provide useful estimates, they do not replace the need for data from pilot tests and the appropriate correction for axial mixing. Table 15-22 lists selected sources of data for mass transfer in packed columns.

Packed columns also are used for applications involving mass transfer with chemical reaction. For example, C. I. Koncsag and A. Barbulescu propose a mass-transfer model for aqueous base extraction of mercaptans from gasoline [*Chem. Eng. Process. Proc. Intensif.* **47:** 1717–1725 (2008)]. They studied this mass transfer rate limited system using a 7.6 cm diameter column packed with SMV 350.Y structured packing.

**Sieve Tray Columns** A schematic diagram of the most common design of sieve tray column (also called a sieve plate or perforated-plate column) is shown in Fig. 15-32*c*. The light liquid is shown as the dispersed phase. The liquid flows up through the perforations of each tray and is thereby dispersed into drops that rise up through the continuous phase. The continuous liquid flows horizontally across each tray and passes to

**Table 15-21 Typical Packed Extractor Performance According to Strigle**

| | Required bed depth for modern random packings, ft (m) | | |
|---|---|---|---|
| Transfer units per bed | Nominal packing size of 1 in (2.5 cm) | Nominal packing size of 1.5 in (3.8 cm) | Nominal packing size of 2 in (5 cm) |
| 1.5 | 4.4 (1.3) | 5.3 (1.6) | 6.2 (1.9) |
| 2.0 | 7.2 (2.2) | 8.6 (2.6) | 10.1 (3.1) |

the tray beneath through the downcomer. For dispersing the heavy phase, the same design may be used, but turned upside down. The trays serve to eliminate (or at least greatly reduce) the vertical recirculation of continuous phase. Mass-transfer rates may be enhanced by the repeated coalescence and redispersion into droplets of the dispersed phase at each tray, although in general the overall efficiency of a sieve tray is fairly low, on the order of 15 to 30 percent. In contrast to packed and most agitated extractors, the sieve tray efficiency remains fairly constant with increasing column diameter because of the absence of backmixing. The higher efficiencies generally are achieved for systems with low to moderate interfacial tension. As discussed earlier, the liquid entering the column at the larger volumetric flow rate generally should be dispersed to obtain satisfactory interfacial area for mass transfer.

***Liquid Distribution*** Very good initial distribution is not as essential in a sieve tray extractor as it is in a packed extractor, because the trays provide redistribution. However, careful design is still required to prevent distributed drops from entering the bottom downcomer (or top upcomer) and to provide uniform dispersion. While the same distributors used in packed columns are applicable, simpler devices also are used. Capped pipes with holes drilled uniformly have been found to be adequate in many cases.

***Drop Size, Holdup, and Interfacial Area*** Drop size is estimated by using one of the models listed in Table 15-15, and holdup is estimated from expressions given in Table 15-16. Interfacial area is then calculated by using Eq. (15-104).

***Sieve Tray Design*** Perforations usually are in the range of 0.125 to 0.25 in (0.32 to 0.64 cm) in diameter, set 0.5 to 0.75 in (1.27 to 1.81 cm) apart, on square or triangular pitch. There appears to be relatively little effect of hole diameter on the mass-transfer rate, except that with systems of high interfacial tension, smaller holes will produce somewhat better mass transfer. The entire hole area is normally set at 3 to 10 percent of the column cross section, although adjustments may be needed. The velocity through the holes should be such that drops do not form slowly at the holes, but rather the dispersed phase streams through the openings as a jet that breaks up into drops at a slight distance from the tray. It is

common practice to set the velocity of liquid exiting the holes to correspond to a Weber number between 4 and 12. This normally gives velocities in the range of 0.5 to 1.0 ft/s (15 to 30 cm/s). The same general guidelines used to specify hole size and velocities for plate dispersers apply to sieve tray design. See Eqs. (15-102) and (15-103) and the related discussions in the subsection Liquid Distributors and Dispersers under Liquid-Liquid Extraction Equipment.

The velocity of the continuous phase entering the downcomer (or upcomer) $V_{\text{dow}}$, which sets the downcomer cross-sectional area, should be set at a value lower than the terminal velocity of some arbitrarily small droplet of dispersed phase, say, $\frac{1}{32}$ or $\frac{1}{16}$ in (0.08 or 0.16 cm) in diameter; otherwise, recirculation of entrained dispersed phase around a tray will result in flooding. The terminal velocity of these small drops can be calculated by using Eqs. (15-113) to (15-118). To prevent drops from entering the downcomer, the downcomer area should be specified to achieve a somewhat higher drop velocity in the flow leaving the downcomer. Downcomer area typically is in the range of 5 to 20 percent of the total cross-sectional area, depending upon the ratio of continuous- to dispersed-phase volumetric flow rates. The downcomers should extend beyond the accumulated layer of dispersed phase on the tray, and the tray area directly opposite downcomers should be kept free of perforations.

The spacing between trays should be sufficient that (1) the "streamers" of dispersed liquid from the holes break up into drops before coalescing into the layer of liquid on the next tray; (2) the cross-flow velocity of continuous-phase liquid does not cause excessive entrainment of the dispersed phase; and (3) the column may be entered through handholes or manholes in the sides for inspection and cleaning. For systems that accumulate an interface rag, provision may be made for periodic withdrawal of the rag through the side of the column between trays. For large columns, tray spacing between 12 and 24 in (30 and 60 cm) is generally recommended.

The height of the coalesced layer at each tray is given by

$$h = \frac{\Delta P_o + \Delta P_{\text{dow}} - \phi_d g\, \Delta\rho L}{(1-\phi_d) g\, \Delta\rho} \tag{15-137}$$

where $L$ is the downcomer length. Equation (15-137) is a slightly simplified form of the expression given by D. Mewes and W. Kunkel [*Ger. Chem. Eng.* **1:** 111–115 (1978)]. In most cases holdup is low, and Eq. (15-137) reduces to $h = (\Delta P_o + \Delta P_{\text{dow}})/(g\Delta\rho)$. The orifice pressure drop $\Delta P_o$ may be calculated by using the model of Th. Pilhofer and R. Goedl [*Chem. Ing. Tech.* **49:** 431 (1977)]:

$$\Delta P_o = \frac{1}{2}\left(1 - \frac{0.71}{\log \text{Re}}\right)^{-2} \rho_d V_o^2 + 3.2\left(\frac{d_o^2 g \Delta\rho}{\sigma}\right)^{0.2} \frac{\sigma}{d_o} \tag{15-138}$$

where $V_o$ is the velocity through the orifice, $d_o$ is the orifice diameter, and $\text{Re} = V_o d_o \rho_d / \mu_d$. The pressure drop through the downcomer $\Delta P_{\text{dow}}$ includes losses due to (1) friction in the downcomer, which should be negligible; (2) contraction and expansion upon entering and leaving the downcomer; and (3) two abrupt changes in direction. These losses total 4.5 velocity heads:

$$\Delta P_{\text{dow}} = \frac{4.5 V_{\text{dow}}^2 \rho_c}{2} \tag{15-139}$$

For large columns, the design should be specified such that the height of the coalesced layer is at least 1 in (2.5 cm) to ensure all the holes are adequately covered, and one should allow for the trays to be slightly out of level. On the other hand, the height of the coalesced layer should not be too large, as this is unproductive column height that unnecessarily increases the total column height requirement. A typical design value is about 2 in (5 cm).

Envelope-style segmental downcomers (Fig. 15-37) often are used in commercial-scale sieve tray extractors instead of circular or pipe-style downcomers. The area of an envelope downcomer is given by

$$A = \frac{H}{6S}(3H^2 + 4S^2) \tag{15-140}$$

The distance $S$ is determined from the column diameter. The distance $H$ is obtained from

$$S = \left[8H\left(\frac{D_{\text{col}}}{2} - \frac{H}{2}\right)\right]^{1/2} \tag{15-141}$$

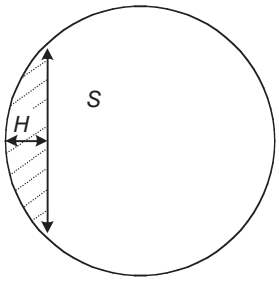

**FIG. 15-37** Dimensions of an envelope-style segmental downcomer or upcomer (shaded area).

The diameter of a circular downcomer with equivalent area is given by

$$D_{\text{eq}} = \sqrt{\frac{4}{\pi} A} \tag{15-142}$$

***Sieve Tray Capacity at Flooding*** The capacity of a sieve tray is determined by hydraulic mechanisms involved in flooding and is not completely understood, especially for larger-diameter columns. Three studies using larger equipment have been reported by J. O. Oloidi, G. Y. Jeffreys, and C. J. Mumford [*Inst. Chem. Eng. Symp. Ser.* **103:** 117–132 (1987)]; A. F. Seibert and J. R. Fair [*Ind. Eng. Chem.* **32:** 2213–2219 (1993)]; and R. B. Eldridge and J. R. Fair [*Ind. Eng. Chem.* **38:** 218–222 (1999)]. An example of sieve tray flooding data is illustrated in Fig. 15-38.

The sieve tray capacity and efficiency are strongly influenced by the height of the coalesced layer. If the height of this layer grows to the outlet of the downcomer, a sharp reduction in efficiency will result because the mass-transfer height will be significantly reduced. In this case, the downcomer area and/or total perforated area should be increased. A flooding model based on the height of the coalesced layer is given by A. F. Seibert and J. R. Fair [*Ind. Eng. Chem. Res.* **32**(10): 2213–2219 (1993)]. The result is shown in Table 15-17 (equation 9), where $L_{dc}$ is the downcomer length, $f_{ha}$ is the fractional hole area, and $f_{da}$ is the fractional downcomer area.

***High Cross-Flow of the Continuous Phase*** Miniplant tests of sieve tray extractors are often performed prior to the final design of a commercial-scale column. The design often is scaled up based on superficial velocities of the dispersed and continuous phases calculated from the volumetric flow rates and the column cross-sectional area. However, in scaling up one must be careful about the cross-flow velocity ($V_{c\text{flow}}$) of the continuous phase. A value may be estimated from

$$V_{c\,\text{flow}} \approx \frac{L_{fp}}{z-h} V_c \tag{15-143}$$

where $L_{fp}$ is the length of flow path, $z$ is the tray spacing, $h$ is the height of coalesced layer, and $V_c$ is the superficial continuous-phase velocity. The magnitude of the cross-flow velocity of the continuous phase can be much greater than that studied in the miniplant. Multiple downcomers or upcomers reduce the flow path length and can be utilized in new designs to reduce cross-flow velocity. Large-diameter multiple downcomer (or upcomer) trays have been reported to provide 10 to 15 percent greater capacity relative to the single-pass tray. A. F. Seibert, J. L. Bravo, and J. R. Fair [*ISEC '02 Proc.* **2:** 1328–1333 (2002)] propose a model for correcting the sieve tray capacity for high cross-flow velocity.

***Mass-Transfer Data*** Mass-transfer data are available from the sources listed in Table 15-23. Mass-transfer performance can be expressed in terms of the number of transfer units per actual tray, or in terms of overall heights of transfer units for a given column configuration. Because sieve trays resemble and basically behave in the manner of stages, performance also can be expressed in terms of a stage efficiency, either as an overall efficiency for the entire tower or, more satisfactorily, as a Murphree efficiency for each tray. The performance of sieve trays in reactive extraction is discussed by R. S. Ettouney, M. A. El-Rifai, and A. O. Ghallab [*Chem. Eng. Process. Proc. Intensif.* **46:** 713–720 (2007)].

***Tray Efficiency*** For low-viscosity systems (< 2 cP), overall sieve tray efficiencies often are between 10 and 30 percent. One of the earliest models for predicting the overall tray efficiency was a very empirical one reported by R. E. Treybal [*Liquid Extraction*, 2d ed., McGraw-Hill, New York, 1963].

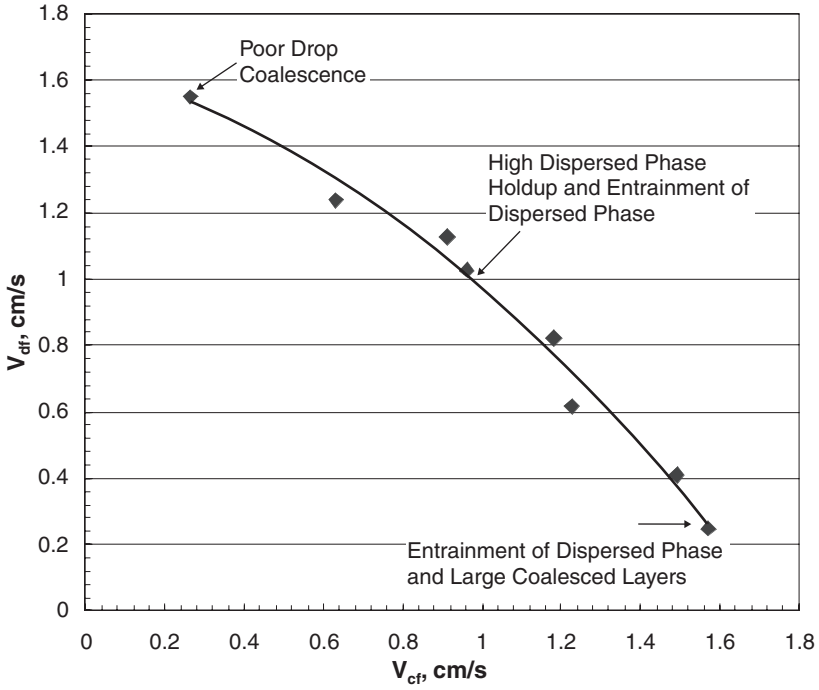

**FIG. 15-38** Sieve tray flooding data. System: toluene (dispersed) + water (continuous). Tray spacing = 30.5 cm. Column diameter = 42.8 cm. [*Taken from Seibert, Bravo, and Fair,* ISEC '02 Proc. **2**, *pp. 1328–1333 (2002), with permission. Copyright 2002 South African Institute of Mining and Metallurgy.*]

R. Krishna Murty and C. V. Rao [*Ind. Eng. Chem. Proc. Des. Dev.* **7**(2): 166–172 (1968)] modified the Treybal model to account for hole diameter:

$$\xi_o = 0.21\left(\frac{z^{0.5}}{\sigma d_o^{0.35}}\right)\left(\frac{V_d}{V_c}\right)^{0.42} \tag{15-144}$$

where $z$ is the tray spacing, cm; $d_o$ is the hole diameter, cm; and $\sigma$ is interfacial tension, dyn/cm. Care must be taken when using the modified Treybal equation for extractors using high dispersed to continuous flow ratios and very low interfacial tension, because in that case the model will predict an unreasonably high tray efficiency. A. F. Seibert and J. R. Fair [*Ind. Eng. Chem.* **32**(10): 2213–2219 (1993)] recommend calculating the local Murphree stage efficiency based on the dispersed phase, assuming a log mean driving force and negligible mass-transfer contribution from drop formation:

$$\xi_{md} = 1 - \exp\left[-\frac{6k_{od}\phi_d(z-h)}{d_p V_d}\right] \tag{15-145}$$

The overall tray efficiency may then be estimated by using

$$\xi_o = \frac{\ln[1+\xi_{md}(\mathcal{E}-1)]}{\ln \mathcal{E}} \tag{15-146}$$

$$\mathcal{E} = m_{dc}^{\text{vol}}\frac{V_d}{V_c} \tag{15-147}$$

Equation (15-145) assumes plug flow of the rising or falling drop population and complete mixing of the continuous phase on the tray. Also see R. B. Eldridge and J. R. Fair, *Ind. Eng. Chem. Res.* **38:** 218–222 (1999); J. A. Rocha et al., *Ind. Eng. Chem. Res.* **28**(12): 1873–1878 (1989); J. A. Rocha, J. C. Cárdenas, and J. A. García, *Ind. Eng. Chem. Res.* **28**(12): 1879–1883 (1989), and G. Shiveler, Paper No. 537a, AIChE Annual Meeting, San Francisco, 2013.

**Baffle Tray Columns** Baffle tray columns are similar to spray columns except that baffles are added to reduce backmixing. The baffles usually are slightly sloped to drain any solids that might settle out in the column and are designed to provide a high open area. E. J. Lemieux [*Hydrocarbon Proc.* **62**(9): 106–111 (1983)] and J. R. Fair [*Hydrocarbon Proc.* **72**(5): 75–79 (1993)] report on the performance and design of these columns for gas-liquid contacting. R. E. Treybal [*Liquid Extraction*, 2d ed., McGraw-Hill, New York, 1963] provides a brief but valuable description of a baffle tray extractor. Although no design equations or performance data are provided, Treybal indicates that commercial tray spacings should be in the range of 10 to 15 cm (4 to 6 in). Treybal also provides an interesting illustration of a baffle tray extractor in operation (Fig. 15-39). This figure shows multiple trays with a very short spacing, with the dispersed light phase moving as a layer of liquid under each tray.

Because baffle tray performance data are not widely available, the results of a pilot-scale study are summarized in Figs. 15-40 to 15-43 [Seibert, A. F., C. Lewis, and J. R. Fair, Paper No. 112a, AIChE Annual Meeting, Indianapolis, 2002]. The study was carried out using a 4.0-in (10.2-cm) diameter column set up with 5 to 30 trays. The trays were arranged in a side-to-side horizontal arrangement, as indicated in Fig. 15-39*a*. The data were generated by using the toluene (dispersed) + acetone + water (continuous) and butanol (dispersed) + succinic acid + water (continuous) systems. The effects of changes in baffle spacing and tray overlap (expressed as the percentage of total tray area covered by the next tray above or below) were measured for transfer of solute from the organic to the aqueous phase.

***Hydraulic Capacity*** The capacity of the baffle trays at flooding was found to depend on system properties as shown in Fig. 15-40. The butanol system with its lower interfacial tension provided a much lower capacity relative to the toluene system with its higher interfacial tension. The capacity was found to be independent of tray spacing. However, capacity was strongly affected by the degree of tray overlap as shown in Fig. 15-41. A. F. Seibert, C. Lewis, and J. R. Fair have proposed a flooding model [Paper No. 112a, AIChE Annual Meeting, Indianapolis, 2002].

***Baffle Tray Efficiency*** Baffle tray mass-transfer efficiency was observed to depend strongly on the tray spacing and system properties. In these studies, a tray spacing of about 10 cm provided a minimum HETS. The data indicate that the performance of baffle trays relative to sieve trays depends upon the interfacial tension of the system. For the high-interfacial-tension system the baffle tray performance (in terms of capacity and mass transfer) is relatively low compared to that of a sieve tray (Fig. 15-42). However, for the low-interfacial-tension system (Fig. 15-43), performance was somewhat better using 62 percent tray overlap.

**TABLE 15-23 Mass-Transfer Data for Sieve Tray Columns**

| System | Column diameter, in | Tray spacing, in | Ref. |
|---|---|---|---|
| Benzene–acetic acid–water | 1.97 | 3.9–6.3 | 27 |
| | 1.97 | 3.2–6.3 | 26 |
| | 2.2 | 2.8–6.3 | 25 |

## AGITATED EXTRACTION COLUMNS

In certain applications, the mass-transfer efficiency of a static extraction column is quite low, especially for systems with moderate to high interfacial tension. In these cases, efficiency may be improved by mechanically agitating the liquid-liquid dispersion within the column to better control drop size and population density (dispersed-phase holdup). Many different types of mechanically agitated extraction columns have been proposed. The more common types include various rotary-impeller columns, the reciprocating-plate column, and the rotating-disk contactor (RDC). The following is a brief review. For more detailed discussion, see J. C. Godfrey and M. J. Slater, eds., *Liquid-Liquid Extraction Equipment*, Wiley, New York, 1994; J. D. Thornton, ed., *Science and Practice of Liquid-Liquid Extraction*, vol. 1, Oxford University Press, Oxford, UK, 1992; and T. C. Lo, M. H. I. Baird, and C. Hanson, eds., *Handbook of Solvent Extraction*, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991.

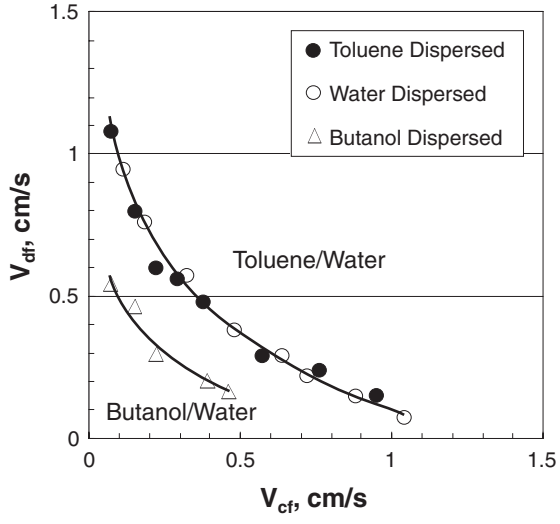

**FIG. 15-40** Capacity characteristics of a baffle tray extractor. Tray overlap = 62 percent. Column diameter = 10.2 cm. [*Taken from Seibert, Lewis, and Fair, Paper No. 112a, AIChE Annual Meeting, Indianapolis (November 2002), with permission. Copyright 2002 AIChE.*]

**Rotating-Impeller Columns** A number of different rotating-impeller column extractors have been proposed and built over the years. Only the Scheibel and Kühni designs are reviewed here. For information about the Oldshue-Rushton design, see L. A. Robbins and R. W. Cusack, Section 15, pp. 38–40, in *Perry's Chemical Engineers' Handbook*, 7th ed., ed. R. H. Perry, D. W. Green, and J. O. Maloney, McGraw-Hill, New York, 1997; and J. Y. Oldshue, chap. 13.4 in *Handbook of Solvent Extraction,* ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991.

***Scheibel Extraction Column*** The original Scheibel column design consisted of a series of knitted-wire-mesh packed sections placed within a vertical column, with a centrally located impeller between each section and no baffles [Scheibel, E. G., and A. E. Karr, *Ind. Eng. Chem.* **42**(6): 1048–1057 (1950)]. A second-generation Scheibel design [Scheibel, *AIChE J.* **2**(1): 74–78 (1956); U.S. Patent 2,850,362 (1958)] added flat partitions or baffles to the ends of each packed section, and the impellers were surrounded by stationary shroud baffles to direct the flow of droplets discharged from the impeller tips. The new baffling arrangement improved efficiency, allowing the design of larger-diameter columns with less power input and decreased height per theoretical stage. A third design by Scheibel [U.S. Patent 3,389,970 (1968)] eliminated the wire-mesh packing and retained the use of baffles and shrouded impellers (Fig. 15-44). The packed sections were replaced by agitated sections. This design was developed because the wire-mesh packed sections were prone to fouling (plugging) and difficult to clean. A Scheibel extractor of this type is very well suited to handling mixtures with high interfacial tension and can be designed with a large number of stages. It is not as well suited for systems that tend to emulsify easily owing to the high shear rate generated by a rotating impeller. Because of its internal baffling, which controls the mixing patterns on the stages, the Scheibel column has proved to be one of the more efficient extractors in terms of height of a theoretical stage; this makes it well suited to applications that require a large number of stages or are located indoors with headroom restrictions. T. L. Holmes, A. E. Karr, and R. W. Cusack [*Solvent Extraction and Ion Exchange* **8**(3): 515–528 (1990)] have published results comparing the efficiency of the Scheibel column to that of other extractors using the system toluene + acetone + water. For additional discussion, see E. G. Scheibel, chap. 13.3 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, eds., Wiley, New York, 1983, and Krieger, Huntington, NY, 1991. A related column design called the AP column consists of alternating sections of Scheibel-type agitators and structured packing [Cusack, R. W., D. Glatz, and T. L. Holmes, *Proc. ESEC'99, Soc. Chem. Ind.*, p. 427 (2001)]. The high open area of the packing allows for higher capacity while the agitation provides increased efficiency.

As with most agitated extractors, the final design of a Scheibel column typically involves scale-up of data generated in a miniplant or pilot-plant test. The column vendor should be consulted for specific information. The key scale-up guidelines are as follows: (1) $D_t(2)/D_t(1) = [Q(2)/Q(1)]^{0.4}$; (2) $Z_t(2)/Z_t(1) = [D_t(2)/D_t(1)]^{0.70}$; (3) stage efficiency is the same for the pilot and full scale; and (4) power per unit volume is the same for each scale [Cusack, R. W., and A. E. Karr, *Chem. Eng. Magazine*, pp. 112–119 (1991)]. Industrial columns up to 10 ft (3 m) in diameter and containing 90 actual stages have been designed using the following general procedures and a 3-in (75-mm) pilot column:

1. Pilot tests usually are conducted in 3-in (75-mm-) diameter columns. The column should contain a sufficient number of stages to complete the extraction. This may require several iterations on column height.

2. The column is run over a range of throughputs $V_d + V_c$ and agitation speeds. At each condition, the concentrations of solute in extract and raffinate streams are measured after steady-state operation has been achieved (usually after three to five turnovers of column volume). At each throughput, the flood point is determined by increasing the agitation until flooding is induced. A minimum of three throughput ranges are examined in this manner. Mass-transfer performance is measured at several agitation speeds up to the flood point.

3. From the preceding mass-transfer and flooding data, the combination of specific throughput and agitation speed that gives the optimum economic performance for the required separation can be determined. This information is used to specify the specific throughput value [gal/(h · ft$^3$) or m$^3$/(h · m$^3$)] and agitation speed (rpm) for the commercial design. However, unlike the

RDC and Karr columns, for which the specific throughput of the scaled-up version is the same as that of the pilot column, it is a characteristic of the Scheibel column that the throughput of the scaled-up column is on the order of three to five times greater than that achieved on the 3-in-diameter pilot column. The limited throughput of the 3-in column is due to its restrictive geometry; these restrictions are removed in the scaled-up columns.

4. Once the column diameter is determined, the stage geometry can be fixed. The geometry of a stage is a complex function of the column diameter. In the 3-in pilot column, the stage height-to-diameter ratio is on the order of 1:3. On a 10-ft (3-m) diameter column, it is on the order of 1:8. The recommended ratio of height to diameter is $Z_t(2)/Z_t(1) = [D_t(2)/D_t(1)]^{0.70}$.

5. The principle of the Scheibel column scale-up procedure is to maintain the same stage efficiency. Therefore, the scaled-up column will have the same number of actual stages as the pilot column. The only difference is that the stages will be taller, to take into account the effect of axial mixing. With the agitator dimensions determined, the speed is then calculated to give the same power input per unit of throughput. Scheibel found that power input can be correlated by

$$P = 1.85\rho\omega^3 D_i^5 \tag{15-148}$$

where $P$ is the power input per mixing stage, $D_i$ is the impeller diameter, $\rho$ is the average liquid density, and $\omega$ is the impeller speed (rotations per unit time).

***Kühni Column*** Like the Scheibel column, the Kühni column uses shrouded (closed) turbine impellers as mixing elements on a central shaft (Fig. 15-45). Perforated partitions or stator plates extend over the vessel cross section to separate the extraction stages and reduce backmixing between stages. The fractional free-flow area between compartments can be adjusted by changing the free area around the rotor shaft and/or the perforations in the stator plate. As the free-flow area increases, throughput increases at the expense of increased axial mixing of the continuous phase and reduced mass-transfer performance. Throughput typically varies from about 30 $m^3/(h \cdot m^2)$ [750 $gal/(h \cdot ft^2)$] to significantly higher values depending upon the specific design factors chosen to meet the requirements of a given application.

A. Mögli and U. Bühlmann [chap. 13.5 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991] outline general considerations for specifying a commercial design from pilot data. The column vendor should be consulted for specific information. The scale-up procedures are based upon hydrodynamic and geometric similarity between the pilot-scale and plant-scale designs. Individual stage geometry (impeller size and free area of the stator plate) may be tailored for each stage, especially in cases where physical properties vary significantly along the column length. A. Mögli and U. Bühlmann suggest design options to maintain a somewhat uniform interfacial area along the column to minimize the impacts of axial mixing. H. R. C. Pratt and G. W. Stevens [chap. 8 in *Science and Practice of Liquid-Liquid Extraction*, vol. 1, ed. J. D. Thornton, Oxford University Press, Oxford, UK, 1992, p. 541] provide recommended scale-up factors for a Kühni column as follows: $D_i/D_t = 0.33$ to 0.5, compartment height = 0.2 to $0.3D_t$, and the fractional free area of the stator plates = 0.2 to 0.4. The minimum recommended diameter for the pilot column is 60 mm (2.4 in) for specifying columns up to 1 m in diameter and 150 mm (6 in) for specifying larger-diameter columns.

A stagewise computational procedure is proposed by A. Kumar and S. Hartland [*Ind. Eng. Chem. Res.* **38**(3): 1040–1056 (1999)] for design of a Kühni column. The procedure considers backflow of the continuous phase, with an attempt to estimate average drop size, drop size distribution, dispersed-phase holdup, flooding velocities, mass-transfer coefficients, and axial mixing. A design example for extraction of aniline from water is presented. This approach to design can be very useful for initial estimates, but as with all agitated extractors, some pilot testing is recommended for a final commercial design. Also see the discussions by M. Asadollahzadeh et al. [*Sep. Purif. Technol.* **158:** 275–285 (2016)] and L. N. Gomes et al. [*Ind. Eng. Chem. Res.* **43**(4): 1061–1070 (2004)].

**Reciprocating-Plate Columns** Another approach to agitating a dispersion within an extraction column is the use of reciprocating plates. This generally results in a more uniform drop size distribution because the shear forces are more evenly distributed over the entire cross section of the column. Reciprocating-plate extractors have a wide turndown range and are well suited to systems with moderate interfacial tension. They often can handle systems exhibiting a tendency to emulsify, and because of their high open-area design, they can handle slurries of solids, some containing as much as 30 percent solids by weight. Several types of reciprocating-plate extractors have been designed; design differences generally involve differences in the plate open area and plate spacing as well as the inclusion or omission of static baffles or downcomers. For detailed discussion of these designs, see T. C. Lo and J. Procházka, chap. 12 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991; and M. H. I. Baird et al., chap. 11 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994.

The Karr reciprocating-plate column (Fig. 15-46) is a popular example. It uses dual-flow plates with 50 to 60 percent open area and has no downcomers [A. E. Karr, *AIChE J.* **5**(4): 446–452 (1959); A. E. Karr and T. C. Lo, *Chem. Eng. Prog.* **72**(11): 68–70 (1976); and A. E. Karr, *AIChE J.* **31**(4): 690–692 (1985)]. Because of the high open area, a Karr column may be operated with relatively

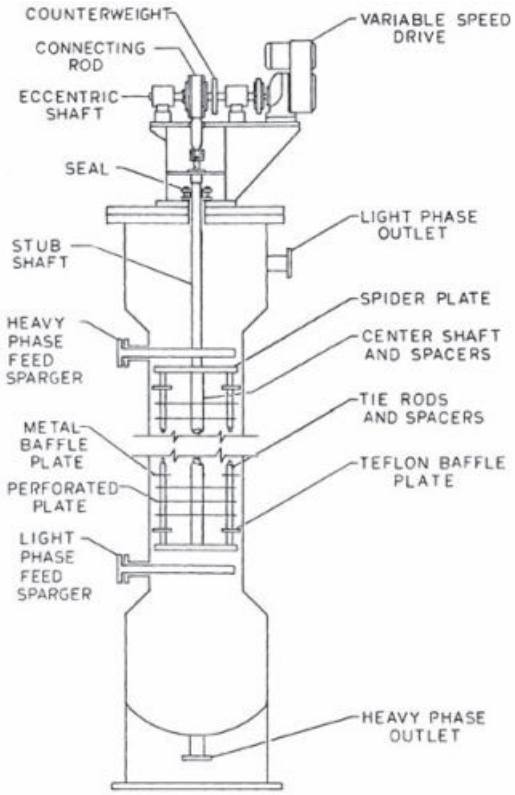

**FIG. 15-46** Karr reciprocating-plate extraction column.

high throughput compared to other types of agitated columns, up to about 1000 gal/(h·ft$^2$) [40 m$^3$/(h·m$^2$)] depending upon the application. The plates are mounted on a central shaft that moves up and down through a stroke length of up to 2 in (5 cm). As the diameter of the column increases, the HETS achieved by the column tends to increase due to axial mixing effects. For columns with a diameter greater than 1 ft (0.3 m), doughnut-shaped baffle plates may be added every five plates (typically) within the plate stack to minimize axial mixing. A Karr column also is well suited for corrosive systems because the plates can be fabricated from nonmetallic materials. H. R. C. Pratt and G. W. Stevens [chap. 8 in *Science and Practice of Liquid-Liquid Extraction*, vol. 1, ed. J. D. Thornton, Oxford University Press, Oxford, UK, 1992, p. 556] provide recommended geometric design and operating conditions for a Karr column as follows: reciprocation amplitude = 1 to 2 in (2.5 to 5 cm) with a 1-in amplitude being most common; reciprocation speed = 10 to 400 complete strokes (up and down) per minute; plate spacing = 2 to 6 in (5 to 15 cm); hole pitch = 0.625 to 0.75 in (1.6 to 1.9 cm); hole diameter = 0.50 to 0.625 in (1.3 to 1.6 cm); plate wall clearance = 1.25 to 2.5 in (3.2 to 6.4 cm). The plate spacing may be graduated to produce uniform drop size and population density along the length of the column, particularly for systems with high solute concentrations and depending upon how physical properties change along the column length [A. E. Karr, U.S. Patent 4,200,525 (1980)].

M. H. I. Baird et al. [chap. 11 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994] discuss and summarize correlations for predicting holdup and flooding, mean drop diameter, axial mixing, mass transfer, and reciprocating-plate column performance. A. Kumar and S. Hartland [*Ind. Eng. Chem. Res.* **38**(3): 1040–1056 (1999)] present a correlation-based computational procedure for design of a Karr reciprocating-plate column, and they give an example for separation of acetone from water by using toluene. A backmixing model is described by A. Stella et al. [*Ind. Eng. Chem. Res.* **45**(19): 6555–6562 (2006)].

As with other agitated extractors, the final design of a commercial-scale Karr column is based on pilot test data. The column vendor should be consulted for specific information. The following general procedure is recommended:

1. For specifying commercial columns up to 6.5 ft (2 m) in diameter, testing in a pilot column of 1-in (25-mm) diameter is sufficient. If the anticipated scaled-up diameter is greater than 6.5 ft, then the pilot tests should be conducted in a 2-in (50-mm) diameter column. The column should be tall enough to accomplish the complete extraction. This may require several iterations on column height.

2. The column is first optimized with regard to plate spacing. The plate spacing is adjusted along the length of the column to obtain the same tendency to flood everywhere in the column. If one particular section appears to flood early, limiting the throughput, then the plate spacing should be increased in this section. This will decrease the power input into that section. Similarly, in sections that appear to be undermixed because the population of drops is low, the plate spacing should be decreased.

3. Once the plate spacing is optimized, the column is run over a range of total throughputs ($V_d + V_c$) and agitation speeds. There should be a minimum of three throughput levels and at each throughput three agitation speeds. After steady state is attained at each condition (usually three to five turnovers of column volume), samples are taken and the separation is measured. At each condition the flood point also is determined. In small-scale tests, the data used for scale-up should be collected at a point very close to flooding, say, 95 percent of flooding. Scaling these data typically results in a commercial-scale unit that operates at roughly 80 or 85 percent of flooding.

4. From the data, plots are made of volumetric efficiency and agitation speed at each throughput level. From these plots the condition that gives the maximum volumetric efficiency is selected for scale-up. For additional discussion, see T. C. Lo and J. Procházka, chap. 12 in *Handbook of Solvent Extraction,* ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991.

5. For scale-up, the following parameters are kept constant: total throughput per unit area, plate spacing, and stroke length. The height and agitation speed of the scaled-up column are then calculated from the following relationships:

$$\frac{Z_t(2)}{Z_t(1)} = \left( \frac{D_{\text{col}}(2)}{D_{\text{col}}(1)} \right)^{0.38} \tag{15-149}$$

$$\frac{\text{SPM}(2)}{\text{SPM}(1)} = \left( \frac{D_{\text{col}}(1)}{D_{\text{col}}(2)} \right)^{0.14} \tag{15-150}$$

Here $Z_t$ is the plate stack height, $D_{\text{col}}$ is the column diameter, SPM is the reciprocating speed (complete strokes per minute), and 1 and 2 denote the pilot column and the scaled-up column, respectively.

A. E. Karr and S. Ramanujam [St. Louis AIChE Symp., March 19, 1987] propose a power per unit volume normalization factor for scale-up of the reciprocation speed if the pilot column plates have a different open area than the industrial scale plates, as follows:

$$\frac{\text{SPM}(2)}{\text{SPM}(1)} = \left( \frac{D_{\text{col}}(1)}{D_{\text{col}}(2)} \right)^{0.14} \left( \frac{\varepsilon(2)^2}{1-\varepsilon(2)^2} \right) \left( \frac{1-\varepsilon(1)^2}{\varepsilon(1)^2} \right) \tag{15-151}$$

where $\varepsilon$ is the fractional open area of the perforated plate.

**Rotating-Disk Contactor** The rotary-disk contactor (RDC) is a vertical column containing an assembly of rotating disks and stationary baffles or stators. A typical design is illustrated in Fig. 15-47. The column is formed into compartments by horizontal doughnut-shaped or annular

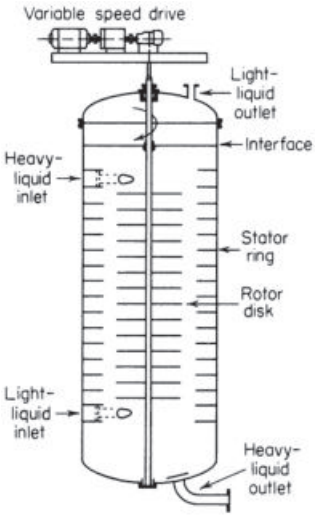

**FIG. 15-47** Typical rotating-disk contactor.

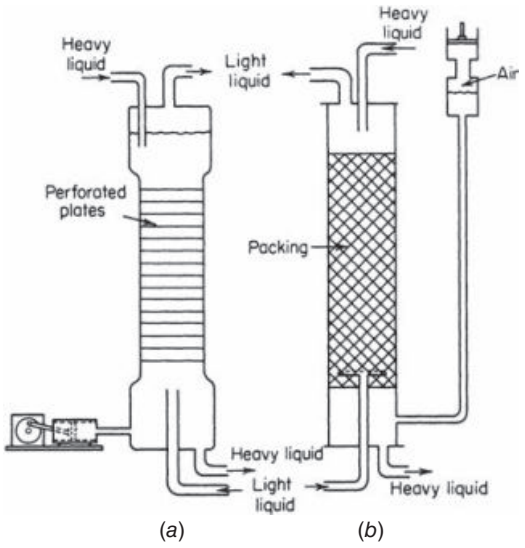

**FIG. 15-48** Pulsed-liquid columns. (*a*) Sieve tray column with pump-type pulse generator. (*b*) Packed column with air pulser.

baffles, and within each compartment agitation is provided by a rotating, centrally located, horizontal disk. The rotating disk is smooth and flat and has a diameter less than that of the opening in the stationary baffles. The RDC extractor has been widely used because of its simplicity of construction, availability in relatively large diameters for high production rates, and low power consumption. For detailed reviews, see chaps. 9 and 17 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994; and chaps. 13.1 and 13.2 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991. Also see A. M. I. Al-Rahawi, *Chem. Eng. Technol.* **30**(2): 184–192 (2007); and C. Drumm and H.-J. Bart, *Chem. Eng. Technol.* **29**(11): 1297–1302 (2006).

The RDC has a moderate throughput typically in the range of 20 to 35 $m^3/(h \cdot m^2)$ [500 to 850 $gal/(h \cdot ft^2)$], and it can be turned down to 20 to 35 percent of the design rate. However, the relatively open arrangement leads to some backmixing and results in only moderate mass-transfer performance. As a consequence, some RDC columns are being replaced by more efficient extractor designs. The RDC can be used for systems with moderate viscosities up to about 100 cP and can be used for systems that tend to foul easily. The RDC also is suitable for systems with slow mass-transfer rates requiring only a few theoretical stages. An RDC can have difficulty handling feeds with emulsion formation tendencies, so it may not be suitable for some systems with low interfacial tension and low density difference.

**Pulsed-Liquid Columns** These are packed or tray column extractors in which a rapid reciprocating motion of relatively short amplitude is applied to the liquid contents to give improved rates of extraction (Fig. 15-48). Liquid pulsing improves the mass-transfer performance at a cost of somewhat reduced throughput. For detailed reviews of this technology, see D. H. Logsdail and M. J. Slater, chap. 11.2 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991; H. R. C. Pratt and G. W. Stevens, chap. 8 in *Science and Practice of Liquid-Liquid Extraction*, vol. 1, ed. J. D. Thorton, Oxford University Press, Oxford, UK, 1992; and H. Haverland and M. J. Slater, chap. 10 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994. Also see J. M. Bujalski et al., *Chem. Eng. Sci.* **61:** 2930–2938 (2006), for discussion of a disk and doughnut type of column extractor operated with pulsed liquid. Externally pulsing the liquid to impart mechanical agitation allows for a sealed agitated extraction column with no moving parts. This feature is important for special applications involving highly corrosive or dangerously radioactive liquids, and it is the main reason why pulsed columns commonly are applied in the extraction and separation of dissolved metals in atomic energy operations. Pulsed-liquid contactors are similar to reciprocating-plate extractors in their basic operation. However, considerably more energy generally is required to move the entire column of liquid than to move the plates. For this reason, a reciprocating-plate or other type of mechanically agitated column design generally is preferred, unless special conditions require a sealed extraction column.

**Raining-Bucket Contactor (a Horizontal Column)** The "raining-bucket" contactor, originally developed by the Graesser Company in the United Kingdom, consists of a horizontal column or shell, as illustrated in Fig. 15-49. The shell slowly rotates about a central axis, and during operation a main liquid-liquid interface is maintained near the centerline. The light phase is continuous in the upper half of the shell, and the heavy phase is continuous in the lower half. Buckets mounted within the shell pick up continuous phase in one half and discharge it as dispersed droplets into the other half. As a result, each phase is dispersed. The raining-bucket design is intended for systems with low density difference and low interfacial tension, that is, systems that tend to emulsify easily. It was originally developed for handling difficult settling systems in the coal-tar industry. A detailed review is given by J. Coleby [chap. 13.6 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991]. Units currently are available through the Biotechna Company.

The rotor assembly of a raining-bucket contactor is made of a series of disks that divide the shell into a series of compartments. Each compartment contains an assembly of buckets. A small gap is maintained between the edge of the disks and the interior wall of the shell to allow for flow between compartments. The gap needs to be small to minimize backmixing. During operation, the phases are fed and removed from opposite ends of the column to produce a countercurrent flow. Throughput generally is low compared to that of other mechanically agitated extractors owing to the limited cross-sectional area available for flow. Rotational speeds are in the range of 0.25 to 40 rpm depending upon the contactor diameter and physical properties of the phases. J. Coleby [chap. 13.6 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991] indicates that raining-bucket contactors can achieve up to 0.3 theoretical stage per compartment depending upon the application. Applications should not involve too high a viscosity in either phase. Dispersing drops in a high-viscosity continuous phase can result in slow liquid-liquid phase separation, and this can severely limit mass-transfer performance and the throughput of the extractor. Experience

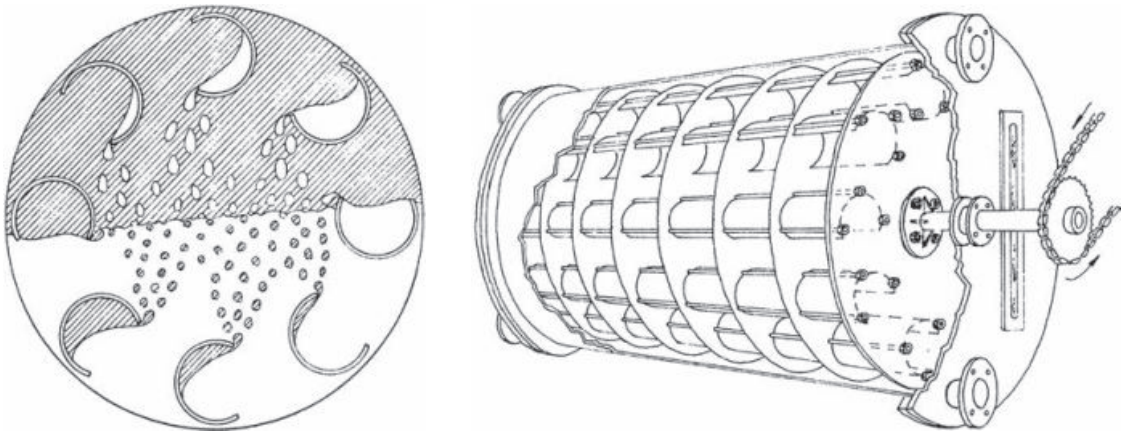

**FIG. 15-49** Schematic views of a Graesser raining-bucket contactor. [*Reprinted from Coleby, Chap. 13.6 in* Handbook of Solvent Extraction, *Lo, Baird, and Hanson, eds., Wiley, New York, 1983; Krieger, Huntington, NY, 1991, with permission.*]

indicates that careful attention to this possibility is needed if viscosity is on the order of 30 cP or greater. A theoretical approach to estimating axial mixing and efficiency in a raining-bucket extractor is presented by M. Dente and G. Bozzano [*Ind. Eng. Chem. Res.* **43**(16): 4761–4767 (2004)]. A biotechnology application is described by S. Jarudilokkul, E. Paulsen, and D. C. Stuckey [*Biotechnol. Prog.* **16**(6): 1071–1078 (2000)].

## MIXER-SETTLER EQUIPMENT

Mixer-settlers are used in hydrometallurgical processing for recovery of metals from aqueous acid solutions, and in multistep batchwise production of specialty chemicals, including pharmaceuticals and agricultural chemicals, among other applications. In principle, any mixer may be coupled with any settler to obtain a complete stage. The function of a single stage within the cascade is to contact the liquids so that equilibrium is closely approached (achieving a high stage efficiency), and then to separate the liquids so they can be routed to the next stage. The design must strike a balance between contacting and settling requirements; that is, the liquids should be mixed with sufficient intensity to suspend drops and facilitate good mass transfer, but not so intensely that drop sizes are too small and settling of the resulting dispersion is problematic.

A mixer-settler operation may be carried out batchwise or with a continuous feed. If batchwise operation is chosen, the same vessel used for mixing often is used for settling. Batchwise extraction in a stirred tank is a common operation in multistep, batchwise manufacture of pharmaceuticals and agricultural chemicals. Such equipment allows flexibility to accommodate batch-to-batch variability, can ensure a single batch remains isolated from other batches throughout the manufacturing process (sometimes a regulatory requirement for pharmaceuticals), and is suitable for multipurpose plants producing a variety of products in campaigns. A batchwise process may be implemented in cocurrent, cross-current, or countercurrent multistage arrangements. A countercurrent operation is carried out as in Figs. 15-6 and 15-22, by initially treating the feed batch with extract solution as the extract leaves the process. The final treatment is carried out using fresh solvent as it enters the process. A two-stage batchwise countercurrent process scheme is common practice.

Continuously operated devices may place the mixing and settling functions in separate vessels or combine them into a single, specially designed vessel with compartments for mixing and settling. Continuous mixer-settlers are particularly attractive for applications requiring several equilibrium stages and long residence times due to slow extraction kinetics, especially for applications involving the use of reactive extractants or viscous fluids. Mixing commonly is done using rotating impellers. Impeller type, shape, size, tip speed, and position within the mixing vessel may be adjusted to optimize the overall design. A static mixer may be a feasible alternative, but only if the required mass transfer can be accomplished in the short contacting time these devices allow, without generating a difficult-to-separate dispersion. Mixer-settlers may offer other advantages, including easy start-up and operation, the ability to handle very high production rates and suspended solids, and the ability to achieve high stage efficiency with proper design. For systems that accumulate rag layers (sludges) between settled liquid layers, the rag material may easily be removed at each settler. As a potential disadvantage, difficult-to-break emulsions may be formed from the shear due to mixing and pumping liquids between tanks. Mixer-settlers also generally require large floor space, and the relatively long residence time in a mixer-settler can be a disadvantage if the desired solute is degraded over time at the required extraction conditions.

**Mass-Transfer Models** Because the mass-transfer coefficient and interfacial area for mass transfer of solute are complex functions of fluid properties and the operational and geometric variables of a stirred-tank extractor or mixer, the approach to design normally involves scale-up of miniplant data. The mass-transfer coefficient and interfacial area are influenced by numerous factors that are difficult to precisely quantify. These include drop coalescence and breakage rates as well as complex flow patterns that exist within the vessel (a function of impeller type, vessel geometry, and power input). Nevertheless, it is instructive to review available mass-transfer coefficient and interfacial area models for the insights they can offer.

The correlation of A. H. P. Skelland and L. T. Moeti [*Ind. Eng. Chem. Res.* **29**(11): 2258–2267 (1990)] for estimating individual continuous-phase mass-transfer coefficients is given by

$$\frac{k_c d_p}{\mathcal{D}_c} = 1.237\times10^{-5}\left(\frac{\mu_c}{\rho_c \mathcal{D}_c}\right)^{1/3}\left(\frac{D_i\omega^2}{g}\right)^{5/12}\left(\frac{D_i}{d_p}\right)^{2} \times\left(\frac{d_p}{D_t}\right)^{1/2}\left(\frac{\rho_d d_p^2 g}{\sigma}\right)^{5/4}\phi_d^{-1/2} \tag{15-152}$$

where $\omega$ is impeller speed (rotations per unit time), $\mathcal{D}_i$ is impeller diameter, $D_t$ is tank diameter, and $D_c$ is the solute diffusion coefficient for the continuous phase. Equation (15-152) is restricted to dispersed-phase holdup values less than $\phi_d = 0.06$. Other studies are described by H. D. Schindler and R. E. Treybal [*AIChE J.* **14**(5): 790–798 (1968)] and by R. B. Keey and J. B. Glen [*AIChE J.* **15**(6): 942–947 (1969)]. Equation (15-152) normally is used to estimate performance for applications in which the feed phase is the continuous phase and the partition ratio for transfer of solute into the extract is large. In this case, the overall resistance to mass transfer is dominated by the continuous-phase resistance (the feed or raffinate phase). Relatively little information is available about individual dispersed-phase mass-transfer coefficients. A. H. P. Skelland and Hu Xien [*Ind. Eng. Chem. Res.* **29**(3): 415–420 (1990)] offer a correlation of $k_d$ values for batchwise extraction of solute from the dispersed phase into the continuous phase.

To use these correlation equations, it is necessary to identify which phase will be dispersed and to estimate the dispersed drop size and holdup as a function of throughput near flooding conditions—for an estimate of interfacial area. For relevant discussions, see the subsections Factors Affecting Which Phase Is Dispersed and Size of Dispersed Drops under Liquid-Liquid Dispersion Fundamentals. Holdup is a complex function of flow rates, impeller type, vessel geometry, and power input, as well as physical properties. For most impeller types, correlations for estimating holdup are not available. However, B. Weinstein and R. E. Treybal [*AIChE J.* **19**(2): 304–312; **19**(4): 851–852 (1973)] offer the following correlations for estimating holdup in a vessel agitated using a six-blade disk-style flat-blade turbine (Rushton):

For a baffled vessel with a gas-liquid surface:

$$\frac{\phi_d}{\phi_{d,\text{feed}}} = 0.764\left(\frac{PQ_d\mu_c^2}{V_t\sigma^3}\right)^{0.300}\left(\frac{\mu_c^3}{Q_d\rho_c^2\sigma}\right)^{0.178}\left(\frac{\rho_c}{\Delta\rho}\right)^{0.0741} \times\left(\frac{\sigma^3\rho_c}{\mu_c^4 g}\right)^{0.276}\left(\frac{\mu_d}{\mu_c}\right)^{0.136} \tag{15-153}$$

For a liquid-full vessel without baffles:

$$\frac{\phi_d}{\phi_{d,\text{feed}}} = 3.39\left(\frac{PQ_d\mu_c^2}{V_t\sigma^3}\right)^{0.247}\left(\frac{\mu_c^3}{Q_d\rho_c^2\sigma}\right)^{0.427}\left(\frac{\rho_c}{\Delta\rho}\right)^{0.430} \times\left(\frac{\sigma^3\rho_c}{\mu_c^4 g}\right)^{0.401}\left(\frac{\mu_d}{\mu_c}\right)^{0.0987} \tag{15-154}$$

Baffles are not needed if the vessel is operated full of liquid with no head space. In Eqs. (15-153) and (15-154), $\phi_{d,\text{feed}}$ is the volume fraction of the phase that ultimately becomes the dispersed phase, for the combined streams entering the vessel: $\phi_{d,\text{feed}} = Q_d/(Q_d + Q_c)$. If $\phi_d/\phi_{d,\text{feed}}$ is calculated to be greater than 1.0, it should be taken as 1.0. These equations are not applicable to other types of impellers.

When an estimate of $\phi_d$ is available, then $a \approx 6\varepsilon\phi_d/d_p$ [Eq. (15-104)]. If the individual mass-transfer coefficients can be estimated with reasonable accuracy, a value for the overall coefficient $k_{or}$ can be calculated from the individual coefficients as in Eq. (15-63). The stage efficiency for a continuous process can then be estimated from

$$\xi_{mr} = 1 - \exp\left(\frac{-k_{or}a\theta}{\phi_d}\right) \tag{15-155}$$

where $\xi_{mr}$ is the Murphree raffinate-based stage efficiency and $\theta$ is the residence time for total liquid in the vessel [Treybal, R. E., "Liquid Extractor Performance," *Chem. Eng. Prog.* **62**(9): 67–75 (1966); and G. S. Laddha and T. E. Degaleesan, *Transport Phenomena in Liquid Extraction*, McGraw-Hill, New York, 1978, p. 418]. Also see the discussion by A. H. P. Skelland and J. S. Kanel [*Ind. Eng. Chem. Res.* **31**(3): 908–920 (1992)]. These authors describe an extraction model framework that includes terms representing drop breakage and coalescence effects.

**Miniplant Tests** As mentioned earlier, for most liquid-liquid extraction applications involving mixer-settlers, the requirements for satisfactory performance with respect to mixing and settling are determined by using small miniplant or pilot-plant tests. For mixer design, the usual procedure is to run continuous experiments for a specific mixer geometry and type of impeller, generating performance data over a range of residence times and agitation intensities. The experimental program typically involves testing a variety of impellers and impeller locations until satisfactory results are obtained, with the ultimate goal of scaling up the miniplant design to achieve the same performance at the commercial scale. The design of settlers is discussed in the section Liquid-Liquid Separation Equipment. With careful design, most extractions require residence times in the range of

1 to 3 min. However, for reaction-enhanced extractions having relatively slow chemical kinetics compared to mass transfer, longer times in the range of 10 to 15 min are not unusual. As noted earlier, it is important to consider the time required to settle the dispersion after mixing and to determine the optimum mixing intensity that provides good mass transfer with reasonable ease of settling.

In these tests, extraction efficiency may be expressed in terms of a Murphree efficiency as

$$\xi = \frac{C_o - C_t}{C_o - C^*} \tag{15-156}$$

where $C_o$ is the initial concentration of solute in the feed, $C_t$ is the concentration in the outlet for a given residence time or at time $t$ for a batch process, and $C^*$ is the concentration at equilibrium. Normally, the extraction efficiency is determined from continuous experiments. If batch extraction data are available for the same solvent-to-feed ratio, the efficiency of a continuous process may be estimated by fitting the batch data to a first-order rate expression

$$\xi_{\text{batch}} = 1 - \exp(-kt_b) \tag{15-157}$$

where $\xi_{\text{batch}}$ for the batch experiment is measured as a function of $t_b$, the batch mixing time [J. C. Godfrey, chap. 12 in *Liquid-Liquid Extraction Equipment,* ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994]. The efficiency of the continuous process is calculated from the expression

$$\xi_{\text{continuous}} = \frac{k\theta}{1 + k\theta} \tag{15-158}$$

where θ is the total liquid residence time for the continuous process. This approach is valid for most diffusion-rate-controlled processes, but may not be valid for reaction-enhanced processes in which the chemical reaction rate may be rate-limiting and not necessarily first-order.

When the ratio of phases entering a mixer-settler stage is far from unity, recycling a portion of the minority phase from the settler back to the mixer sometimes improves the settling of the dispersion by boosting the phase ratio in the settler. [See the subsection Gravity Decanters (Settlers) under Liquid-Liquid Phase Separation Equipment.] The stage efficiency also may be enhanced. For example, when the extract (solvent) is the minority phase (because $K$ is greater than unity) and mass-transfer rates are poor, recycling the settled extract phase can boost the mass-transfer efficiency [R. E. Treybal, *Ind. Eng. Chem. Fundam.* **3**(3): 185–188 (1964)].

**Liquid-Liquid Mixer Design** Many different types of impellers are used for liquid-liquid extraction, including flat-blade, pitched-blade, and axial-flow turbines, marine-type propellers, and special pump-mix impellers. With pump-mix designs, the impeller serves not only to mix the fluids, but also to move the fluids through the extraction stages of a mixer-settler cascade. The agitated vessel should be baffled if the vessel is operated with a gas-liquid surface, to avoid forming a vortex. As noted earlier in reference to Eq. (15-154), baffles are not needed if the vessel is operated with the liquid full [B. Weinstein and R. E. Treybal, *AIChE J.* **19**(2): 304–312 (1973)].

The design of a liquid-liquid mixer includes specification of impeller type and rotational speed (or tip speed), the number of impellers required, the ratio of impeller diameter to vessel diameter $D_i/D_t$, and the location of impeller(s) and any baffles within the vessel. A single impeller generally can be used for vessels with a height-to-diameter ratio less than 1.2 and liquid density ratios within the range of $0.9 < \rho_d/\rho_c < 1.1$. Multiple impeller designs are used to improve circulation and power distribution in tall vessels. For detailed discussions of liquid-liquid mixer design, see D. E. Leng and R. V. Calabrese, chap. 12 in *Handbook of Industrial Mixing, Science and Practice,* ed. E. L. Paul, V. A. Atiemo-Obeng, and S. M. Kresta, Wiley, New York, 2004; and M. F. Edwards and M. R. Baker, chap. 7, and M. F. Edwards, M. R. Baker, and J. C. Godfrey, chap. 8, in *Mixing in the Process Industries*, 2d ed., ed. N. Harnby, M. F. Edwards, and A. W. Nienow, Butterworth-Heinemann, Oxford, UK, 1992. Also see D. Daglas and M. Stamatoudis, *Chem. Eng. Technol.* **23**(5): 437–440 (2000), for a discussion of the effect of impeller vertical position on drop size; and M. Willie, G. Langer, and U. Werner, *Chem. Eng. Technol.* **24**(5): 475–479 (2001), for a discussion of the influence of power input on drop size distribution for a variety of impeller types.

The mixing power per unit volume $P/\mathcal{V}$ is a function of impeller rotational speed ω, impeller diameter $D_i$, and the Power number ($P_o$) for the type of impeller and vessel geometry:

$$\frac{P}{\mathcal{V}} = P_o\left(\frac{\rho_m \omega^3 D_i^5}{\mathcal{V}_{\text{tank}}}\right) \tag{15-159}$$

In Eq. (15-159), the mixture mean density is given by

$$\rho_m = \phi_d \rho_d + (1 - \phi_d)\rho_c \tag{15-160}$$

Power numbers for different impeller types depend upon the impeller Reynolds number. Representative relationships of Power number versus Reynolds number for several types of impellers are given in Fig. 15-50. For additional information on a variety of impellers, see Sec. 6 and R. R. Hemrajani and G. B. Tatterson, chap. 6 in *Handbook of Industrial Mixing, Science and Practice,* ed. E. L. Paul, V. A. Atiemo-Obeng, and S. M. Kresta, Wiley, New York, 2004.

The power $P$ in Eq. (15-159) does not include losses associated with the motor and drive unit. These losses can contribute as much as 30 to 40 percent to the overall power requirement. The drive supplier should be consulted for specific information. For pump-mix impellers, knowledge of the power characteristics for pumping is required in addition to that for mixing. For a discussion of these special cases, see J. C. Godfrey, chap. 12 in *Liquid-Liquid Extraction Equipment,* ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994; and K. K. Singh et al., *Ind. Eng. Chem. Res.* **46**(7): 2180–2190 (2007).

A. H. P. Skelland and G. G. Ramsay [*Ind. Eng. Chem. Res.* **26**(1): 77–81 (1987)] correlated the minimum impeller speed needed to completely disperse one liquid in another in an agitated vessel with standard baffles as follows:

$$\frac{\omega_{\min}^2 \rho_m D_i}{g\,\Delta\rho} = C^2\left(\frac{D_t}{D_i}\right)^{2\alpha} \phi^{0.106}\left(\frac{\mu_m^2 \sigma}{D_i^5 \rho_m g^2 \Delta\rho^2}\right)^{0.084} \tag{15-161}$$

The mixture mean density is given by Eq. (15-160), and the mixture mean viscosity is given by

$$\mu_m = \frac{\mu_c}{1 - \phi_d}\left(1 + \frac{1.5\mu_d \phi_d}{\mu_d + \mu_c}\right) \tag{15-162}$$

The authors determined correlation constants $C$ and α for five common types of impellers (two axial-flow impellers and three radial-flow impellers) and four impeller locations within a standard tank configuration. The specific power requirement can then be estimated by using Eq. (15-159). The power required to disperse one liquid phase into another typically is in the range of 0.2 to 0.8 kW/m$^3$ (1 to 4 hp/1000 gal) [Edwards, M. F., M. R. Baker, and J. C. Godfrey, chap. 8 in *Mixing in the Process Industries*, 2d ed., ed. N. Harnby, M. F. Edwards, and A. W. Nienow, Butterworth-Heinemann, Oxford, UK, 1992, p. 144].

**Scale-Up Criteria** It is common practice to scale up a miniplant design on the basis of equal residence time, constant power per unit volume, and geometric similarity such that the ratio $D_i/D_t$ is held constant and the same types of impeller, tank geometry, and baffling are used. R. E. Treybal [*Chem. Eng. Prog.* **62**(9): 67–75 (1966)] indicated that in using this criterion, stage efficiency for liquid-liquid extraction is likely to increase on scale-up, so it is expected to yield a conservative design. With this approach, $P/D_i^3$ is constant and proportional to $P_o\omega^3 D_i^5/D_i^3 = P_o\omega^3 D_i^2$. Assuming that the Power number is independent of scale, this yields the relationship

$$\frac{\omega(2)}{\omega(1)} = \left(\frac{D_t(1)}{D_t(2)}\right)^{2/3} = \left(\frac{D_t(1)}{D_t(2)}\right)^{2/3} \tag{15-163}$$

A. H. P. Skelland and G. G. Ramsay [*Ind. Eng. Chem. Res.* **26**(1): 77–81 (1987)] indicated that Eq. (15-163) is somewhat conservative, in general agreement with Treybal. Based on an analysis of mixing data generated at low holdup, they indicate that the exponent ⅔ may be replaced with 0.71 as a scale-up rule. Skelland and Ramsay also considered the criteria for scale-up to a tank design involving a different ratio of $D_i/D_t$ at the large scale.

D. E. Leng and R. V. Calabrese [chap. 12 in *Handbook of Industrial Mixing: Science and Practice*, ed. E. L. Paul, V. A. Atiemo-Obeng, and S. M. Kresta, Wiley, New York, 2004, p. 732] showed that constant power per unit volume yields the following relationship if a change in drop size is desired (again, for applications with low holdup):

$$\frac{d_{\max}(1)}{d_{\max}(2)} \approx \frac{\omega(2)^{6/5} D_i(2)^{4/5}}{\omega(1)^{6/5} D_i(1)^{4/5}} \quad \text{for Re} = \frac{\rho_m \omega D_i^2}{\mu_m} > 10^4 \tag{15-164}$$

Equation (15-164) reduces to Eq. (15-163) when $d_{\max}(1)$ is set equal to $d_{\max}(2)$.

The constant power per unit volume scale-up criterion is equivalent to scaling the impeller tip speed ($S_{\text{tip}} = \pi D_i \omega$) by the ratio $S_{\text{tip}}(2)/S_{\text{tip}}(1) = [D(2)/D(1)]^{1/3}$. It follows that when the tank diameter is doubled, the impeller tip speed must increase by a factor of 1.26 to maintain constant power

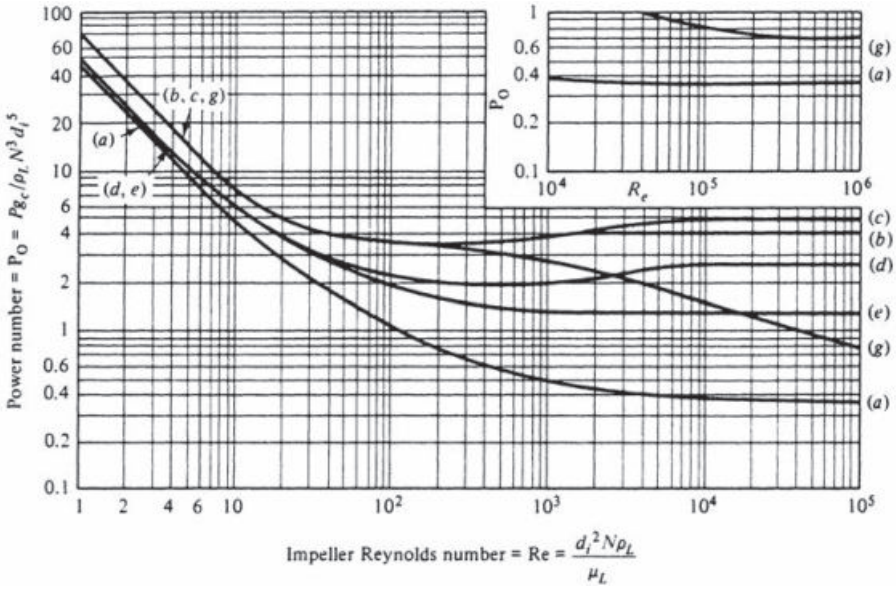

**FIG. 15-50** Power for agitation impellers immersed in single-phase liquids, baffled vessels with a gas-liquid surface (except curves *c* and *g*). Curves correspond to (*a*) marine impellers; (*b*) flat-blade turbines, width = $D_i/5$; (*c*) disk flat-blade turbines (Rushton) with or without a gas-liquid surface; (*d*) curved blade turbines; (*e*) pitched blade turbines; (*g*) flat-blade turbines, no baffles, no gas-liquid interface, no vortex.

Notes on Fig. 15-50:

1. All the curves are for axial impeller shafts, with liquid depth equal to the tank diameter $D_t$.
2. Curves *a* to *e* are for open vessels, with a gas-liquid surface, fitted with four baffles, baffle width = $D_t/10$ to $D_t/12$. The impeller is set at a distance $C = D_i$ or greater from the bottom of the vessel.
3. Curve *a* is for marine propellers, $D_i/D_t \approx \frac{1}{3}$. The effect of changing $D_i/D_t$ is apparently felt only at very high Reynolds numbers.
4. Curves *b* to *e* are for turbines. For disk flat-blade (Rushton) turbines, curve *c*, the effect of changing $D_i/D_t$ is negligible in the range $0.15 < D_i/D_t < 0.50$. For open types (without the disk), curve *b*, the effect of $D_i/D_t$ may be strong.
5. Curve *g* is for disk flat-blade turbines operated in unbaffled vessels filled with liquid and covered, so that no vortex forms. If baffles are present, the power characteristics at high Reynolds numbers are essentially the same as curve *b* for baffled open vessels, with only a slight increase in power.
6. For very deep tanks, two impellers normally are mounted on the same shaft, one above the other. For all flat-blade turbines, at a spacing of $1.5D_i$ or greater, the combined power for both will approximate that for a single turbine.

SOURCE: R. E. Treybal, *Mass-Transfer Operations*, McGraw-Hill, New York, 1980, p. 152. For more detailed information, consult Paul, Atiemo-Obeng, and Kresta, eds., *Handbook of Industrial Mixing*, Wiley, New York, 2004.

per unit volume. If the Skelland and Ramsay exponent of 0.71 is applied in Eq. (15-163) instead of ⅔, then tip speed scales as $S_{tip}(2)/S_{tip}(1) = [D(2)/D(1)]^{0.29}$ and doubling the tank diameter involves increasing the tip speed by a factor of 1.22.

W. Podgórska and J. Baldyga [*Chem. Eng. Sci.* **56:** 741–746 (2001)] presented a model of drop breakage and coalescence and compared four scale-up criteria for agitated liquid-liquid dispersions:

I. Equal power per unit volume and geometric similarity
II. Equal average circulation time and geometric similarity
III. Equal power per unit mass and equal average circulation time ($D_i/D_t \neq$ constant)
IV. Equal tip speed and geometric similarity

For slow-coalescing systems and systems at low holdup, the rate of drop breakage dominates. In this case, according to the analysis of Podgórska and Baldyga, criteria I and II yield smaller drops on scale-up, and criteria III and IV yield larger drops. For fast-coalescing systems, the rate of drop coalescence begins to dominate breakage. In this case, the authors indicate that I and III yield nearly the same drop size with scale-up, II yields much smaller drops, and IV yields larger drops. Podgórska and Baldyga recommend III for fast-coalescing systems, although they point out a limitation in terms of the maximum size of tank that this criterion will allow. See J. De Bona et al. [*Chem. Eng. J.* **296:** 112–121 (2016)] for discussion of special cases where the normal assumption of uniform solute concentration in the dispersed phase is not valid.

Based on the analyses just described, when taken together, it appears that scaling according to constant power per unit volume and geometric similarity generally will give satisfactory results, although the resulting design may not be optimal. For a new design, generally it is advisable to specify a variable-speed drive that can operate within a range of tip speeds. This provides flexibility for further adjustment and optimization of the process in the plant, and it also allows flexibility to accommodate variability in feed composition (a likely scenario in an industrial process).

**Specialized Mixer-Settler Equipment** As mentioned earlier, any mixer and settler can be combined to produce a stage, and the stages are in turn arranged in a multistage cascade. A great many specialized designs have been developed in an effort to reduce costs—for example, by minimizing or eliminating interstage pumping or by combining the various stages into a single vessel. With proper design, these devices generally can achieve overall stage efficiencies in excess of 80 percent, with many providing 90 to 95 percent stage efficiency. Only a few of the more commonly used types are mentioned here. For more detailed discussions, see chaps. 9.1 to 9.5 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991; J. C. Godfrey, chap. 12 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994; K. T. Hossain et al., *Ind. Eng. Chem. Process Des. Dev.* **22**(4): 553–563 (1983); N. L. Eckert and L. S. Gormely, *Chem. Eng. Res. Des.* **67:** 175–184 (1989); and K. K. Singh et al., *AIChE J.* **54**(1): 42–55 (2008).

Several pump-mix combinations have been developed by industry to simplify overall plant layout and minimize the number of pumps for greater economy. The IMI axial pump-mix and draft tube (Fig. 15-51*a*) has the pumping and mixing impellers on the same shaft. The upper part of the tank contains the draft tube and the mixing impeller. The pumping impeller for transferring the dispersion to the settler is in the lower part of the tank. There is a potential disadvantage of forming smaller and hard to separate drops when pumping a dispersion versus pumping a single phase. The Kemira design (Fig. 15-51*b*) uses a pumping impeller located near the bottom of the tank along with a mixing impeller located near the central zone of the tank. The draft tube is eliminated, and a dispersion is not pumped in this design. The Davy CMS design (Fig. 15-52) uses a pump-mix impeller in a large tank that provides both mixing and settling capability over a wide range of phase flow ratios. The dispersion occurs in the central section of the tank, and the separation occurs in the upper and lower separation zones.

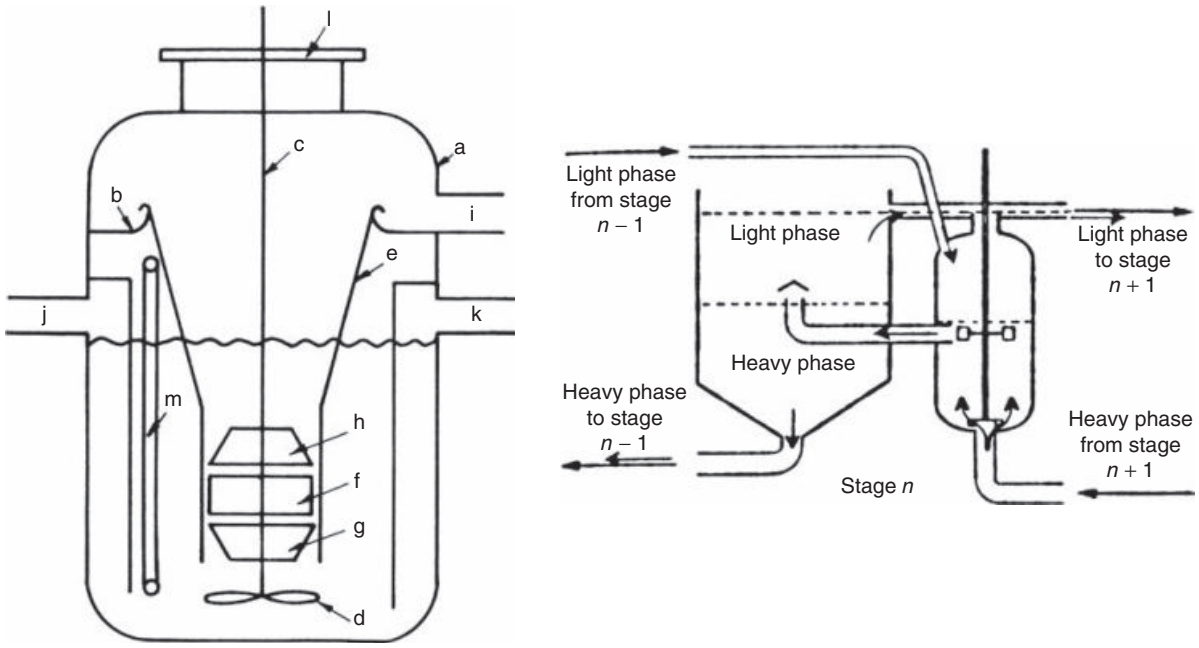

**FIG. 15-51** Types of pump-mix arrangements for mixer-settler extractors. (*a*) IMI pump mix with mixing and pumping impellers (a, vessel; b, internal deck; c, shaft; d, mixing impeller; e, draft tube; f, pumping impeller; g and h, guide vanes; i, dispersion discharge; j, light-phase feed; k, heavy-phase-feed; l, mounting flange; m, sight glass). (*b*) Kemira mixer-settler. [*Figure 15-51a taken from Lo, Baird, and Hanson, eds.,* Handbook of Solvent Extraction, *Wiley, New York, 1983; Krieger, Huntington, NY, 1991), with permission. Figure 15-51b taken from Mattila,* ISEC '74 Proc., *London, 1974, with permission.*]

A compact alternating arrangement of mixers and settlers has been adopted in many of the "box-type" extractors developed originally for processing radioactive solutions. These designs are used for many other processes, with literally dozens of modifications. An example is the pump-mix mixer-settler (Fig. 15-53), in which adjacent stages have common walls [Coplan, B. V., J. K. Davidson, and E. L. Zebroski, *Chem. Eng. Prog.* **50**(8): 403–408 (1954)]. In this case, the impellers pump as well as mix by drawing the heavy liquid upward through the hollow impeller shaft and discharging it at a higher level through the hollow impeller. Rectangular tanks are not ideal for good mixing; however, the compromise in mixing and settling performance is offset by the compact and economical design.

Vertical arrangement of the stages is desirable, for then a single drive may be used for agitators and the floor space requirement of a cascade is reduced to that of a single stage. The Lurgi extractor configuration has the mixer and

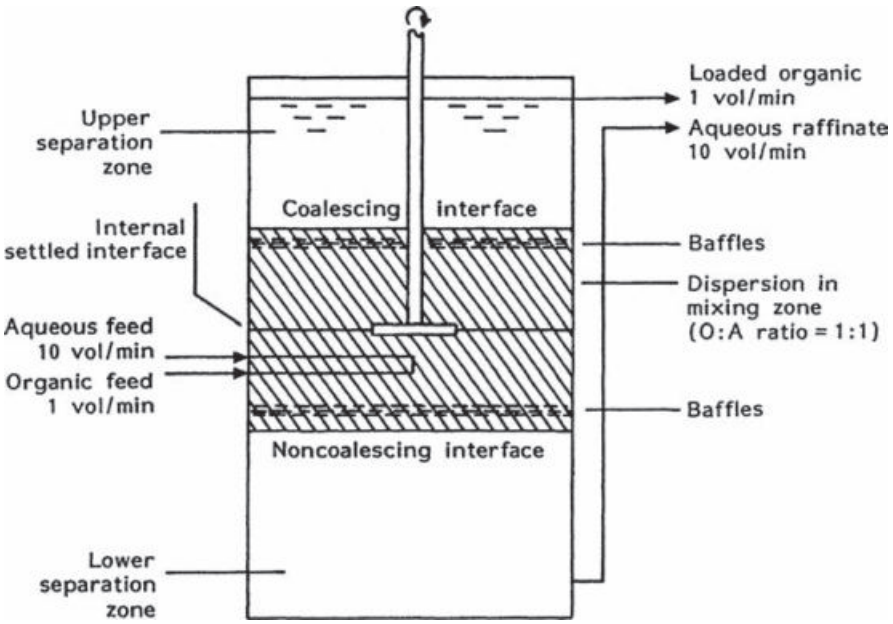

**FIG. 15-52** Davy CMS extractor with pump-mix impeller and phase separation zones. [*Reprinted from Godfrey and Slater, eds.,* Liquid-Liquid Extraction Equipment, *Wiley, New York, 1994), with permission. Copyright 1994 John Wiley & Sons Ltd.*]

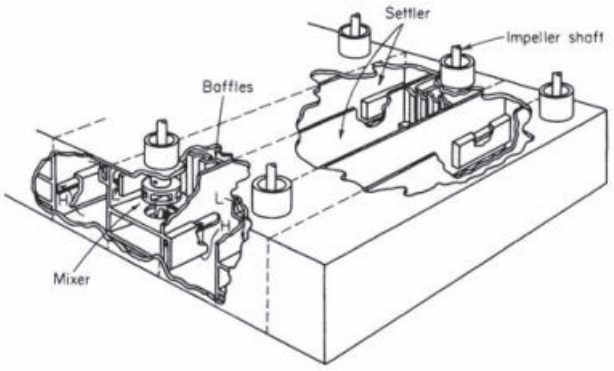

**FIG. 15-53** Pump-mix box-type mixer-settler. [*Taken from Coplan, Davidson, and Zebroski,* Chem. Eng. Prog. ***50,*** *p. 403 (1954), with permission.*]

settlers in separate vertical shells interconnected with piping [Guccione, E., *Chem. Eng. Magazine* **73**(4): 78–80 (1966)]. A great many other designs are known. For example, the Fenske and Long extractor [Fenske, M. R., and R. B. Long, *Chem. Eng. Prog.* **51**(4): 194–198 (1955); Long, R. B., and M. R. Fenske, *Ind. Eng. Chem.* **53**(10): 791–798 (1961); Long, R. B., *Ind. Eng. Chem. Fundam.* **1:** 152 (1962)] is a vertical stack of mixer-settler stages. This design employs a reciprocating plate at each stage to mix the two phases.

**Suspended-Fiber Contactor** The Merichem Fiber-Film® contactor is used in petroleum refining operations to wash hydrocarbon streams with caustic or other treating solutions [Suarez, F. J., U.S. Patent 5,997,731 (1999)]. The hydrocarbon feed and wash fluid are brought together within a vertical pipe or wash column containing fibers suspended from the top, as shown in Fig. 15-54. The two liquids flow concurrently down the column through the bed of fibers. The fibers are attached at the top of the column but not at the bottom. Liquid-liquid contacting is facilitated through capillary and surface-wetting effects. This arrangement avoids (or minimizes) the formation of small, dispersed drops, and this helps to minimize entrainment of aqueous phase into the hydrocarbon outlet. Little information about the mass-transfer performance and design requirements for this type of contactor has been published.

## CENTRIFUGAL EXTRACTORS

A centrifugal extractor multiplies the force of gravity acting on two liquid phases. Centrifugal extractors can facilitate a liquid-liquid extraction process by reducing diffusion path lengths and increasing the driving force for liquid-liquid phase separation. They can achieve very high specific throughput with very low liquid residence time. A wide variety of machine types are available, ranging from relatively simple devices used primarily for phase separation or for single-stage liquid-liquid contacting with separation to more complex machines designed to provide the equivalent of multistage liquid-liquid contacting within a single unit. Some machines are designed to handle feeds containing solids such as whole fermentation broth. This section provides a brief overview with a description of several machines for illustration. More detailed descriptions of centrifuge design and performance are available from equipment vendors. For additional discussion, see R. A. Leonard, "Design Principles and Applications of Centrifugal Contactors for Solvent Extraction," chap. 10 in *Ion Exchange and Solvent Extraction: A Series of Advances* (volume 19), ed. B. A. Moyer, CRC Press, Boca Raton, Fla., 2010; U. Janoske and M. Piesche, *Chem. Eng. Technol.* **22**(3): 213–216 (1999); R. A. Leonard, D. B. Chamberlain, and C. Conner, *Sep. Sci. Tech.* **32**(1–4): 193–210 (1997); E. Blass, chap. 14 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994; K. Schügerl, *Solvent Extraction in Biotechnology,* Springer-Verlag, Berlin, 1994; F. Otillinger and E. Blass, "Mass Transfer in Centrifugal Extractors," *Chem. Eng. Technol.* **11:** 312–320 (1988); and M. Hafez, chap. 15 in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991.

Centrifugal extractors can be beneficial when the liquid density difference is small, when short contact time is needed to avoid product degradation, when feed and solvent easily emulsify, or in cases where high specific throughput is needed due to limitations in available floor space or ceiling height. Centrifugal extractors also can provide flexibility in operation in cases where feed variability is high, by allowing adjustment of feed rate and rotational speed as needed to obtain satisfactory performance. Potential disadvantages generally derive from difficulties associated with maintaining high-speed rotating machinery, relatively high purchase prices compared to those of some other types of extractors, and limitations as to the number of theoretical stages that can be achieved per machine (generally less than one or up to five or six theoretical stages, depending upon throughput and the type of machine). Another consideration for some machines with close internal clearances is the potential for plugging if any solids are present in the feed; however, as previously noted, some machines are specifically designed to handle and discharge solids.

Commercial-scale centrifuges normally are continuously fed machines unless the scale of the operation is very low, as in some low-volume bioprocessing operations where very-high-$g$ operation and long processing times are needed. A continuously fed centrifugal extractor can deliver high multiples of $g$ at much lower residence time (given by holdup volume of the feed phase divided by volumetric feed rate) compared to a batch process. The maximum hydraulic capacity (or nominal capacity) of a continuously operated machine often is not realized in commercial applications because the feed rate needs to be turned down in order to have sufficient residence time for good extraction and phase separation performance.

In evaluating options, it generally is not possible to accurately predict performance because of the complexity of the hydrodynamics within a centrifuge. While high-$g$ operation can promote good performance, in certain

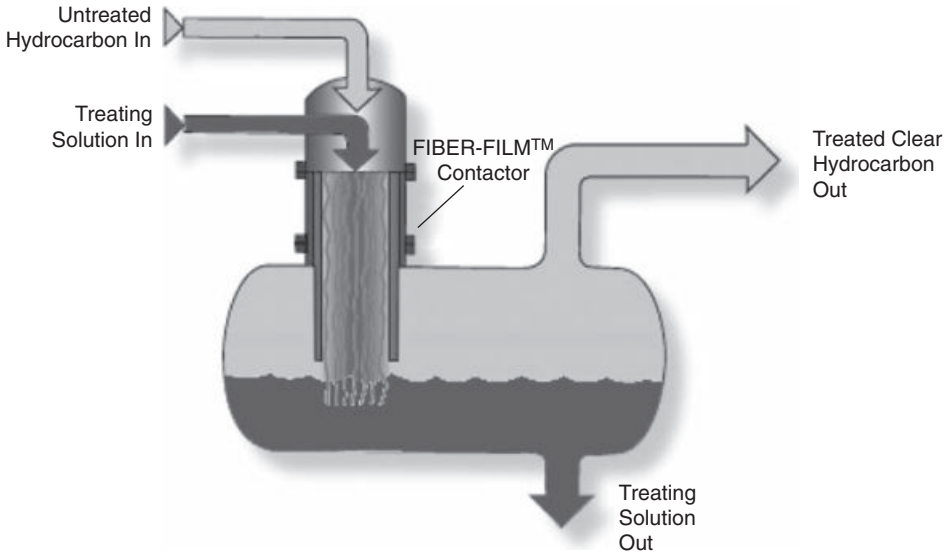

**FIG. 15-54** Merichem Fiber-Film™ contactor. (*Courtesy of Merichem Chemicals and Refinery Services, LLC.*)

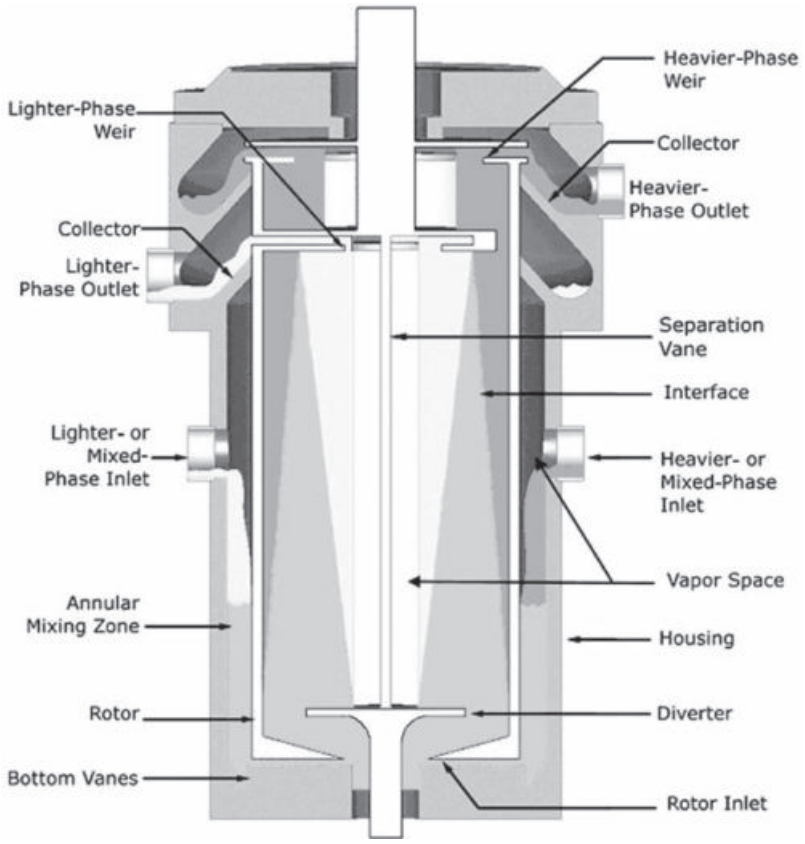

**FIG. 15-55** CINC centrifugal separator. (*Courtesy of CINC Processing Equipment, Inc.*)

cases the extremely rapid acceleration generated within the machine also can promote backmixing or emulsification. Miniplant tests using small units generally are needed, and vendors often offer testing services.

**Single-Stage Centrifugal Extractors** The types of centrifuges used in extraction operations are quite varied. Differences include vertical versus horizontal configuration, fluid-filled versus operation with an air core, pressurized or unpressurized operation, generation of low to extremely high multiples of gravitational acceleration (500 up to 20,000 × *g* or higher), as well as differences in the liquid holdup volume, design of internals, internal clearances, and purchase price. The simpler machines, such as the CINC separator (Fig. 15-55) and the Rousselet-Robatel model BXP, have relatively large internal clearances. An air core is maintained within the machine, and liquid layers decant over internal weirs. Flow restrictions in the overflow piping need to be minimized to avoid any pressure imbalance between light- and heavy-liquid overflow lines because this can affect the location of the liquid-liquid interface and the liquid overflow/underflow split. These machines often are used for washing operations and other extraction applications with high *K* values requiring few theoretical stages. They often serve as the separator in a mixer-settler stage, such that solvent and feed are first mixed in a static mixer or a separate vessel before being fed to the centrifuge. Some mixing occurs within the centrifuge itself, so if the extraction is sufficiently fast, solvent and feed might be fed directly to the centrifuge to accomplish both mixing and phase separation. Multiple units can be connected in a countercurrent mixer-settler cascade if needed. Processes with five to seven units are typical, while processes with as many as 50 units have been reported. Multiple-unit mixer-settler processes utilizing centrifuges at each stage generally involve production of high-value, low-volume products. Stacked-disk types of machines also are available from numerous vendors and may be used in a similar extraction scheme (generally requiring some type of mixer in the feed line). These machines contain an internal stack of conical disks with a small gap between disks on the order of millimeters [Janoske, U., and M. Piesche, *Chem. Eng. Technol.* **22**(3): 213–216 (1999); and Mannweiler, K., and M. Hoare, *Bioproc. Biosystems Eng.* **8**(1–2): 19–25 (1992)]. Stacked-disk machines can be thought of as inclined-plate or lamella-type decanters operating in a centrifugal field (see the subsection Liquid-Liquid Phase Separation Equipment). They magnify the separation power by greatly reducing the distance the dispersed phase must travel before coalescing at a surface, at the expense of somewhat higher complexity and closer internal clearances.

Figure 15-55 shows a cutaway drawing of a CINC separator showing an outer annular space where solvent and feed mix before entering the interior of a rotating drum. Although this type of machine is not designed to separate solids from feeds, a clean-in-place option is offered to facilitate periodic removal of solids that accumulate in the internals. In applications in which one or more of the feed liquids is somewhat viscous, special consideration must be given to the design of the centrifuge internals such that pressure drop through the machine is not excessive. In certain applications, feed with viscosities as high as several hundred centipoise may be handled; however, special modifications to the internals are needed, and throughput must be reduced compared to that in typical operation. Maximum or nominal volumetric flow capacities for CINC machines range from 110 L/h to 136 $m^3$/h (0.5 to 600 gal/min) depending upon the size of the unit. The Rousselet-Robatel design is somewhat similar. These machines range in size from 50 L/h up to 80 $m^3$/h (0.2 to 350 gal/min). They are designed to generate only moderate centrifugal force and are generally limited to applications requiring no more than about 25,000 $g \cdot s$ [maximum *g* acceleration times the liquid residence time (in seconds) based on total volumetric flow rate and liquid holdup in the machine].

The CENTREK single-stage extractor from MEAB consists of a funnel-shaped centrifugal-bowl centrifuge mounted above a mixing tank containing a submerged stirrer. An internal "hydrolock" is used to control the position of the liquid-liquid interface in the bowl. According to the manufacturer, this is especially important for multistage, cascade operation. The unit can tolerate some amount of solids in the feed and is available in nominal capacities of 20 L/h to 20 $m^3$/h (0.1 to 90 gal/min).

**Centrifugal Extractors Designed for Multistage Performance** At the other end of the spectrum are the more complex machines designed to provide multistage or differential liquid-liquid contacting and separation within a single unit. Some machines promote the formation of very thin films or small drops for efficient liquid-liquid contacting and separation. Others provide multiple zones for mixing and separating the phases. All are designed with complex internals and close clearances. These machines

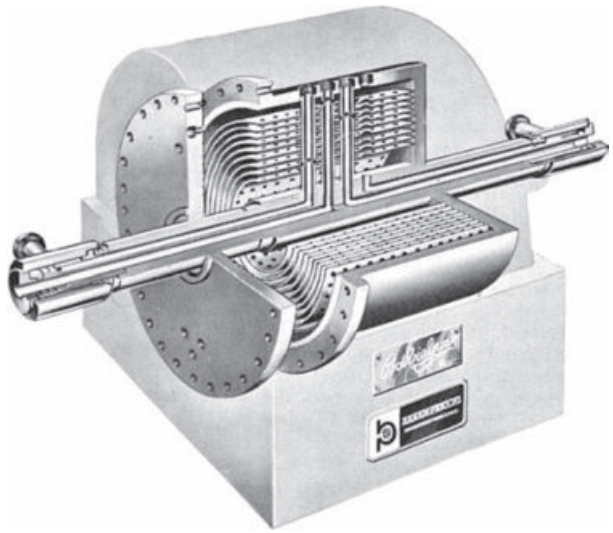

**FIG. 15-56** Podbielniak centrifugal extractor. (*Courtesy of B&P Littleford.*)

typically achieve two to five theoretical stages depending upon operating conditions, with some authors claiming as many as seven or eight stages.

The classic machine of this type is the Podbielniak extractor (Fig. 15-56). The body of the extractor is a horizontal cylindrical drum containing concentric perforated cylinders. The liquids are introduced through the horizontal rotating shaft with the help of special mechanical seals; the light liquid is fed internally to the drum periphery and the heavy liquid to the axis of the drum. Rapid rotation (up to several thousand revolutions per minute, depending on size) causes radial counterflow of the liquids, which then flow out through the shaft. Materials of construction include steel, stainless steel, Hastelloy, and other corrosion-resistant alloys. The Podbielniak design provides extremely low holdup of liquid per stage, and this led to its extensive use in the extraction of antibiotics, such as penicillin and the like, for which multistage extraction and phase separation must be done rapidly to avoid chemical destruction of the product at the acidic extraction conditions [Podbielniak, W. J., H. R. Kaiser, and G. J. Ziegenhorn, chap. VI in *Chemical Engineering Progress Symposium Series No. 100*, vol. **66:** 43–50 (1970)]. Podbielniak extractors have been used in all phases of pharmaceutical manufacturing, in petroleum processing (both solvent refining and acid treating), in the extraction of uranium from ore leach liquors, and for clarification and phase separation work. F. M. Jacobsen and G. H. Beyer [*AIChE J.* **2**(3): 283–289 (1956)] describe operating characteristics and the number of theoretical stages achieved for a specific application.

The Quadronics (Liquid Dynamics) extractor is a horizontally rotated device, a variant of the Podbielniak extractor, in which either fixed or adjustable orifices may be inserted radially as a package. These permit control of the mixing intensity as the liquids pass radially through the extractor. Flow capacities, depending on machine size, range from 0.34 to 340 $m^3/h$ (1.5 to 1500 gal/min).

The Luwesta (Centriwesta) extractor is a development from Coutor [H. Eisenlohr, *Ind. Chemist* **27:** 271 (1951)]. This centrifuge revolves about a vertical axis and contains three actual stages. It operates at 3800 rotations per minute and handles approximately 5 $m^3/h$ (1300 gal/h) total liquid flow at 12-kW power requirement. Provision is made in the machine for the accumulation of solids separated from the liquids, for periodic removal. It is used, more extensively in Europe than in the United States, for the extraction of acetic acid, pharmaceuticals, and similar products.

The de Laval extractor contains a number of perforated cylinders revolving about a vertical shaft [Palmqvist, F. T. E., and S. Beskow, U.S. Patent 3,108,953 (1959)]. The liquids follow a spiral path about 25 m (82 ft) long, in countercurrent fashion radially, and mix when passing through the perforations. There are no published performance data.

The Rousselet-Robatel LX multistage centrifugal extractor is designed with up to seven internal mixing/separation stages. Each stage consists of a mixing chamber where the two phases are mixed by means of a stationary agitation disk mounted on a central drum. The high relative speed between the stationary disk and the rotating walls of the mixing chamber creates a liquid-liquid dispersion with high interfacial area to facilitate rapid mass transfer. The agitation disk and the mixing chamber's inlet and outlet channels form a pump that draws the two phases from the adjacent stages and transfers the dispersion to a settling chamber, where it is separated by centrifugal force. The manufacturer claims that high stage efficiencies can be achieved. Extract and raffinate phases are removed from the machine by gravity discharge, or an internal centripetal pump can be employed to discharge these streams under pressure. Nominal flow rates range from 25 L/h up to 80 $m^3/h$.

## PROCESS CONTROL CONSIDERATIONS

**General References:** Wilkinson, W. L., and J. Ingham, chap. 27.2, and Plonsky, S. P., chap. 27.3, in *Handbook of Solvent Extraction*, ed. T. C. Lo, M. H. I. Baird, and C. Hanson, Wiley, New York, 1983, and Krieger, Huntington, NY, 1991.

### STEADY-STATE PROCESS CONTROL

Control of a continuous liquid-liquid extraction process generally refers to maintaining satisfactory dispersion of one phase in another for good mass-transfer performance while also maintaining the required production rate. This must be done without entering a flooding condition. It is common practice to set up a continuously fed extractor to handle a range of feed rates while maintaining other operating variables at constant preset values. These include the solvent flow rate, temperatures, and mechanical variables (if agitation or centrifugation is employed). For extraction processes that experience large swings in feed flow rate, the solvent flow rate may be manipulated to maintain a constant solvent-to-feed ratio, in order to reduce the volume of extract that needs to be processed. In this case, the extractor must be able to operate within a fairly wide range of volumetric throughput.

A common cause of upsets in operation is contamination of the feed by trace amounts of impurities that affect interfacial tension and drop coalescence, so it is important to control upstream operations to avoid contamination. Upsets or deviations from desired performance also can be caused by changes in the purity of solvent entering from solvent recovery equipment, so adequate control of closely coupled solvent recovery operations is needed to ensure good extractor performance. Periodic monitoring of the interfacial tension of light and heavy phases at the feed location (where interfacial tension is likely to be lowest due to higher solute concentration) may be useful for understanding the range of values that can be tolerated, and trends in the data may provide warning of an impending flooding or coalescence problem.

Steady-state control of a continuously fed extraction column requires maintenance of the location of the liquid-liquid interface at one end of the column. The main interface should be maintained at the top of the column when the light phase is dispersed and at the bottom of the column when the heavy phase is dispersed. If needed, extraction columns can be designed with an expanded-diameter settling zone to facilitate liquid-liquid phase separation by reducing liquid velocities and the area available for drop coalescence. If sufficient clarification of the phases cannot be achieved, then it may be necessary to add an external device such as a gravity decanter or packed coalescer. (See the subsection Liquid-Liquid Phase Separation Equipment.) Sometimes a column is built with expanded ends at both top and bottom to allow the option of operating with either phase dispersed.

The position of the main operating interface in an extraction column, whether located at the top or the bottom, generally is controlled by adjusting the outlet flow of the heavy phase; the heavy-phase outlet valve opens to lower the interface and closes to raise the interface, and the light phase is allowed to overflow the top of the column. The location of the liquid-liquid interface can be determined using a sensor such as a guided wave radar probe. Older techniques include measuring the differential pressure (if density difference is sufficiently large) or the capacitance of the liquid across the settling zone ( for aqueous/organic systems). A float-based technique that rests at the position of the interface can also be used. The general interface control concept is illustrated in Fig. 15-57. O. Weinstein, R. Semiat, and D. R. Lewin [*Chem. Eng. Sci.* **53**(2): 325–339 (1997)] studied the light-phase dispersed case (with the main interface maintained at the top of the column) and recommend controlling the main interface level by manipulating the continuous-phase feed flow rate instead of the continuous-phase outlet flow rate. The authors developed a dynamic model of the hydrodynamics and mass transfer in a countercurrent liquid-liquid extraction column, and the simulation results indicate faster dynamic response using their alternative scheme.

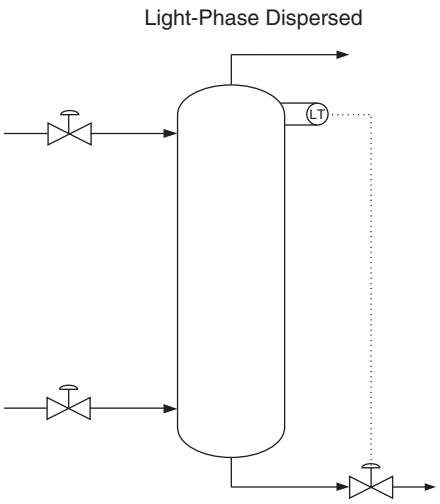

**FIG. 15-57** Typical interface control for a light-phase dispersed process (with the main interface located at the top of the column). The same basic arrangement can be used for the heavy-phase dispersed case, but the level transmitter would be located differently to reflect the location of the main interface at the bottom of the column.

When a continuous extraction column begins to flood, often one of the first indications is the appearance of an interface at the wrong end of the column; so adding instrumentation that can detect such an interface (such as one or more conductivity probes when phase inversion involves the formation of a continuous aqueous phase) may help identify a flooding condition in time to take corrective action. Sometimes a rag layer will accumulate at the liquid-liquid interface, and it is necessary to provide a means for periodically draining the rag to avoid entrainment into the extract or raffinate. It may be useful to add instrumentation that can detect the rag at high positions to warn an operator before breakthrough occurs; however, often the approach taken is to drain the interface region on a predetermined schedule. Installing sensors to detect a rag layer can be problematic because they are easily fouled.

For a continuous extraction column, it is important to control the holdup of each phase within the column to obtain high interfacial area for good mass transfer. For nonagitated extraction columns, this is set by proper design of the internals and maintaining flow velocities during operation within a fairly narrow range of values needed for good performance. Agitated columns allow greater flexibility in this regard because agitation intensity can be adjusted in the plant to maintain good performance over a wider range of flow velocities and as the properties of the feed change. In industrial practice, agitation intensity normally is set at a constant rate or manually adjusted at infrequent intervals in response to a significant change in feed characteristics. Model-based control schemes offer potential for automatic adjustment of agitation intensity and other variables for faster response [Mjalli, F. S., *Chem. Eng. Sci.* **60**(1): 239–253 (2005); and Mjalli, F. S., N. M. Abdel-Jabbar, and J. P. Fletcher, *Chem. Eng. Processing* **44**(3): 531–542 and 543–555 (2005)]. Careful programming will be needed to avoid inappropriate control actions when sensors are out of calibration. Real-time measurement of dispersed-phase holdup also may be helpful; J. Chen et al. [*Ind. Eng. Chem. Res.* **41**(7): 1868–1872 (2002)] report a method for a pulsed-liquid column. They studied a system consisting of 30 percent trialkyl($C_{6-8}$) phosphine oxide in kerosene + nitric acid solution, with the acid phase dispersed.

For some extraction operations, particularly fractional extractions, it may be useful to control a temperature profile across the process. In extraction columns, this is normally done by controlling the temperature of entering feed and solvent streams. Heating jackets generally are not effective because of insufficient heat-transfer area. Internal heating or cooling coils are problematic because they are difficult and expensive to install and can interfere with other column internals and liquid-liquid traffic within the column. For fractional extraction, the stripping and washing operations may be carried out in separate equipment with external heating or cooling of the streams entering the equipment.

For startup of column extractors, generally it is best to start from dilute-solute conditions to avoid unstable operation. For example, when starting a column in which the feed is the continuous phase, first fill the column with solute-lean feed liquid before starting the flow of solvent and actual feed. This way, the solvent quickly becomes dispersed, and mass transfer approaches steady state from dilute conditions, promoting faster and more stable startup.

### SIEVE TRAY COLUMN INTERFACE CONTROL

Control of the main liquid-liquid interface for a sieve tray column can be counterintuitive because of complexity caused by the presence of multiple interfaces within the column. For example, if the interface level is too high, the usual control response is to allow the heavy phase to flow out the bottom of the column for a time until the desired level is reached (using the scheme outlined in Fig. 15-57). Ideally, this should lower the interface level, as shown in Fig. 15-58*a*. This is a typical response for most differential contactors such as packed or spray columns. However, for the sieve tray column, the initial response can actually be a rise in the interface level for a short time (Fig. 15-58*b*). In some cases, this can result in entrainment of heavy phase out the top of the tower. This inverse response is caused by changes in the coalesced layer heights at each tray. Neglecting any correction for dispersed-phase holdup, the height of the coalesced layer is affected by the pressure drop through the sieve holes and downcomer:

$$h \approx \frac{\Delta P_o + \Delta P_{\text{dow}}}{\Delta \rho g} = \frac{C_1 V_o^2 + C_2 V_{\text{dow}}^2}{\Delta \rho g} \tag{15-165}$$

where $h$ is the coalesced layer height, $\Delta P_o$ is the pressure drop through perforations, $\Delta P_{\text{dow}}$ is the pressure drop through the downcomer, $V_o$ is the average velocity through a perforation (orifice), $V_{\text{dow}}$ is the average velocity through the downcomer, and $C_1$ and $C_2$ are constants related to tray geometry and physical properties. Tray designs often vary as to which contribution, orifice or downcomer pressure drop, controls the height of the coalesced layer. The inverse response can cause significant control problems if the downcomer pressure drop is much greater than the orifice pressure drop, and this issue should be addressed during design.

Prog.* **90**(9): 29–40 (1994); and Jacobs, J. L., and W. R. Penney, chap. 3 in *Handbook of Separation Process Technology*, ed. R. W. Rousseau, Wiley, New York, 1987.

### OVERALL PROCESS CONSIDERATIONS

The ability to separate a mixture of two liquid phases is critical to the successful operation of many chemical and refining processes. Besides its obvious importance to liquid-liquid extraction and washing operations, liquid-liquid phase separation can be a critical factor in other operations, including two-liquid-phase reaction, azeotropic distillation, crude oil processing, and industrial wastewater treatment. Sometimes the required phase separation can be accomplished within the main process equipment, such as an extraction column or a batchwise, stirred-tank reactor; but in many cases a stand-alone separator is used. These include many types of gravity decanters (or settlers), filter-type coalescers, coalescers filled with granular media, centrifuges, and hydrocyclones.

The path that a liquid-liquid mixture takes through a chemical process on its way to the separator often has a dramatic impact on separation difficulty once the mixture arrives. For this reason, the first steps toward designing a decanter or other type of liquid-liquid phase separator should include a study of the overall process flow sheet to determine whether changes in upstream processing conditions can make for an easier and more robust separation. For example, if the main stream entering the separator is produced by mixing a number of smaller streams, look for opportunities to remove fine solids that contaminate the main stream by filtering solids from one or more small streams before they enter the larger stream. Also, standard centrifugal pumps are notorious for producing stable dispersions. If this type of pump is used upstream of a separator, determine whether the turbulence caused by the pump is contributing to phase separation difficulty and if so, consider using gravity or pressurized flow (if possible) or replacing a high-shear pump and piping system with a lower-shear design.

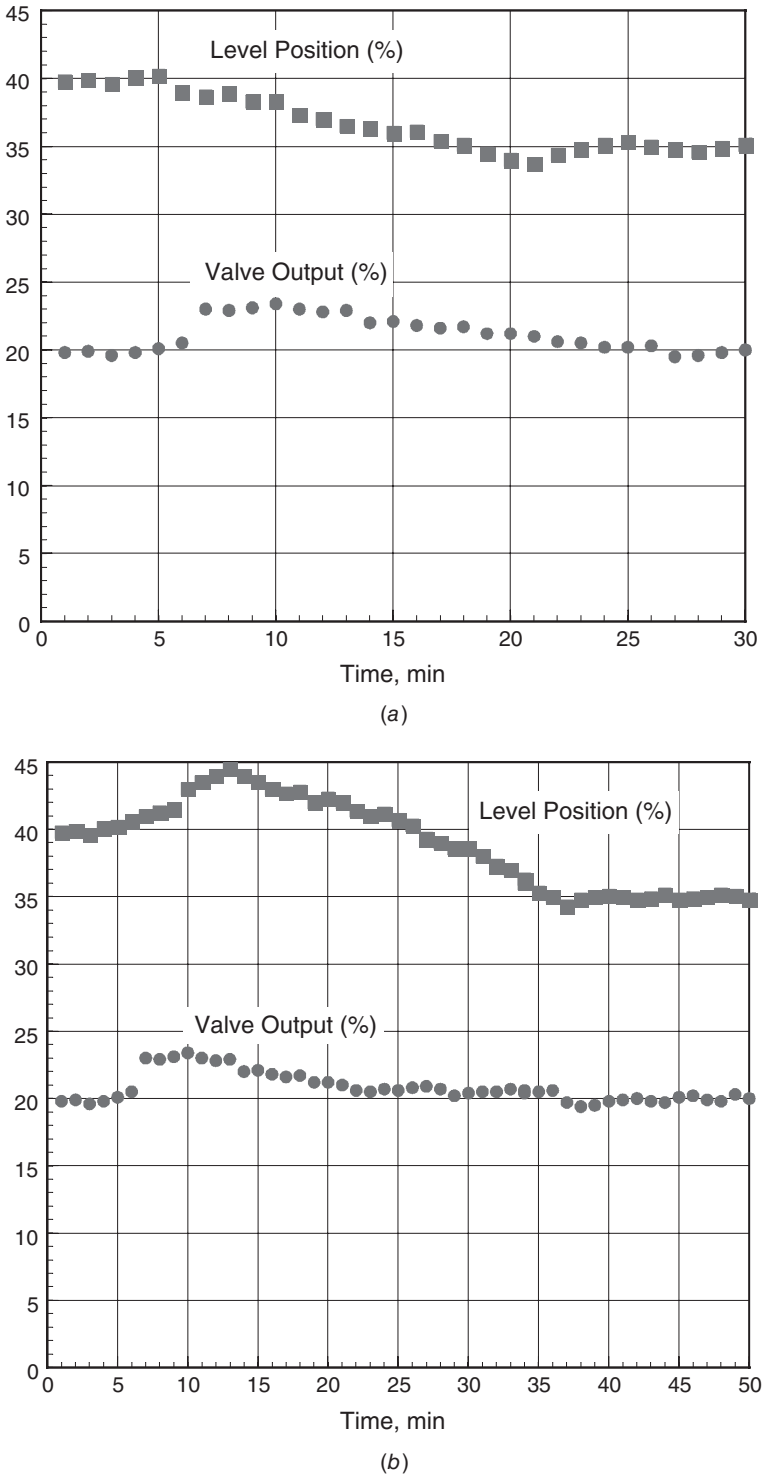

**FIG. 15-58** Dynamic response to a change in heavy-phase flow rate. (*a*) Normal dynamic response to increasing outlet heavy-phase flow (packing). (*b*) Dynamic response to increasing outlet heavy-phase flow rate (sieve trays).

If a dispersion proves to be particularly difficult to separate, it may be due to the presence of some contaminant acting as a surfactant. Such contaminants may be oxidation products produced in trace amounts owing to leakage of air into the process, or they may be the products of corrosion of upstream equipment. They also may be materials that are intentionally added upstream to solve a problem there, such as cleaning agents or antifouling agents, but their presence, even in very small concentration, may cause unintended phase separation difficulties downstream.

## FEED CHARACTERISTICS

Traditionally, the guidelines for selection and design of a gravity decanter or other type of separator focus on the size of dispersed drops. However, drop diameter often cannot be accurately predicted during the design of a new process, especially the size of the smaller drops in the distribution of drop sizes, and often this information is not available for an existing process because of sampling difficulties. Furthermore, knowledge of drop size alone is not

**TABLE 15-24 Shake Test Characterizations**

| Type | Shake test observations | Interfacial tension* | Density difference* | Viscosity of each phase* | Presence of fine solids or surfactants* |
|---|---|---|---|---|---|
| I | Dispersion band collapses within 5 min with crystal-clear liquids on top and bottom | Moderate to high, 10 dyn/cm or higher | $\Delta\rho > 0.1$ g/cm$^3$ | $\mu < 5$ cP | Negligible |
| II | Dispersion band collapses within 10 to 20 min with clear liquids on top and bottom | Moderate, ~10 dyn/cm | $\Delta\rho > 0.1$ g/cm$^3$ | $\mu < 20$ cP | Negligible |
| III | Dispersion band collapses within 20 min but one or more phases remain cloudy | Low to moderate, 3–10 dyn/cm | $\Delta\rho > 0.05$ g/cm$^3$ | $\mu < 100$ cP | Might be present in low concentration |
| IVa | Stable dispersion is formed (dispersion band does not collapse within an hour or longer)—high viscosity | Low to high | $\Delta\rho > 0.1$ g/cm$^3$ | $\mu > 100$ cP in one of the phases | Negligible |
| IVb | Stable dispersion is formed—low interfacial tension | < 3 dyn/cm | $\Delta\rho > 0.1$ g/cm$^3$ | $\mu < 100$ cP | Negligible |
| IVc | Stable dispersion is formed—low density difference | Low to high | $\Delta\rho < 0.05$ g/cm$^3$ | $\mu < 100$ cP | Negligible |
| IVd | Stable dispersion is formed—stabilized by surface-active components or solids | Low | $\Delta\rho > 0.1$ g/cm$^3$ | $\mu < 100$ cP | Enough surfactant/ solids to keep emulsion stable |

*Typical physical properties. Behavior also depends upon the shear history of the fluid. For this test, a sample is characterized by the results of the shake test (second column), not its physical properties. Physical properties are listed only as typical values.

sufficient because it says nothing about the rate of drop coalescence. In light of this, it is recommended instead to characterize the feed material in terms of the results of simple shake tests, as indicated in Table 15-24. This basic information can be very helpful in identifying an appropriate separator type.

In Table 15-24, feed materials are classified into four main types according to the results of a shake test. Typical values of interfacial tension, density difference, and viscosity also are listed. The shake test can be as simple as shaking a representative feed by hand in a sealed graduated cylinder (about an inch in diameter) for 15 seconds. The graduated cylinder is then placed on the bench, the time is recorded, and the progress of the separation is observed. For systems with drops that coalesce quickly, a sharp interface will quickly form between two settling liquid layers, and the rate at which drops fall or rise to the interface will determine the rate of phase separation or clarification of the layers. For many other systems, however, drops will accumulate at the interface forming a dispersion band, that is, a layer of slowly coalescing drops, and the rate at which the drops coalesce determines the rate of phase separation. Whether a system is fast-coalescing or slow-coalescing is an important question that is easily answered by performing a simple shake test. Figure 15-59 illustrates the details of a batch settling profile. Once the dispersion band has disappeared, one or both of

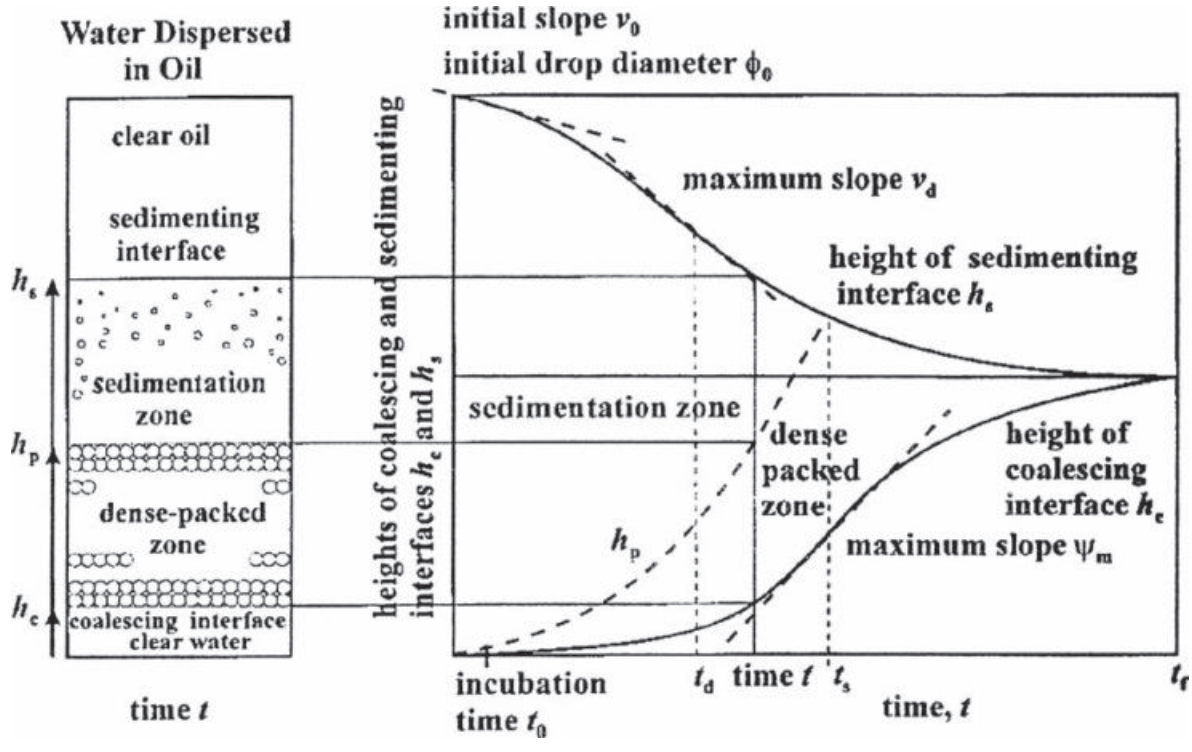

**FIG. 15-59** Batch settling profile showing four regions: a top clarified phase, a sedimentation zone, a dense-packed dispersion zone, and a bottom clarified phase. [*Reprinted from Jeelani, Panoussopoulos, and Hartland,* Ind. Eng. Chem. Res. ***38****(2), pp. 493–501 (1999), with permission. Copyright 1999 American Chemical Society.*] Consult the original article for a detailed description.

the phases may remain cloudy. If so, this typically indicates the presence of droplets on the order of 100 μm in diameter or smaller. To reduce variability, this type of test can be implemented using a glass vessel with shaft-driven pitch-blade impeller and baffles to avoid vortexing. For additional discussion of dispersion properties, see the subsection Liquid-Liquid Dispersion Fundamentals.

## GRAVITY DECANTERS (SETTLERS)

Gravity decanters or settlers are simple vessels designed to allow time for two liquid phases to settle into separate layers (Fig. 15-60). Ideally, clear top and bottom layers form above and below a sharp interface or dispersion band. The top and bottom layers serve as clarifying zones. The height of the dispersion band, if present, generally remains constant during steady-state operation, although it may vary with position. The choice of where to locate the phase boundary within the vessel depends on whether more or less height is needed in the upper or lower clarification zones to obtain the desired clarity in the discharge streams. It can also depend on whether the inventory of one particular layer within the vessel should be minimized, as when handling reactive fluids such as monomers. Gravity decanters are well suited for separating type I feeds defined in Table 15-24 and, in most cases, type II feeds as well. It is common for coalescence to be the limiting factor in the separation of type II mixtures, so the design and sizing of the decanter will differ from those of the fast-coalescing systems.

**Design Considerations** Gravity decanters normally are specified as horizontal vessels with a length-to-diameter ratio greater than 2 (and often greater than 4) to maximize the phase boundary (cross-sectional area) between the two settled layers. This provides more effective utilization of the vessel volume compared to vertical decanters, although vertical decanters may be more practical for low-flow applications or when space requirements limit the footprint of the vessel.

The volume fraction of the minority phase is an important parameter in the operation of a decanter. Vessels handling less than 10 to 20 percent dispersed phase typically contain a wider distribution of droplet diameters with a long tail in the small size range [Barnea, E., and J. Mizrahi, *Trans. Instn. Chem. Engrs.* **53:** 61–69 (1975)]. These decanters have a smaller capacity than when they contain more-concentrated dispersions. If one of the phases has a concentration lower than 20 percent in the feed mixture, it might be worthwhile to recycle the low-concentration phase to the feed point to boost the phase ratio within the separator vessel. Also, in certain cases increasing the operating temperature increases the drop coalescence rate. The result of either is a reduction in the dispersion band height for a given throughput, allowing an increase in the capacity of the settler. This behavior often can be attributed to a reduction in the continuous-phase viscosity.

Numerous methods are used to control the location of the interface inside the decanter. A boot or sump sometimes is included in the design to increase the path traveled by the heavy phase before exiting the vessel, to maximize the clarification zone for the light phase, or to minimize the inventory of heavy phase within the vessel. The interface can even be located inside the boot for one of these reasons. When a rag layer forms at the interface between settled layers, adding one or more nozzles in the vicinity of the interface will allow periodic draining of the rag (Fig. 15-61). Instruments such as differential pressure cells, conductance probes, or density meters are commonly used to control the location of the interface in a decanter. These instruments can be prone to fouling, and their operation can be compromised by the presence of a dispersion band or a rag layer. In that case, an alternative is to use an overflow leg or seal loop as illustrated in Figs. 15-60 and 15-61. The following expression can be used to specify the loop dimensions [Bocangel, J., *Chem. Eng. Magazine* **93**(2): 133–135 (1986); and Aerstin, F., and G. Street, *Applied Chemical Process Design*, Plenum, New York, 1982]:

$$Z_2 = \frac{(h_L + Z_1 - Z_3)\rho_L}{\rho_H} + Z_3 - h_H \tag{15-166}$$

where $Z_1$, $Z_2$, and $Z_3$ are the heights shown in Fig. 15-61 and $h_L$ and $h_H$ are the head losses in the light- and heavy-liquid discharge piping. An overflow leg can work reasonably well, provided that the densities of the two phases and the height of the dispersion band do not change significantly in operation (as in an upset). The light phase also may be removed through a takeoff tube entering the vessel from the bottom. This design provides added flexibility by allowing adjustment of the pipe length in the field without altering the vessel itself. Care should be taken to avoid the possibility of inducing a swirling motion as liquid enters the top of the weir. Swirling motions may be avoided or minimized by adding vanes or slots at the entrance.

To allow the phases to settle and remain calm, any form of turbulence or vortexing inside the decanter should be avoided. Introduction of the feed

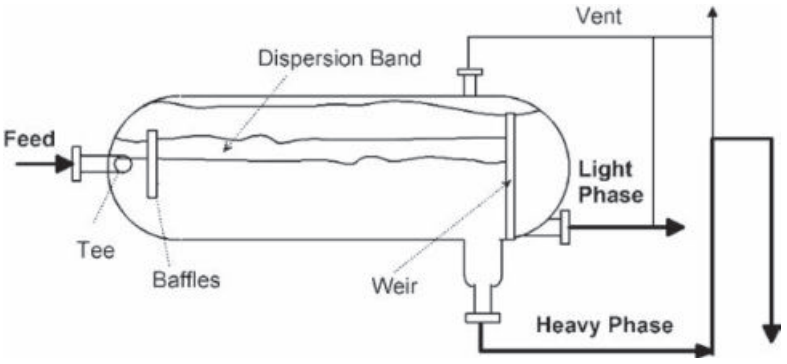

**FIG. 15-60** Typical horizontal gravity decanter design.

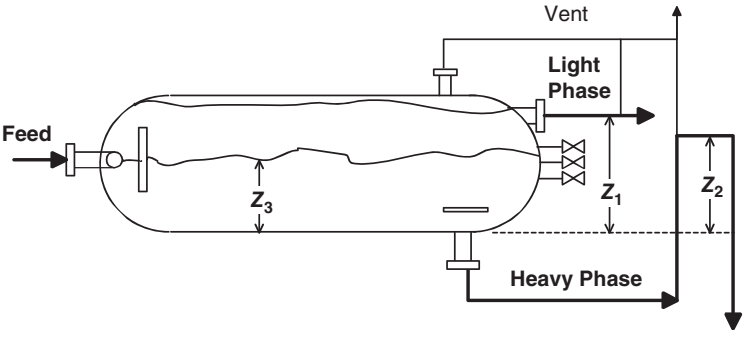

**FIG. 15-61** Overflow loop for the control of the main interface in a decanter.

stream into the decanter should be located close to the interface to facilitate phase separation. Turbulence can arise from the inlet liquid entering the vessel at too high a velocity, forming a jet that disturbs the liquid layers. To counter these flow patterns, the feed into the gravity settler should enter the vessel at a velocity of less than about 1 m/s (3 ft/s) as a general rule. This can be achieved by enlarging the feed line in the last 1 to 2 m (3 to 6 ft) leading to the vessel, to slow down the feed velocity at the inlet nozzle. In addition, a quiet feed zone may be created by installing a baffle plate in front of the feed pipe or a cap at the end of the feed line, with slots machined into the side of the pipe. Some designers are now using computational fluid dynamics (CFD) methods to analyze general flow patterns as an aid to specifying decanter designs.

**Vented Decanters** When the liquid-liquid stream to be decanted also contains a gas or vapor, provisions for venting the decanter must be included. This often is the case when decanting overheads condensate from an azeotropic distillation tower operating under vacuum, as some amount of air leakage is virtually unavoidable, or when decanting liquids from an extractor operating at a higher pressure. A common design used for this service when the amount of gas is low is shown in Fig. 15-62. The feed enters the vessel at a point below the liquid level, so any gas must flow up through the liquid before disengaging in the vapor head space. An alternative design is illustrated in Fig. 15-63. With this design, the feed is introduced to the top of the vessel in the vapor headspace so that gases can be freely discharged and disengaged with no back-pressure. One drawback to this approach is that the feed liquids are dropped onto the light liquid surface, and significant quantities of heavy liquid may be carried over to the light liquid draw-off nozzle owing to the resulting turbulence. To mitigate this effect, a quiescent zone may be provided immediately below the top feed nozzle by means of a perforated baffle, as shown in Fig. 15-63. The baffle separates the disturbance caused by the entering feed from a calm separation zone where the two liquid phases can coalesce and disengage prior to draw-off.

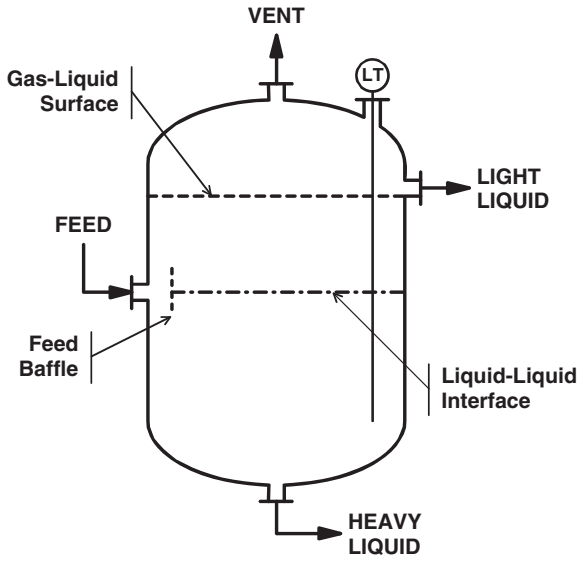

**FIG. 15-62** Vertical decanter with submerged feed.

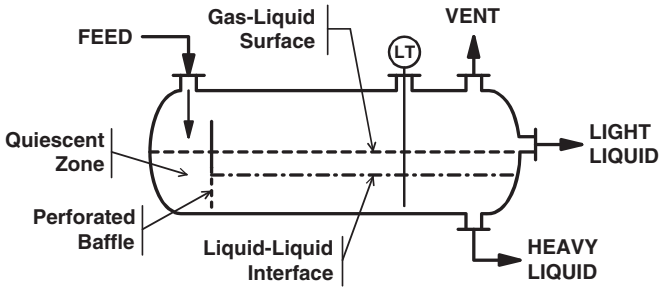

**FIG. 15-63** Horizontal decanter with feed entering from the top and a baffled quiescent zone.

**Decanters with Coalescing Internals** Adding coalescing internals may improve decanter performance by promoting the growth of drops and may reduce the size of vessel required to handle dispersions with slow coalescence (as in type II systems in Table 15-24). A wide variety of internals have been used, including wire mesh, knitted wire or fibers, and flat or corrugated plates. When plates are used, the coalescer is sometimes referred to as a lamella-type coalescer. Plates typically are arranged in packets installed at a slight angle with respect to horizontal. The plates shorten the distance that drops must rise or fall to a coalescing surface and guide the flow of the resulting coalesced film [Menon, W., W. Rommel, and E. Blass, *Chem. Eng. Sci.* **48**(1): 159–168 (1993); and Menon, W., and E. Blass, *Chem. Eng. Technol.* **14:** 11–19 (1991)]. Arranging the plates in packets of opposite slopes promotes flow reversal, and this may lead to more frequent drop–drop collisions [Berger, R., *Int. Chem. Eng.* **29**(3): 377–387 (1989)]. The Merichem Fiber-Film® contactor described earlier in the subsection Suspended-Fiber Contactor under Mixer-Settler Equipment also may be used to promote the growth of dispersed drops in a stream feeding a gravity decanter. The dispersed phase normally must preferentially wet the coalescence media for the media to be effective. If the feed contains solids, the potential for plugging the internals should be carefully evaluated. In certain cases, it may be necessary to allow access to the vessel internals for thorough cleaning. For more information, see E. Müller et al., "Liquid-Liquid Extraction," *Ullmann's Encyclopedia of Industrial Chemistry*, 6th ed., Wiley-VCH, New York, 2002, updated online, 2008.

**Sizing Methods** Sizing a decanter involves quantifying the relationship between the velocity of liquid to the phase boundary between settled layers and the average height of a dispersion band formed at the boundary. For fast-coalescing systems, the height of the dispersion band is negligible. Performance is determined solely by the rate of droplet rise or fall to the interface compared with the rate of flow through the decanter. In this case, design methods based on Stokes' law may be used to size the decanter, and residence time in the vessel becomes a key factor. In many cases, however, coalescence is slow and the shake tests show a coalescence band that requires a fair amount of time to disappear. Then performance is determined by the volumetric flow rate of liquid to the boundary between the two settled layers, the boundary area available for coalescence, and the steady-state height of the dispersion band. For these systems, residence time is not a reliable guide for decanter design.

***Stokes' Law Design Method*** This method is described by W. B. Hooper and L. L. Jacobs [sec. 1.11 in *Handbook of Separation Techniques for Chemical Engineers,* 3d ed., ed. P. A. Schweitzer, McGraw-Hill, New York, 1997]; and by L. L. Jacobs and W. R. Penney [chap. 3 in *Handbook of Separation Process Technology*, ed. R. W. Rousseau, Wiley, New York, 1987]. It assumes that the drop coalescence rate is rapid and relies on knowledge of drop size. The terminal settling velocity of a drop is computed by using Stokes' law

$$u_t = \frac{gd^2\Delta\rho}{18\mu_c} \tag{15-167}$$

where $d$ is a characteristic minimum drop diameter. (See Sec. 6 for a detailed discussion of terminal settling velocity.) Note that which phase is continuous and which is dispersed can make a significant difference, as only the continuous-phase viscosity appears in Eq. (15-167). The decanter size is then specified such that

$$\frac{Q_c}{A} < u_t \tag{15-168}$$

where $Q_c$ is the volumetric flow rate of the continuous phase and $A$ is the cross-sectional area between the settled layers. This analysis assumes no effect of swirling or other deviation from quiescent flow, so a safety factor of 20 percent often is applied. Hooper as well as Jacobs and Penney both indicate that designing for a Reynolds number $\mathrm{Re} = VD_h\rho_c/\mu_c$ less than 20,000 or so should provide sufficiently quiescent conditions, where $V$ is the continuous-phase cross-flow velocity and $D_h$ is the hydraulic diameter of the continuous-phase layer (given by four times the flow area divided by the perimeter of the flow channel, including the interface). However, this Reynolds number criterion is a general guideline rather than a firm not-to-exceed number. Both sources cite multiple Reynolds number ranges where varying degrees of swirling effects might be encountered. In particular, decanters with large hydraulic diameters will result in higher Reynolds numbers for a given velocity, which does not necessarily mean that quiescent conditions are contraindicated. In these cases, a high Reynolds number may only indicate that viscous drag effects due to the vessel walls are insignificant relative to inertial forces and do not influence the flow profile through the decanter.

Decanter design methods based on Stokes' law generally assume a minimum design droplet size of 150 μm, and this appears to be a reasonably conservative value for many chemical process applications. However, the size of drops created in a process is highly dependent on a number of factors such

as agitation and turbulence in the liquid, and in particular on the interfacial tension of the liquid-liquid system at process temperatures. The general rule of a minimum design drop size of 150 μm is probably adequate for systems with interfacial tensions of 10 dyn/cm or more as in type I and II systems in Table 15-24, but at lower interfacial tensions a smaller drop size specification may be needed because of the ease of formation of secondary dispersions. For separating secondary dispersions, it is common to assume a design drop size of no more than 100 μm with drop sizes less than 10 μm often being typical [Speth, H., et al., *Sep. Purif. Technol.* **29:** 113–119 (2002) and Clayfield, E. J., et al., *J. Coll. Int. Sci.* **104**(2): 500–511 (1985)]. For more detailed discussion, see S. Hartland and S. A. K. Jeelani, chap. 13 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994, pp. 509–516.

The method just described neglects any reduction in settling velocity due to the presence of neighboring drops at high population density (hindered settling). For best results, experimental data showing the relationship between settling velocity and initial dispersed-phase holdup should be generated. A simplified expression that neglects any drop coalescence during settling may be suitable for approximate design purposes

$$u_t \approx u_{t\infty}(1-\phi_o)\frac{\mu_c}{\mu_d} \tag{15-169}$$

where $u_t$ is an average settling velocity used to specify the decanter design, $u_t\infty$ is the velocity of an isolated drop calculated from Eq. (15-167), and $\phi_o$ is the initial holdup. For more detailed discussion, see M. Ishii and N. Zuber, *AIChE J.* **25:** 843–855 (1979); and P. K. Das, *Chem. Eng. Technol.* **20:** 475–477 (1997).

***Design Methods for Systems with Slow Coalescence*** For slow-coalescing systems, simple Stokes' law calculations will not provide a reliable design. Instead, it is necessary to understand the height of the dispersion band as a function of throughput. S. A. K. Jeelani and S. Hartland [*AIChE J.* **31:** 711–720 (1985)] recommend correlating decanter performance by using an expression of the form

$$\frac{1}{Q/A} = \frac{1}{k_1 \Delta H} + \frac{1}{k_2} \tag{15-170}$$

where $\Delta H$ is an average steady-state dispersion band height, $Q$ is total volumetric throughput, and $k_1$ and $k_2$ are empirical constants. The general relationship between $\Delta H$ and $Q/A$ also may be expressed in terms of a power law equation of the form

$$\Delta H \propto \left(\frac{Q}{A}\right)^a \propto \left(\frac{Q_c}{A}\right)^a \propto \left(\frac{Q_d}{A}\right)^a \tag{15-171}$$

Equations (15-170) and (15-171) represent decanter performance for a given feed with constant properties, that is, a constant composition and phase ratio. Note that the analysis can be done in terms of total flow $Q$ or the flow of continuous phase $Q_c$ or dispersed phase $Q_d$. Typically, the value of the exponent $a$ is greater than 2.5 [Barnea, E., and J. Mizrahi, *Trans. Inst. Chem. Eng.* **53:** 61–91 (1975); and Golob, J., and R. Modic, *Trans. Inst. Chem. Eng.* **55:** 207–211 (1977)]. The required size of a commercial-scale decanter may be determined by operating a small miniplant decanter to obtain values for the constants in Eqs. (15-170) and (15-171). Scale-up to the larger size generally follows the same relationship as long as the phase ratio and other operating variables are maintained constant. A commercial-scale decanter normally is designed for a throughput $Q/A$ that yields a value of $\Delta H$ no larger than 15 percent of the total decanter height. Designs specifying taller dispersion bands are avoided because a sudden change in feed rate can trigger a dramatic increase in the height of the dispersion band that quickly floods the vessel. The dynamic response of $\Delta H$ has been studied by S. A. K. Jeelani and S. Hartland [*AIChE J.* **34**(2): 335–340 (1988)].

In certain cases, batch experiments may be used to size a continuous decanter [Jeelani, S. A. K., and S. Hartland, *AIChE J.* **31:** 711–720 (1985)]. In a batch experiment similar to the simple shake test described earlier, the change in the height of the dispersion band with time may follow a relationship given by

$$\frac{1}{-dh/dt} = \frac{1}{k_1 h} + \frac{1}{k_2} \tag{15-172}$$

where $h$ is the height of the batch dispersion band varying with time $t$. The constants $k_1$ and $k_2$ in Eq. (15-172) are the same as those used in the steady-state equation [Eq. (15-170)], assuming the batch test conditions (phase ratio and turbulence) are the same. Jeelani and Hartland have derived a number of models for systems with different coalescence behaviors [Jeelani, S. A. K., and S. Hartland, *Chem. Eng. Sci.* **42**(8): 1927–1938 (1987)]. The most appropriate coalescence model is determined in batch tests and then is used to estimate $\Delta H$ versus throughput $Q/A$ for a continuous decanter. For additional information, see S. Hartland and S. A. K. Jeelani, chap. 13 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994; C. Nadiv and R. Semiat, *Ind. Eng. Chem. Res.* **34**(7): 2427–2435 (1995); S. A. K. Jeelani and S. Hartland, *Ind. Eng. Chem. Res.* **37**(2): 547–554 (1998); S. A. K. Jeelani, K. Panoussopoulos, and S. Hartland, *Ind. Eng. Chem. Res.* **38**(2): 493–501 (1999); and G.-Z. Yu and Z.-S. Mao, *Chem. Eng. Technol.* **27**(4): 407–413 (2004). Development of design methods for specifying continuous decanters with coalescing internals using batch test data is a current area of research [Mungma, N., P. Chuttrakul, and A. Pfennig, *Jurnal Teknologi* **67**(4): 55–58 (2014)].

Several authors have derived correlations relating the height of the dispersion band to the density of each phase, the density difference, the viscosities, and the interfacial tension of aqueous/organic or aqueous/aqueous two-phase systems [Golob, J., and R. Modic, *Trans. Inst. Chem. Eng.* **55:** 207–211 (1977); and J. A. Asenjo et al., *Biotech. and Bioeng.* **79**(2): 217–223 (2002)]. These correlations can provide useful estimates, but the results are generally valid only for the systems similar to those used to develop the correlations, and they should be used with caution. For new applications, some experimental work will be needed for reliable design.

## OTHER TYPES OF SEPARATORS

**Packed Coalescers** As noted earlier, adding coalescing internals to a decanter can improve decanter performance by promoting the growth of small drops. The same concept can be applied in a separate coalescer vessel to treat the stream feeding the decanter. Systems of type III or type IV (Table 15-24) in particular may benefit, that is, applications involving a need to break a secondary dispersion. Coalescers can also be effective in promoting phase separation and collection when the concentration of the dispersed phase is very low (<150 mg/L).

Coalescers typically are packed with a granular material, corrugated lamellar sheets, a mesh material (made of metal wire, fiberglass, or polymer filaments), or fine fibers of various types in woven or nonwoven composite sheets. In vertical coalescers, the typical flow configuration is upflow if the light phase is dispersed and downflow if the heavy phase is dispersed. Coalescers containing fairly large media such as beds of granules or wire mesh may be able to tolerate a feed containing some fine solids, although occasional backwashing or sparging of the media may be required to remove solids buildup and maintain coalescer pressure drop and efficiency. Coalescers containing fine granules, fine fibers, or porous membranes generally require that the feed be free of solids to avoid plugging, so prefiltration may be necessary. For more detailed information, see J. Li and Y. Gu, *Sep. Purif. Technol.* **42:** 1–13 (2005); C. Shin and G. G. Chase, *AIChE J.* **50**(2): 343–350 (2004); T. H. Wines and R. L. Brown, *Chem. Eng. Magazine* **104**(12): 104–109 (1997); and P. M. Hennessey et al., *Hydrocarbon Proc.* **74:** 107–124 (1995).

In most applications, the packing material should be wetted by the dispersed phase to some degree for best performance; however, this will depend on the size of dispersed droplets. For very fine droplets on the order of 10 μm or smaller, surface wetting is not the primary coalescence mechanism [Davies, G. A., and G. V. Jeffreys, *Filtration and Separation*, pp. 349–354 (July/August 1969)]. In these cases, the packing promotes coalescence by providing a tortuous path that holds dispersed drops in close contact, facilitating drop–drop collisions. In other cases involving larger drops, a drop interception and wettability mechanism becomes important; that is, the media provide a target for drop–solid surface collisions, and the surface becomes wetted with drops that merge together and leave the media as larger drops. In this case, an intermediate (optimum) wettability may be needed to most effectively promote the growth and dislodging of drops from the media [Shin, C., and G. G. Chase, *AIChE J.* **50**(2): 343–350 (2004)]. In general, the degree to which flow path/collision mechanisms and/or surface wettability are important for good performance depends on the drop size distribution and dispersed-phase holdup in the feed, as well as system physical properties and whether surfactants or fine particulates are present. (See the subsection Stability of Liquid-Liquid Dispersions under Liquid-Liquid Dispersion Fundamentals.) All this affects the choice of media, media size and porosity, and coalescer dimensions as a function of throughput. For a given application, some experimental work generally will be needed to sort this out and identify an effective and reliable design.

In cases where wettability is important, various types of sand, zeolites, glass fibers, and other inorganic materials may be used to facilitate coalescence of aqueous drops dispersed in organic feeds. Carbon granules, polymer beads, or polymer fibers may be useful in coalescing organic drops dispersed in water. Sparse oil dispersions in water may be effectively treated with resin bead beds at high removal efficiencies [R. T. O'Connell, Technical

Reprints, T-237 (1981) and T-246 (1983), Graver Water Systems]. The packing material should resist disarming by impurities, meaning that impurities should not become adsorbed and degrade the surface wettability characteristics over time. This can happen with charged or surfactant-like impurities; S. Paria and P. K. Yuet [*Ind. Eng. Chem. Res.* **45**(2): 712–718 (2006)] describe the adsorption of cationic surfactants at sand–water interfaces, a phenomenon that can alter surface wettability. In a few cases, the packing needs to age in service to develop its most effective surface properties. J. R. Madia et al. [*Env. Sci. Technol.* **10**(10): 1044–1046 (1976)] describe a chromatography method for screening potential media with regard to surface wettability.

For granular bed coalescers, typical granule sizes include 12 × 16 Tyler screen mesh (between 1.4 and 1 mm) and 24 × 48 Tyler mesh (0.7 to 0.3 mm). Smaller sizes sometimes are used as well. Typical bed heights range from 8 in to 4 ft (0.2 to 1.2 m), with the taller beds used with the larger granules. Layered beds may be used. For example, the front of the coalescer may contain a thin layer of fine media with low porosity and high tortuosity characteristics to facilitate drop–drop collisions of very small droplets, followed by a layer of coarser media having the wetting characteristics needed to further grow and shed larger drops.

For fine-fiber coalescers, the coalescing media normally are arranged in the form of a filter cartridge. T. H. Wines and R. L. Brown [*Chem. Eng. Magazine* **104**(12): 104–109 (1997)] describe a coalescing mechanism in which a drop (on the order of 0.2 to 50 μm) becomes adsorbed onto a fiber and then moves along the fiber with the bulk liquid flow until colliding with another adsorbed drop at the intersection where two fibers cross. Fiber diameter and wettability are important properties because they affect porosity (tortuous path) and wettable surface area. Like a packed-bed coalescer, a filter-type coalescer may be constructed in layers: an initial prefilter zone to remove particulates and minimize fouling, a primary coalescence zone where small droplets grow to larger ones, and a secondary coalescence zone with greater porosity and having surface-wetting characteristics optimized to grow the larger drops. New experimental materials having specific surface roughness characteristics that affect wettability and facilitate oil–water separation have been reported [Kota, A. K., et al., *Nat. Commun.* **3**(8): 1025 (2012); and Kwon, G., et al., *MRS Commun.* **5**(3): 475–494 (2015)].

Pressure drop, an important consideration in the design of any coalescer, depends upon media size and shape, bed height or filter thickness, and throughput. Methods for calculating pressure drop through packed beds and porous media are described in Sec. 6. For approximately spherical media, the pressure drop due to frictional losses, assuming incompressible media, may be estimated from

$$\frac{\Delta P}{L} = \frac{150(1-\varphi)^2 \mu V}{d_m^2 \varphi^3} + \frac{1.75 \rho_c V^2}{d_m \varphi^3} \qquad \mathrm{Re}_{\mathrm{particle}} = \frac{V \rho_c d_m}{\mu} \le 10 \qquad (15\text{-}173)$$

where $L$ is the length of the packed section, $V$ is the superficial velocity of the total liquid flow, $d_m$ is an equivalent spherical diameter of the media particles (given by six times the mean ratio of particle volume to particle surface area), and φ is the volume fraction of voids (flow channels) within the bed [Ergun, S., *Chem. Eng. Prog.* **48**(2): 89–94 (1952)]. Also see M. Leva, *Chem. Eng. Magazine* **56**(5): 115–117 (1949), or M. Leva, *Fluidization*, McGraw-Hill, New York, 1959. The minimum value of φ for a tightly ordered bed of uniform spherical particles is 0.26, but of course for real media this will vary depending upon the particle size distribution and particle shape. The second term in Eq. (15-173) often is neglected at $\mathrm{Re}_{\mathrm{particle}} \le 1$. For fiber media, $d_m$ can be thought of as a characteristic fiber dimension. For a discussion of pressure drop through fiber beds, see C. Shin and G. G. Chase, *AIChE J.* **50**(2): 343–350 (2004); and J. Li and Y. Gu, *Sep. and Purif. Tech.* **42:** 1–13 (2005). In practice, pressure drop data may be correlated by using an equation of the same form as Eq. (15-173), $\Delta P/L = aV + bV^2$, where $a$ and $b$ are empirically determined constants. Media and equipment suppliers generally will have some experimental data showing $\Delta P/L$ versus flow rate.

**Membrane-Based Coalescers** Membranes used for liquid-liquid phase separation generally are classified as microfiltration membranes (pore sizes greater than about 0.1 μm) or ultrafiltration membranes (pore sizes generally in the range of 0.01 to 0.1 μm). Most membrane-based coalescers described in the literature function by size exclusion. Microporous membranes are used for initial pretreatment of process water to remove relatively large dispersed oil drops. Ultrafiltration membranes may be used to concentrate the remaining microdroplets or micelles. In typical applications, the majority of the continuous phase flows through the pores of the membrane by pressure difference and collects on the permeate side as a clarified solution. The microdroplets or micelles are rejected and flow with the remaining continuous phase (the retentate), tangentially along the membrane surface to the retentate outlet of the membrane module [Voges, Wu, and Dalan, *Chem. Process.* **63**(4): 40–43 (2001)]. Ultrafiltration membranes can be very efficient at removing colloidal particles of an emulsion but normally will not stop dissolved oil from permeating. In some applications, fouling can occur owing to deposition of a coalesced layer that obstructs the pores. For applications involving oil-in-water dispersions and permeation of water, the rate of fouling by oil deposition may be reduced by using a hydrophilic membrane material or hydrophilic surface treatments [Munirasu, S., M. A. Haija, and F. Banat, *Proc. Saf. Environ.* **100:** 183–202 (2016); and Moslehyani, A., et al., *Jurnal Teknologi* **78**(1): 217–222 (2016)].

Selecting the membrane best suited for a given application requires laboratory testing. The membrane material must be compatible with the feed, and the module should exhibit high permeation flow while maintaining good micelle rejection. The pore size and the molecular weight cutoff reported by the manufacturer are good indicators of membrane performance potential, but other factors such as membrane/solute interaction and fouling ultimately determine practical feasibility. Key operating parameters include temperature, feed flow rate, and permeate-to-feed ratio. Scale-up consists of adding membrane modules to handle the required production rate [Eykamp, W., and J. Steen, chap. 18 in *Handbook of Separation Process Technology,* ed. R. W. Rousseau, Wiley, New York, 1987].

New experimental membranes with specific surface roughness and porosity that affect wettability and facilitate oil–water separation have been reported [Kota, A. K., et al., *Nat. Commun.* **3**(8): 1025 (2012); and Kwon, G., et al., *MRS Commun.* **5**(3): 475–494 (2015)]. These materials can be made to exhibit a variety of surface properties, including superhydrophilic/superoleophobic behavior. The authors describe processes employing both hydrophilic/oleophobic and hydrophobic porous membranes, with the separation of oil and water being driven by a difference in the capillary forces acting on the two liquid phases.

Another approach to clarifying an oil-in-water dispersion involves the use of a hydrophobic microporous membrane with intentional permeation of the oil phase through the membrane [Mercelat, A. Y. J., "Fundamental Study of Hydrophobic Microporous Membrane Contactors for the Recovery of Insoluble Oil from Oil–Water Mixtures," PhD dissertation, University of Texas at Austin, 2016]. This technology is an outcome of a program to improve the recovery of submicron oil droplets (<0.5 μm) from lysed algae slurries [Seibert, A. F., and M. Poenie, U.S. Patent appl. 2011/0174734 A1 (2011)]. With this approach employing a hydrophobic membrane, oil droplets dispersed in a continuous aqueous phase are fed on the shell side of a hollow-fiber microporous membrane contactor. The oil droplets coalesce on the outer surface of the hydrophobic hollow fibers to form an oil film. As a result, water is retained on the shell side while oil permeates the membrane and exits through the tube side. The rate of oil permeation depends on the transmembrane pressure differential and the amount of oil entering in the feed [Mercelat, ibid.].

**Centrifuges** A stacked-disk centrifuge or other type of centrifuge may be a cost-effective option for liquid-liquid phase separation whenever the use of a gravity decanter/coalescer proves to be impractical because rates of drop settling or coalescence are too low. This may be the case for type III and type IV systems (Table 15-24) in particular. Factors involved in specifying a centrifuge are discussed in the subsection Centrifugal Extractors under Liquid-Liquid Extraction Equipment.

**Hydrocyclones** Liquid-liquid hydrocyclones, like centrifuges, utilize centrifugal force to facilitate the separation of two liquid phases [Svarovsky, L., and M. T. Thew, eds., *Hydrocyclones: Analysis and Applications,* Kluwer, Dordrecht, NL, 1992; Svarovsky, L., *Hydrocyclones*, Holt, Rinehart, and Winston, New York, 1984; and Bradley, D., *The Hydrocyclone*, Pergamon, Oxford, UK, 1965]. Instead of using rotating internals, as in a centrifuge, a hydrocyclone generates centrifugal force using fluid pressure to create rotational fluid motion (Fig. 15-64). Feed enters the hydrocyclone through a tangential-entry nozzle. A primary vortex rich in the heavy phase forms along the inner wall, and a secondary vortex rich in the light phase forms near the centerline. The underflow stream (heavy phase) exits the cyclone through the apex of the cone (underflow nozzle). The overflow stream (light phase) exits through the vortex finder, a tube extending from the cylinder roof into the interior. The feed split can be adjusted by changing the relative diameters of the vortex finder and underflow nozzle. A hydrocyclone is not completely filled with liquid; an air core exists at the centerline. A commercial-scale hydrocyclone multiplies the force of gravity by a factor of 100 to 1000 or so, depending on the diameter and operating pressure. Hydrocyclones traditionally have been used for liquid-solid separations, but by adjusting their design (cone angle and length, vortex finder length, and so on) they can be applied to liquid-liquid separations [R. Mozley, *Filtration and Sep.*, pp. 474–477 (Nov./Dec. 1983)]. For example, they are widely used to remove oil from oily process water [D. Hadjiev et al., chap. 4 in *Environmental Technologies and Trends*, Springer, Berlin, 1997].

Identifying the optimal hydrocyclone geometry for a given application involves the use of flow calculations as a guide, with some experimental testing needed to refine the design [C. Gomez et al., *Soc. Petrol. Eng. J.* **7**(4): 353–361 (2002); J. Caldentey et al., *Soc. Petrol. Eng. J.* **7**(4): 362–372 (2002); and

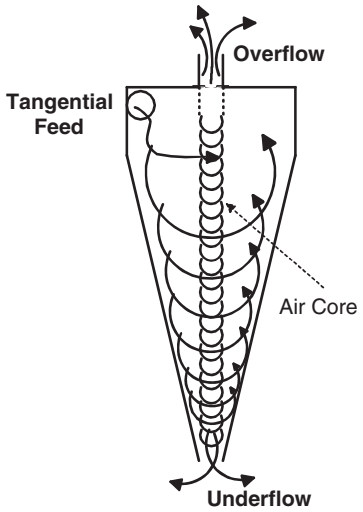

**FIG. 15-64** Flow patterns in a hydrocyclone.

D. A. Colman and M. T. Thew, *Chem. Eng. Res. Des.* **61**(7): 233–240 (1983)]. The efficiency of separation will depend upon fluid viscosity, density difference, the inlet dispersed-phase drop size distribution, and interfacial tension. Because fluid flow generally is turbulent at the top of a hydrocyclone and the rotation of liquid within the device produces a high shear field, mixtures with low interfacial tension may tend to emulsify or create foam. Choosing a material of construction for the cone that is wetted by the heavy phase may improve the effectiveness of the device. In testing a specific geometry, the main operating variables are the feed pressure, the feed flow rate, and the split ratio; that is, the relative amounts of fluid exiting top and bottom, with adjustments made by changing the sizes of orifices in the underflow and overflow nozzles. If testing indicates satisfactory performance, hydrocyclones can be relatively inexpensive and simple-to-operate units (no moving parts). Because sufficient centrifugal force cannot be generated in large-diameter units, scale-up consists of connecting multiple small units in parallel. Units are sometimes placed in series to provide multiple stages of separation. Numerical simulations of hydrocyclone performance and flow profiles are described by Z. S. Bai and H.-L. Wang [*Chem. Eng. Technol.* **29**(10): 1161–1166 (2006)] and by S. Murphy et al. [*Chem. Eng. Sci.* **62:** 1619–1635 (2007)].

**Electrotreaters** In an electrostatic coalescer, an electric field is applied to a dispersion to induce dipoles or net charges on the suspended drops, which facilitates their migration and coalescence [Waterman, L. C., *Chem. Eng. Prog.* **61**(10): 51–57 (1965); and Yamaguchi, M., chap. 16 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994]. This technology is applicable only to a nonconductive continuous phase and an aqueous dispersed phase. Once the water drops are sufficiently large, they settle to the bottom of the vessel while the clarified oil phase migrates to the top. The top and bottom zones are kept quiet and out of the electric field. In cases where inlet salt content is high, a multistage, countercurrent desalting system can be used. Units with ac or dc voltage are available.

Electrotreaters are high-voltage electrostatic devices that can arc under certain conditions. For this reason, a careful review of safety considerations is needed, especially for applications involving flammable liquids. Evaluating feasibility and generating design data normally involve close consultation with the equipment vendors. This technology is applied on a very large scale in the petroleum industry for desalting of crude oil.

# EMERGING DEVELOPMENTS

## MEMBRANE-BASED PROCESSES

**Polymer Membranes** Extraction processes employing polymer membranes are sometimes referred to as nondispersive or pertraction operations. The use of membranes in extraction offers a number of potential advantages including (1) constant well-defined mass-transfer area; (2) the ability to operate at very low solvent-to-feed ratios independent of other operating variables; (3) very low holdup of solvent and product within the extractor, thus providing low residence time similar to a centrifugal extractor; (4) dispersion-free liquid-liquid contacting that eliminates the need for liquid-liquid interface control and phase separation; (5) elimination of entrainment; (6) no requirement for a difference in density between liquid phases; and (7) linear scale-up by addition of extra modules in parallel, so performance at large scale can be determined directly from small-scale tests using a single module. This last point suggests, however, that the economy of scale may not be as large as it is for extractors that are scaled up as a single larger unit.

The most important advantages that membranes can offer to the process designer are those that overcome an inherent limitation of another type of extractor, as in the ability to handle liquids with close or even equal densities and the ability to operate at extremely low solvent-to-feed ratios. The types of applications where membrane extraction is likely to be most attractive include solids-free (or pre-filtered) feeds with moderate to high interfacial tension (to avoid breakthrough) and a solute partition ratio greater than 50 or so. In principle, $K > 50$ allows operation using a solvent-to-feed ratio of 1:25 or less ( for an extraction factor of 2). The primary disadvantages of membrane-based extractors are the added mass-transfer resistance across the membrane, limited fiber-side or tube-side throughput, and concerns about plugging and fouling from insoluble solids and limited membrane life in industrial service. The useful life of a membrane module is a critical factor, as the frequency with which membrane modules must be replaced has a dramatic impact on overall cost.

For most liquid-liquid extraction applications, a porous membrane is used and extraction involves transfer through a liquid-liquid interface immobilized within the pores. One of the most promising contactors for this type of extraction is the microporous hollow-fiber (MHF) contactor (Fig. 15-65). The MHF contactor resembles a shell-and-tube heat exchanger in which the tube walls are porous and are capable of immobilizing a liquid-liquid interface within the pores. For a hydrophobic polymeric membrane which is preferentially wetted by the hydrocarbon, the hydrocarbon solvent phase usually is fed to the interior of the fiber (the fiber-bore side), while the aqueous carrier phase is fed to the shell side. In this configuration, the aqueous fluid is maintained at a higher pressure relative to the hydrocarbon phase, to immobilize the liquid-liquid interface within each pore. Care must be taken to avoid using excessive shell-side pressures, or breakthrough of the aqueous phase can occur. This breakthrough pressure is a function of the interfacial tension and pore size. Earlier versions of MHF contactors provided a parallel-flow design, but this design suffered from shell-side bypassing [Seibert, A. F., et al., *Sep. Sci. Technol.* **28**(1–3): 343 (1993)]. An improved design eliminates bypassing by incorporating a central baffle, shell-side cross-flow distribution, and uniform fiber spacing (Fig. 15-65 and Table 15-25).

As in conventional extraction, the mass transfer of solute occurs across a liquid-liquid interface. However, unlike in conventional extraction, the interface is maintained in submicron pores, and three mass-transfer resistances are present: tube-side ($k_t$), shell-side ($k_s$), and pore or membrane-side ($k_m$). The overall mass-transfer coefficient $k_{os}$ based on the aqueous phase (shell side) and a hydrophobic membrane with pores filled by the hydrocarbon phase is given by

$$\frac{1}{k_{os}} = \frac{1}{m^{\text{vol}} k_t} + \frac{1}{m^{\text{vol}} k_m} + \frac{1}{k_s} \tag{15-174}$$

where $m^{\text{vol}}$ is the local slope of the equilibrium line for the solute of interest, with the equilibrium concentration of solute in the tube-side liquid plotted on the $y$ axis and the equilibrium concentration of solute in the shell-side liquid plotted on the $x$ axis. Equation (15-174) assumes the tube-side fluid wets the pores.

The mass-transfer efficiencies of various MHF contactors have been studied by many researchers. L. Dahuron and E. L. Cussler [*AIChE J.* **34**(1): 130–136 (1988)] developed a membrane mass-transfer coefficient model ($k_m$); M.-C. Yang and E. L. Cussler [*AIChE J.* **32**(11): 1910–1916 (1986)] developed a shell-side mass-transfer coefficient model ($k_s$) for flow directed radially into the fibers; and R. Prasad and K. K. Sirkar [*AIChE J.* **34**(2): 177–188 (1988)] developed a tube-side mass-transfer coefficient model ($k_t$). Additional studies have been published by R. Prasad and K. K. Sirkar ["Membrane-Based Solvent Extraction," in *Membrane Handbook*, ed. W. S. W. Ho and K. K. Sirkar, Chapman and Hall, London, 1992]; by B. W. Reed, M. J. Semmens, and

Membane Sci.* **213**(1–2): 181–193 (2003) and *J. Membrane Sci.* **255**(1–2): 133–140 (2005)]; by B. Saikia, N. N. Dutta, and N. N. Dass [*J. Membrane Sci.* **225**(1–2): 1–13 (2003)]; by S. Bocquet et al. [*AIChE J.* **51**(4): 1067–1079 (2005)]; and by S. Schlosser, R. Kertesz, and J. Martak [*Sep. Purif. Technol.* **41:** 237 (2005)]. For an overall review of membrane-based extraction processes, see A. K. Pabby and A. M. Sastre [*J. Membrane Sci.* **430:** 263–303 (2013)]. A review of mass-transfer correlations for hollow-fiber membrane modules is given by T. Liang and R. L. Long [*Ind. Eng. Chem. Res.* **44**(20): 7835–7843 (2005)]. T. Eksangsri, H. Habaki, and J. Kawasaki [*Sep. Purif. Technol.* **46:** 63–71 (2005)] discuss the effect of hydrophobic versus hydrophilic membranes for a specific application involving transfer of solute from an aqueous feed to an organic solvent. A. J. Karabelas and A. G. Asimakopoulou [*J. Membrane Sci.* **272**(1–2): 78–92 (2006)] discuss process and equipment design considerations. A 650 kg/h commercial application of the hollow-fiber contactor is described by W. Ratajczak et al. for extraction of phenol from hydrocarbons using aqueous alkali solution [*Przemysł Chemiczny* **86:** 262 (2007); and Š. Schlosser and J. Marták, *Membrany - Teoria i Praktyka - Zeszyt III*, pp. 123–153, Toruń, Poland, 2009, in English, download from researchgate.net, April 2016].

In general, researchers have treated MHF contactors as differential contacting devices. However, A. F. Seibert and J. R. Fair [*Sep. Sci. Technol.* **32**(1–4): 573–583 (1997)] and A. F. Seibert et al. [*ISEC '96 Proc.* **2:** 1137 (1996)] suggest that the baffled MHF contactor can be treated as a staged countercurrent contactor. Their recommendations are based on studies using a commercial-scale membrane extraction system. Also see the discussion by H. M. Yeh [*J. Membrane Sci.* **269**(1–2): 133–141 (2006)] regarding the use of internal reflux in a parallel plate membrane module to boost liquid velocities for enhanced performance.

Emulsion liquid-membrane (ELM) extraction involves the intentional formation of an emulsion between two immiscible liquid phases followed by suspension of the emulsion in a third liquid that forms an outer continuous phase. The encapsulated liquid and the continuous phase are miscible. The liquid-membrane phase is immiscible with the other phases and normally must be stabilized by using surfactants. If the continuous phase is aqueous, the suspended phase is a water-in-oil emulsion. If the continuous phase is organic, the emulsion is the oil-in-water type. This technology differs from traditional liquid-liquid extraction processes in that it allows transfer of solute between miscible liquids by introducing an immiscible liquid membrane between them. A typical process involves first forming a stable emulsion and contacting it with the continuous phase to transfer solute between the encapsulated phase and the continuous phase, followed by steps for separating the emulsion and continuous phases and breaking the emulsion. The emulsion must be sufficiently stable to remain intact during processing, but not so stable that it cannot be broken after processing, and this may present a challenge for commercial implementation. The technology is described by J. W. Frankenfeld and N. N. Li [chap. 19 in *Handbook of Separation Process Technology*, ed. R. W. Rousseau, Wiley, New York, 1987].

Potential applications of ELM extraction include separation of aromatic and aliphatic hydrocarbons [M. Chakraborty and H.-J. Bart, *Chem. Eng. Technol.* **28**(12): 1518–1524 (2005)], separation and concentration of amino acids [M. P. Thien, T. A. Hatton, and D. I. C. Wang, *Biotech. and Bioeng.* **32**(5): 604–615 (1988)], and recovery of penicillin G from fermentation broth [K. H. Lee, S. C. Lee, and W. K. Lee, *J. Chem. Technol. Biotechnol.* **59**(4): 365–370, 371–376 (1994); S. C. Lee et al., *J. Membrane Sci.* **124**: 43–51 (1997); and S. C. Lee and S. M. Yeo, *J. Ind. Eng. Chem.* **8**(2): 114–119 (2002)]. The latter application involves transfer of the penicillin G solute ($pK_a = 2.7$) from the continuous phase (consisting of a filtered broth adjusted to a pH of about 3) into the membrane phase (typically *n*-lauryltrialkylmethyl amine extractant dissolved in kerosene) and then into the interior aqueous phase (clean water at a pH of about 8). S. C. Lee et al. [*J. Membrane Sci.* **124:** 43–51 (1997)] show that the operation can be carried out in a continuous countercurrent extraction column. The product is later obtained by separating the emulsion droplets from the continuous phase by using filtration, and this is followed by breaking the emulsion and isolating the interior aqueous phase from the amine extractant phase. A polyamine surfactant is used to stabilize the emulsion during extraction. In another study, J. Laso et al. [*Ind. Eng. Chem. Res.* **54**(12): 3218–3224 (2015)] report laboratory-scale process data for both nondispersive and ELM extraction schemes for liquid-liquid extraction of zinc from spent pickling liquor, both carried out using hollow-fiber membrane contactors.

Supported liquid-membrane (SLM) processes involve the introduction of a microporous solid membrane to serve as a support for the liquid membrane. See the review by N. M. Kocherginsky, Q. Yang, and L. Seelam [*Sep. Purif. Technol.* **53:** 171–177 (2007)]. The microporous membrane provides

well-defined interfacial area and eliminates the need for a surfactant. As in the penicillin ELM application described previously, SLM applications often employ an extractant solution as the liquid-membrane phase to enable a facilitated transport mechanism. The extractant species interacts with the desired solute at the feed side and then carries the solute across the membrane to the other side, where solute transfers into a stripping solution. Such a process, whether using a surfactant-stabilized emulsion or a supported liquid membrane, allows forward and back extraction (or stripping) in a single operation. Example applications include the extraction of metal ions from aqueous solution [Ho, W. S. W., and B. Wang, *Ind. Eng. Chem. Res.* **41**(3): 381–388 (2002); L. Canet and P. Seta, *Pure Appl. Chem.* (*IUPAC*) **73**(12): 2039–2046 (2001)] and the recovery of aromatic acids or bases from an aqueous feed [Dastgir, M. G., et al., *Ind. Eng. Chem. Res.* **44**(20): 7659–7667 (2005)]. One of the challenges encountered in using supported liquid membranes is the difficulty in controlling trans-membrane pressure drop and maintaining the liquid membrane on the support; it may become dislodged and entrained into the flowing phases. Various approaches to stabilizing the supported liquid have been proposed. These are discussed by Dastgir et al. [ibid.].

A related technology termed thin layer extraction involves immobilizing an extractant liquid within a thin microporous solid. Solute is transferred from the feed liquid by repeatedly exposing the supported extractant first to the feed liquid and then to a recipient liquid (stripping solution) [Lavie, R., *AIChE J.* **54**(4): 957–964 (2008); U.S. patent 8,021,554 (2011); and *Ind. Eng. Chem. Res.* **53**(47): 18283–18290 (2014)].

## ELECTRICALLY ENHANCED EXTRACTION

An electric field may be used to enhance the performance of an aqueous-organic liquid-liquid contactor by promoting either drop breakup or drop coalescence, depending upon the operating conditions and how the field is applied. The technology normally involves dispersing an electrically conductive phase (the aqueous phase) within a continuous nonconductive phase, applying a high-voltage electric field (either ac or dc) across the continuous phase, and taking advantage of the effect the electric field has on the shape, size, and motion of the dispersed drops. The potential advantages of this technology include more precise control of drop size and motion for improved control of mass transfer and phase separation within an extractor. Potential disadvantages include the requirement for more complex equipment, difficulties in scaling up the technology to handle large production rates, and safety hazards involved in processing flammable liquids in high-voltage equipment.

A number of different equipment configurations and operating concepts have been proposed. M. Yamaguchi [chap. 16 in *Liquid-Liquid Extraction Equipment*, ed. J. C. Godfrey and M. J. Slater, Wiley, New York, 1994] classifies the proposed equipment into three general types: perforated-plate and spray columns, mixed contactors, and liquid-film contactors. For example, M. Yamaguchi and M. Kanno [*AIChE J.* **42**(9): 2683–2686 (1996)] describe an apparatus in which a dc voltage is applied between two electrodes in the presence of a nitrogen gas interface. Aqueous drops form in the presence of the electric field, and they are first attracted to the gas-liquid interface. Once the drops contact the interface, the charge on the drops is reversed, and the drops fall back to coalesce at the bottom of the vessel. P. J. Bailes and E. H. Stitt [U.S. Patent 4,747,921 (1988)] describe a rotating-impeller extraction column containing alternating zones of high voltage (to promote dispersed drop coalescence) and high-intensity mixing (to promote redispersion of drops). In this design, the electric field serves to promote drop coalescence so that dispersed drops experience alternating drop breakup and growth as they move through the agitated column. T. C. Scott and R. M. Wham [*Ind. Eng. Chem. Res.* **28**(1): 94–97 (1989)] and T. C. Scott, D. W. DePaoli, and W. G. Sisson [*Ind. Eng. Chem. Res.* **33**(5): 1237–1244 (1994)] describe a nonagitated apparatus called an emulsion-phase contactor. This device employs an electric field to induce the formation of a stable emulsion or dispersion band, with clear organic and aqueous layers above and below. The aqueous phase is fed to the middle or top of the dispersion band; it flows down through the band and is removed from a clarified aqueous zone maintained at the bottom. The lighter organic phase is fed to the bottom; it moves up through the dispersion band and is removed from the top. The net result is countercurrent contacting with very high interfacial area and significantly improved mass transfer in terms of the number of transfer units achieved for a given contactor height.

Another approach involves electrostatically spraying aqueous solutions into a continuous organic phase to create dispersed drops within a spray column contactor [L. R. Weatherley et al., *J. Chem. Technol. Biotechnol.* **48**(4): 427–438 (1990)]. A high voltage is applied between electrodes, one connected to a nozzle where dispersed drops are formed and the other placed within the continuous organic phase. J. Petera et al. [*Chem. Eng. Sci.* **60:** 135–149 (2005)] discuss the modeling of drop size and motion within such a device. For additional discussion, see C. Tsouris et al. [*Ind. Eng. Chem. Res.* **34**(4): 1394–1403 (1995)], C. Tsouris et al. [*AIChE J.* **40**(11): 1920–1923 (1994)], G. Gneist and H.-J. Bart [*Chem. Eng. Technol.* **25**(2): 129–133, **25**(9): 899–904 (2002)], and T. Elperin and A. Fominykh [*Chem. Eng. Technol.* **29**(4): 507–511 (2006)].

## PHASE TRANSITION EXTRACTION AND TUNABLE SOLVENTS

Phase transition extraction (PTE) involves transitioning between single-liquid-phase and two-liquid-phase states to facilitate a desired separation. A. Ullmann, Z. Ludmer, and R. Shinnar [*AIChE J.* **41**(3): 488–500 (1995)] showed that extraction of an antibiotic from fermentation broth into an organic solvent could be improved by transitioning across a UCST phase boundary using heating and cooling. The results showed much higher stage efficiency compared to a standard extraction technique without phase transition and much faster phase separation. The phase transition may be induced by a change in temperature or a change in composition through addition and/or removal of organic solvents or antisolvents [R. Gupta, R. Mauri, and R. Shinnar, *Ind. Eng. Chem. Res.* **35**(7): 2360–2368 (1996)]. N. Alizadeh and K. Ashtari describe a temperature-change-induced phase transition process for extracting silver(I) from aqueous solution using dinitrile solvents [*Sep. Purif. Technol.* **44:** 79–84 (2005)]. Another process that exploits a phase transition to facilitate separation and recycle of solvent after extraction utilizes ethylene oxide–propylene oxide copolymers in aqueous two-phase extraction of proteins [J. Persson et al., *J. Chem. Technol. Biotechnol.* **74:** 238–243 (1999)]. After extraction, the polymer-rich extract phase is heated above its LCST to form two layers: an aqueous layer containing the majority of protein and a polymer-rich layer that can be decanted and recycled to the extraction. An example involving use of glycol ether solvent is given by J. R. Allen et al. [*Biotechnol. Prog.* **23**(5): 1163–1170 (2007)].

Another approach termed organic aqueous tunable solvents (OATS) utilizes pressurized $CO_2$ to control phase splitting and tune partition ratios in organic + water mixtures [P. Pollet et al., *Acc. Chem. Res.* **43**(9): 1237–1245 (2010); and C. A. Eckert et al., *J. Phys. Chem. B*, **108**(47): 18108–18118 (2004)]. The addition of $CO_2$ at pressures of 3 to 80 bar sometimes causes phase splitting of a normally miscible organic + water system, yielding an organic phase rich in $CO_2$ (the gas-expanded phase) and an aqueous phase containing little $CO_2$. The $CO_2$ dissolved in the organic phase acts as an antisolvent such that change in the $CO_2$ pressure causes change in the distribution of solute between the organic and aqueous phases. This gas-expanded-liquid technique is of particular interest for improving reaction-extraction schemes used in multistage processing of pharmaceuticals and other specialty chemicals by enabling a process wherein a desired reaction is carried out in a batch reactor at conditions of complete organic + water miscibility, followed by the addition of $CO_2$ to the reactor to induce phase splitting for product isolation and recovery/recycle of homogeneous catalyst. After decantation of one or both liquid layers for further processing, the $CO_2$ can be vented and the cycle repeated.

In related studies, T. Adrian, J. Freitag, and G. Maurer [*Chem. Eng. Technol.* **23**(10): 857–860 (2000)] have demonstrated the ability to induce phase splitting in the completely miscible 1-propanol + water system by pressurization with $CO_2$ at pressures above 74 bar. The partition ratio for transfer of methyl anthranilate from the aqueous phase to the organic phase varied between 1 and about 13 with change in pressure and temperature. J. Lu et al. [*Ind. Eng. Chem. Res.* **43**(7): 1586–1590 (2004)] demonstrated a reduction in the lower critical solution temperature for the partially miscible THF + water system by the addition of $CO_2$ at more moderate pressures (on the order of 10 bar). The authors showed that the partition ratio for transfer of a water-soluble dye from the organic phase to the aqueous phase can be increased dramatically by increasing $CO_2$ pressure.

## IONIC LIQUIDS AND DEEP EUTECTIC SOLVENTS

Ionic liquids are low-melting organic salts that are liquids at or near ambient temperature [R. D. Rogers and K. R. Seddon, *Science* **302:** (2003); and M. C. J. Moita et al., *J. Chem. Eng. Data* **57:** 2702–2709 (2012)]. A well-known example is 1-butyl-3-methylimidazolium hexafluorophosphate (commonly denoted by [BMIM][$PF_6$]). A new class of ionic liquid analogue known as a deep eutectic solvent is formed by mixing a hydrogen bond acceptor compound (such as choline chloride, a quaternary ammonium salt) with a metal salt or a hydrogen bond donor (such as glycerol) to form a low-melting eutectic mixture [E. L. Smith, A. P. Abbott, and K. S. Ryder, *Chem. Rev.* **114**(21): 11060–11082 (2014); and S. P. Verevkin et al., *Ind. Eng. Chem. Res.* **54**(13): 3498–3504 (2015)]. Characteristic physical properties of ionic liquids and their analogues include very low vapor pressure and high viscosity (relative to molecular organic solvents). The solvation, polarity, and miscibility behavior of the liquid can vary widely depending on composition. Both hydrophobic and hydrophilic ionic liquids are available.

The potential use of ionic liquids (and their analogues) for liquid-liquid extraction has gained considerable attention [G. Parkinson, *Chem. Eng. Prog.* **100**(9): 7–9 (2004); *Ionic Liquids IIIB: Fundamentals, Challenges, and Opportunities*, ed. R. D. Rogers and K. R. Seddon, Oxford University Press, Oxford, UK, 2005; S. T. Anjan, *Chem. Eng. Prog.* **102**(12): 30–39 (2006); and X. Han and D. W. Armstrong, *Acc. Chem. Res.* **40**(11): 1079–1086 (2007)]. Potential applications in industrial processing include olefin/paraffin separation [G. J. Belluomini, et al., *Ind. Eng. Chem. Res.* **48**(24): 11168–11174 (2009); and Y. Wang et al., *J. Chem. Eng. Data* **60**(1): 28–36 (2015)], extraction of high-boiling organics from water [D.-Z. Chen et al., *Sep. Purif. Technol.* **104:** 263–267 (2013); and L. Y. Garcia-Chavez, B. Schuur, and A. B. de Haan, *Ind. Eng. Chem. Res.* **52**(13): 4902–4910 (2013)], extraction of aromatics from aliphatic hydrocarbons [M. Larriba et al., *Ind. Eng. Chem. Res.* **52**(7): 2714–2720 (2013)], and extractive desulfurization of liquid fuels [S. A. Dharaskar et al., *Ind. Eng. Chem. Res.* **53**(51): 19845–19854 (2014)]. The use of ionic liquids to extract metal ions from aqueous solution is discussed by A. E. Visser et al. [*Sep. Sci. Technol.* **36**(5–6): 785–804 (2001)] and by K. Nakashima et al. [*Ind. Eng. Chem. Res.* **44**(12): 4368–4372 (2005)].

The possibility of switching a solvent system from ionic to nonionic states also has been investigated [P. G. Jessop et al., *Nature* **436:** 1102 (2005)]. The authors report that a 50:50 blend of 1-hexanol and 1,8-diazabicyclo-[5.4.0]-undec-7-ene (DBU) becomes ionic when $CO_2$ is bubbled through the solution. The $CO_2$ reacts to form a mixture of 1-hexylcarbonate anion and $DBUH^+$ cation, a viscous ionic liquid. The reaction can be reversed by using $N_2$ to strip the weakly bound $CO_2$ from solution. This returns the solution to its less viscous, nonionic state and provides a basis for a switchable solvent system. In another example, a change in temperature from about 20°C to 80°C is used to switch transfer of solute-carrying polymer micelles between an aqueous phase and [BMIM][$PF_6$] ionic liquid [Z. Bai and T. P. Lodge, *Langmuir* **26**(11): 8887–8892 (2010)]. The partitioning of micelles, which is reversible, is driven by the lower critical solution temperature (LCST) phase behavior of the polymer in water.

The challenges involved in using ionic liquids for extraction appear similar to those encountered using nonvolatile extractants dissolved in a diluent, including difficulty dealing with buildup of high-boiling impurities in the solvent phase over time. Additionally, solvent stability and recovery will need to be quite high for the process to be economical if the cost of makeup solvent is high. Potential advantages include the possibility of obtaining higher $K$ values, allowing the use of lower solvent-to-feed ratios. Also, very low volatility allows for essentially zero fugitive emissions to the environment and may allow simpler extract and raffinate separations. For example, volatile components may easily be separated from the ionic liquid by using evaporation under vacuum instead of multistage distillation.

## MINIATURIZED EXTRACTION

The implementation of liquid-liquid extraction within micro- and milliscale devices is an active research area [Gürsel, I. V., et al., *Chem. Eng. J.* **283:** 855–868 (2016); Ciceri, D., J. M. Perera, and G. W. Stevens, *J. Chem. Technol. Biotechnol.* **89:** 771–786 (2014); and Assmann, N., A. Ładosz, and P. R. von Rohr, *Chem. Eng. Technol.* **36**(6): 921–936 (2013)]. Such work may be directed at miniaturization of chemical processes to overcome heat and mass transfer limitations inherent in large-scale equipment (process intensification) or to minimize inventories of hazardous intermediates. It also may be directed toward the development of high-throughput research tools for rapid screening of chemistry and chemical processing options, or for the development of inexpensive, portable analytical chemistry devices and sensors. Potential advantages of miniaturization derive from high surface-to-volume ratios, short diffusion path length, and the inherent portability of a small device. Miniaturization also may enable modular design approaches via plug and play of specialized devices. Potential disadvantages include difficulties mixing and separating liquids in very small channels, difficulty handling systems of high interfacial tension, and difficulty realizing reasonably large production rates when chemical production is the goal. Compared to extraction practices employed in traditional large-scale manufacturing operations, the miniaturization approach is inherently limited to low production volumes; however, production may be increased to some extent by scaling up from micro- to milli-scale devices, by continuous operation, and by using multiple devices in parallel. The scalability of such devices is discussed by A. Woitalka, S. Kuhn, and K. F. Jensen [*Chem. Eng. Sci.* **116:** 1–8 (2014)]. The application of surfactants and electric fields to facilitate mass transfer and phase separation is discussed by J. G. Kralj, M. A. Schmidt, and K. F. Jensen [*Lab Chip* **5:** 531–535 (2005)]. Miniaturized extraction columns are described by A. Holbach et al. [*Chem. Eng. Process. Process Intensif.* **80**(1): 21–28 (2014)]; and by C. Schulze et al. [*Chem. Ing. Tech.* **87**(8): 1052 (2015)].

## Nomenclature and Units

| | |
|---|---|
| $a$ | Specific external surface area per unit bed volume, $m^2/m^3$ |
| $a_v$ | Surface area per unit particle volume, $m^2/m^3$ particle |
| $A$ | Surface area of solid, $m^2/kg$ |
| $A_s$ | Chromatography peak asymmetry factor (Fig. 16-27) |
| $b$ | Correction factor for resistances in series (Fig. 16-12) |
| $c$ | Fluid-phase concentration, $mol/m^3$ fluid |
| $c_p$ | Pore fluid-phase concentration, $mol/m^3$ |
| $c^s$ | Fluid-phase concentration at particle surface, $mol/m^3$ |
| $C^\circ_{pf}$ | Ideal gas heat capacity, $J/(mol \cdot K)$ |
| $C_s$ | Heat capacity of sorbent solid, $J/(kg \cdot K)$ |
| $d_p$ | Particle diameter, m |
| $D$ | Fluid-phase diffusion coefficient, $m^2/s$ |
| $D_{app}$ | Apparent diffusion coefficient, $m^2/s$ [Eq. (16-76)] |
| $D_L$ | Axial dispersion coefficient, $m^2/s$ [Eq. (16-79)] |
| $D_p$ | Pore diffusion coefficient, $m^2/s$ [Eqs. (16-64), (16-66), (16-67), (16-69)] |
| $D_s$ | Adsorbed-phase (solid, surface, particle, or micropore) diffusion coefficient, $m^2/s$ [Eqs. (16-70), (16-71)] |
| $D_0$ | Diffusion coefficient corrected for thermodynamic driving force, $m^2/s$ [Eq. (16-71)] |
| $\bar{D}$ | Ionic self-diffusion coefficient, $m^2/s$ [Eqs. (16-73), (16-74)] |
| $F$ | Fractional approach to equilibrium |
| $F_v$ | Volumetric flow rate, $m^3/s$ |
| $h$ | Enthalpy, J/mol; reduced height equivalent to theoretical plate [Eq. (16-183)] |
| htu | Reduced height equivalent to a transfer unit [Fig. (16-13)] |
| HETP | Height equivalent to a theoretical plate, m [Eq. (16-158)] |
| HTU | Height equivalent to a transfer unit, m [Eq. (16-92)] |
| $J$ | Mass-transfer flux relative to molar average velocity, $mol/(m^2 \cdot s)$; $J$ function [Eq. (16-148)] |
| $k$ | Rate coefficient, $s^{-1}$ [Eq. (16-83)] |
| $k_a$ | Forward rate constant for reaction kinetics, $m^3/(mol \cdot s)$ |
| $k_c$ | Rate coefficient based on fluid-phase concentration driving force, $m^3/(kg \cdot s)$ (Table 16-12) |
| $k_f$ | External mass-transfer coefficient, m/s [Eq. (16-78)] |
| $k_n$ | Rate coefficient based on adsorbed-phase concentration driving force, $s^{-1}$ (Table 16-12) |
| $k'$ | Retention factor [Eq. (16-156)] |
| $K$ | Isotherm parameter |
| $K^e$ | Molar selectivity coefficient |
| $K'$ | Rational selectivity coefficient |
| $L$ | Bed length, m |
| $m$ | Isotherm exponent; flow ratio in TMB or SMB systems [Eq. (16-199)] |
| $M_r$ | Molecular mass, kg/kmol |
| $M_s$ | Mass of adsorbent, kg |
| $n$ | Adsorbed-phase concentration, mol/kg adsorbent or $mol/m^3$ adsorbent |
| $n^s$ | Monolayer adsorption capacity, mol/kg adsorbent or $mol/m^3$ adsorbent; ion-exchange capacity, g-equiv/kg or g-equiv/$m^3$ |
| $N$ | Number of transfer units or number of reaction units; $k_f aL/(\varepsilon \nu^{ref})$ for external mass transfer; $15(1-\varepsilon)\varepsilon_p D_p L/(\varepsilon \nu^{ref} r_p^2)$ for pore diffusion; $15\Lambda D_s L/(\varepsilon \nu^{ref} r_p^2)$ for solid diffusion; $k_n \Lambda L/(\varepsilon \nu^{ref})$ for linear driving-force approximation; $k_a c_{ref} \Lambda L/[(1-R)\varepsilon \nu^{ref}]$ for reaction kinetics (Table 16-13) |
| $N_p$ | Number of theoretical plates [Eq. (16-157)] |
| $N_{Pe}$ | $\nu^{ref} L/D_L$, bed Peclet number (number of dispersion units) |
| $p$ | Partial pressure, Pa; switch time, s |
| $P$ | Pressure, Pa |
| $P^s$ | Vapor pressure, Pa |
| Pe | Particle-based Peclet number, $d_p \nu/D_L$ |
| $Q_i$ | Amount of component $i$ injected with feed, mol |
| $r, R$ | Separation factor [Eqs. (16-30), (16-32)]; particle radial coordinate, m |
| $r_c$ | Column internal radius, m |
| $r_m$ | Stokes-Einstein radius of molecule, m [Eq. (16-68)] |
| $r_p$ | Particle radius, m |
| $r_{pore}$ | Pore radius, m |
| $r_s$ | Radius of subparticles, m |
| $\Re$ | Gas constant, $Pa \cdot m^3/(mol \cdot K)$ |
| Re | Reynolds number based on particle diameter, $\rho_f d_p \varepsilon \nu/\mu$ |
| Sc | Schmidt number, $\mu/(\rho_f D)$ |
| Sh | Sherwood number, $k_f d_p/D$ |
| $t$ | Time, s |
| $t_c$ | Cycle time, s |
| $t_f$ | Feed time, s |
| $t_R$ | Chromatographic retention time, s |
| $T$ | Absolute temperature, K |
| $u$ | Superficial velocity, m/s |
| $u_s$ | Adsorbent velocity in TMB or SMB systems, $kg/(m^2 \cdot s)$ |
| $u_f$ | Fluid-phase internal energy, J/mol |
| $u_s$, $u_{sol}$ | Stationary-phase and sorbent solid internal energy, J/kg |
| $\nu$ | Interstitial velocity, m/s |
| $V_f$ | Extraparticle fluid volume, $m^3$ |
| $W$ | Volume adsorbed as liquid, $m^3$; baseline width of chromatographic peak, s (Fig. 16-26) |
| $x$ | Adsorbed-phase mole fraction; particle coordinate, m |
| $y$ | Fluid-phase mole fraction |
| $z$ | Bed axial coordinate, m; ionic valence |

### Greek Letters

| | |
|---|---|
| $\alpha$ | Separation factor or selectivity |
| $\beta$ | Scaling factor in Polanyi-based models; slope in gradient elution chromatography [Eq. (16-190)] |
| $\Delta$ | Peak width at half height, s (Fig. 16-26) |
| $\varepsilon$ | Extraparticle void fraction of packed bed (extraparticle porosity); adsorption potential in Polanyi model, J/mol |
| $\varepsilon_p$ | Intraparticle void fraction (intraparticle porosity) |
| $\varepsilon_b$ | Total bed void fraction (inside and outside particles) [(Eq. 16-4)] |
| $\gamma$ | Activity coefficient |
| $\Gamma$ | Surface excess, $mol/m^2$ (Fig. 16-4) |
| $\kappa$ | Boltzmann constant |
| $\lambda$ | Isosteric heat of adsorption, J/mol [Eq. (16-7)] |
| $\Lambda$ | Partition ratio [Eq. (16-125)] |
| $\Lambda^\infty$ | Ultimate fraction of solute adsorbed in batch |
| $\mu$ | Fluid viscosity, $kg/(m \cdot s)$ |
| $\mu_0$ | Zeroth moment, $mol \cdot s/m^3$ [Eq. (16-153)] |
| $\mu_1$ | First moment, s [Eq. (16-154)] |
| $\nu$ | Kinematic viscosity, $m^2/s$ |
| $\Omega$ | Cycle-time dependent LDF coefficient [Eq. (16-91)] |
| $\omega$ | Parameter defined by Eq. (16-185*b*) |
| $\varphi$ | Volume fraction or mobile-phase modulator concentration, $mol/m^3$ |
| $\pi$ | Spreading pressure, N/m [(Eq. (16-20)] |
| $\psi_p$, $\psi_s$ | LDF correction factors (Table 16-12) |
| $\Psi$ | Mechanism parameter for combined resistances (Fig. 16-12) |
| $\rho$ | Subparticle radial coordinate, m |
| $\rho_b$ | Bulk adsorbent density in a packed bed, $kg/m^3$ |
| $\rho_f$ | Fluid density, $kg/m^3$ |
| $\rho_p$ | Particle density, $kg/m^3$ [Eq. (16-1)] |
| $\rho_s$ | Skeletal particle density, $kg/m^3$ [Eq. (16-2)] |
| $\sigma^2$ | Second central moment, $s^2$ [Eq. (16-155)] |
| $\tau$ | Dimensionless time [Eq. (16-120)] |
| $\tau_1$ | Dimensionless time [Eq. (16-127) or (16-129)] |
| $\tau_p$ | Tortuosity factor [Eq. (16-65)] |
| $\xi$ | Particle dimensionless radial coordinate ($r/r_p$) |
| $\zeta$ | Dimensionless bed axial coordinate ($z/L$) |

### Subscripts

| | |
|---|---|
| $a$ | Adsorbed phase |
| $f$ | Fluid phase |
| $i, j$ | Component index |
| tot | Total |

### Superscripts

| | |
|---|---|
| - | An averaged concentration |
| ^ | A combination of averaged concentrations |
| * | Dimensionless concentration variable |
| $e$ | Equilibrium |
| ref | Reference (indicates feed or initial values) |
| $s$ | Saturation |
| SM | Service mark |
| TM | Trademark |
| 0 | Initial fluid concentration in batch |
| 0′ | Initial adsorbed-phase concentration in batch |
| $\infty$ | Final state approached in batch |

# DESIGN CONCEPTS

## INTRODUCTION

Adsorption and ion exchange share so many common features in regard to application in batch and fixed-bed processes that they can be grouped together for a unified treatment. These processes involve the transfer and resulting distribution of one or more solutes between a fluid phase and a sorbent. The partitioning of a single solute between fluid and adsorbed phases or the selectivity of a sorbent toward multiple solutes makes it possible to separate solutes from a bulk fluid phase or from one another.

This section treats batch and fixed-bed operations and reviews process cycles and equipment. In practice, fixed-bed operation with the sorbent in granule, bead, or pellet form is the predominant way of conducting sorption separations and purifications. Therefore, fixed beds including chromatographic separations are given primary attention here with respect to both interpretation and prediction.

Adsorption involves, in general, the accumulation (or depletion) of solute molecules at an interface (including gas–liquid interfaces, as in foam fractionation, and liquid–liquid interfaces, as in detergency). Here we consider only solid adsorbents and ion exchangers and thus only gas–solid and liquid–solid interfaces, with solute distributed selectively between the fluid and solid phases. Adsorption is typically restricted to the interfacial surface; thus, highly porous solids with very large internal area per unit volume are preferred. Adsorbent surfaces are often physically and/or chemically heterogeneous, and bonding energies may vary widely from one site to another. For separations or temporary storage, we usually seek to promote physical adsorption or *physisorption,* which involves van der Waals forces, and retard chemical adsorption or *chemisorption,* which involves chemical bonding (and often dissociation, as in catalysis). The former is well suited for a regenerable process, while the latter generally destroys the capacity of the adsorbent.

Adsorbents are natural or synthetic materials of amorphous or microcrystalline structure. Those used on a large scale, in order of quantity used, are activated carbon, molecular sieves, silica gel, and activated alumina [see Keller, Anderson, and Yon (1987) in General References].

Ion exchange usually occurs throughout a swollen cross-linked charged polymer, termed a resin. In cation exchange, ions of positive charge (cations) from the fluid (usually an aqueous solution) replace dissimilar ions of the same charge initially in the resin. In anion exchange the same process occurs but involving ions of negative charge (anions). In both cases the ion exchanger contains permanently bound functional groups. Cation-exchange resins generally contain bound sulfonic acid groups; less commonly, these groups are carboxylic, phosphonic, phosphinic, and so on. Anion-exchange resins generally involve quaternary ammonium groups (strongly basic) or other amino groups (weakly basic).

Most ion exchangers in large-scale use are based on synthetic resins that are either preformed and then functionalized with ionogenic groups, as for polystyrene, or formed from ionogenic monomers (e.g., olefinic acids, amines, or phenols). Certain natural and synthetic zeolites are also used as ion exchangers.

Ion exchange may be thought of as a reversible reaction involving chemically equivalent quantities. A common example for cation exchange is the water-softening reaction

$$Ca^{++} + 2NaR \rightleftharpoons CaR_2 + 2Na^+$$

where R represents a stationary univalent anionic site in the polyelectrolyte network of the exchanger phase.

Table 16-1 classifies sorption operations by the type of interaction and the basis for the separation. In addition to the normal sorption operations of adsorption and ion exchange, some other similar separations are included. Applications are discussed in the subsection Process Cycles.

***Example 16-1 Surface Area and Pore Volume of Adsorbent*** A simple example will show the extent of internal area in a typical granular adsorbent. A fixed bed is packed with particles of a porous adsorbent material. The bulk density of the packing is 500 kg/m$^3$, and the interparticle void fraction is 0.40. The intraparticle porosity is 0.50, with two-thirds of this in cylindrical pores of diameter 1.4 nm and the rest in much larger pores. Find the surface area of the adsorbent and, if solute has formed a complete monomolecular layer 0.3 nm thick inside the pores, determine the percent of the particle volume and the percent of the total bed volume filled with adsorbate.

From surface-area-to-volume ratio considerations, the internal area is practically all in the small pores. One gram of the adsorbent occupies 2 cm$^3$ as packed and has 0.4 cm$^3$ in small pores, which gives a surface area of 1150 m$^2$/g (or about 1 mi$^2$ per 5 lb or 6.3 mi$^2$/ft$^3$ of packing). Based on the area of the annular region filled with adsorbate, the solute occupies 22.5 percent of the internal pore volume and 13.5 percent of the total packed-bed volume.

## DESIGN STRATEGY

The design of sorption systems is based on a few underlying principles. First, knowledge of *sorption equilibrium* is required. This equilibrium, between solutes in the fluid phase and the solute-enriched phase of the solid, supplants what in most chemical engineering separations is a fluid–fluid equilibrium. The selection of the sorbent material with an understanding of its equilibrium properties (i.e., capacity and selectivity as a function of temperature and component concentrations) is of primary importance. Second, because sorption operations take place in batch, in fixed beds, or in simulated moving beds, the processes have *dynamical character.* Such operations generally do not run at steady state, although steady state may be approached in a simulated moving bed. Fixed-bed processes often approach a periodic condition called a periodic state or cyclic steady state, with several different feed steps constituting a cycle. Thus, some knowledge of how transitions travel through a bed is required. This introduces both time and space into the analysis, in contrast to many other chemical engineering operations that can be analyzed

**TABLE 16-1 Classification of Sorptive Separations**

| Type of interaction | Basis for separation | Examples |
|---|---|---|
| Adsorption | Equilibrium | Numerous purification and recovery processes for gases and liquids |
| | | Activated carbon-based applications |
| | | Desiccation using silica gels, aluminas, and zeolites |
| | | Oxygen from air by PSA using LiX and 5A zeolites |
| | Rate | Nitrogen from air by PSA using carbon molecular sieve |
| | | Nitrogen and methane using titanosilicate ETS-4 |
| | Molecular sieving | Separation on *n*- and *iso*-parafins using 5A zeolite |
| | | Separation of xylenes using zeolite |
| Ion exchange (electrostatic) | Equilibrium | Deionization |
| | | Water softening |
| | | Rare earth separations |
| | | Recovery and separation of pharmaceuticals (e.g., amino acids, proteins) |
| Ligand exchange | Equilibrium | Chromatographic separation of glucose-fructose mixtures with Ca-form resins |
| | | Removal of heavy metals with chelating resins |
| | | Affinity chromatography |
| Solubility | Equilibrium | Partition chromatography |
| None (purely steric) | Equilibrium partitioning in pores | Size exclusion or gel permeation chromatography |

at steady state with only a spatial dependence. For accurate design, it is crucial to understand fixed-bed performance in relation to adsorption equilibrium and rate behavior. Finally, many *practical aspects* must be included in design so that a process starts up and continues to perform well, and that it is not so overdesigned that it is wasteful. While these aspects are process-specific, they include an understanding of dispersive phenomena at the bed scale and, for regenerative processes, knowledge of aging characteristics of the sorbent material, with consequent changes in sorption equilibrium.

**Characterization of Equilibria** Phase equilibrium between fluid and sorbed phases for one or many components in adsorption or two or more species in ion exchange is usually the single most important factor affecting process performance. In most processes, it is much more important than mass and heat transfer rates; a doubling of the stoichiometric capacity of a sorbent or a significant change in the shape of an isotherm would often have a greater impact on process performance than a doubling of transfer rates.

A difference between adsorption and ion exchange with completely ionized resins is indicated in the *variance* of the systems. In adsorption, part of the solid surface or pore volume is vacant. This diminishes as the fluid-phase concentration of solute increases. In contrast, for ion exchange the sorbent has a fixed total capacity and merely exchanges solutes while conserving charge. Variance is defined as the number of independent variables in a sorption system at equilibrium—that is, variables that one can change separately and thereby control the values of all others. Thus, it also equals the difference between the total number of variables and the number of independent relations connecting them. Many cases arise in which ion exchange is accompanied by chemical reaction (neutralization or precipitation, in particular), or adsorption is accompanied by evolution of sensible heat. The concept of variance helps greatly to assure correct interpretations and predictions.

The working capacity of a sorbent depends on fluid concentrations and temperatures. Graphical depiction of sorption equilibrium for single-component adsorption or binary ion exchange (monovariance) is usually in the form of isotherms [$n_i = n_i(c_i)$ or $n_i(p_i)$ at constant $T$] or isosteres [$p_i = p_i(T)$ at constant $n_i$]. Representative forms are shown in Fig. 16-1. An important dimensionless group dependent on adsorption equilibrium is the **partition ratio** [see Eq. (16-125)], which is a measure of the relative affinities of the sorbed and fluid phases for solute.

Historically, isotherms have been classified as *favorable* (concave downward) or *unfavorable* (concave upward). These terms refer to the spreading tendencies of transitions in fixed beds. A favorable isotherm gives a compact transition, whereas an unfavorable isotherm leads to a broad one.

***Example 16-2 Calculation of Variance*** In mixed-bed deionization of a solution of a single salt, there are eight concentration variables: two each for cation, anion, hydrogen, and hydroxide. There are six connecting relations: two for ion exchange and one for neutralization equilibrium, and two ion-exchanger and one solution electroneutrality relation. The variance is therefore $8 - 6 = 2$.

**Adsorbent/Ion Exchanger Selection** Guidelines for sorbent selection are different for regenerative and nonregenerative systems. For a nonregenerative system, one generally wants a high capacity and a strongly favorable isotherm for a purification and additionally high selectivity for a separation. For a regenerative system, high overall capacity and selectivity are again desired, but needs for cost-effective regeneration leading to a reasonable working capacity influence what is sought after in terms of isotherm shape. For separations by pressure-swing adsorption (or vacuum pressure-swing adsorption), generally one wants a linear to slightly favorable isotherm

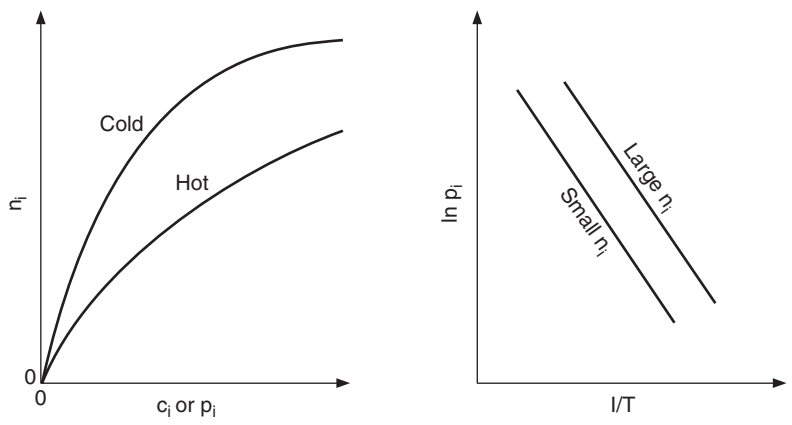

**FIG. 16-1** Isotherms (*left*) and isosteres (*right*). Isosteres plotted using these coordinates are nearly straight parallel lines, with deviations caused by the dependence of the isosteric heat of adsorption on temperature and loading.

**TABLE 16-2 Methods of Analysis of Fixed-Bed Transitions**

| Method | Purpose | Approximations |
|---|---|---|
| Local equilibrium theory | Shows wave character—simple waves and shocks<br>Usually indicates best possible performance<br>Better understanding | Mass and heat transfer very rapid<br>Dispersion usually neglected<br>If nonisothermal, then adiabatic |
| Mass-transfer zone | Design based on stoichiometry and experience | Isothermal<br>MTZ length largely empirical<br>Regeneration often empirical |
| Constant pattern and related analyses | Gives asymptotic transition shapes and upper bound on MTZ | Deep bed with fully developed transition |
| Full rate modeling | Accurate description of transitions<br>Appropriate for shallow beds, with incomplete wave development<br>General numerical solutions by finite difference or collocation methods | Various to few |

(although purifications can operate economically with more strongly favorable isotherms). Temperature-swing adsorption usually operates with moderately to strongly favorable isotherms, in part because one is typically dealing with heavier solutes, and these are adsorbed rather strongly (e.g., organic solvents on activated carbon and water vapor on zeolites). Exceptions exist, however; for example, water is adsorbed on silica gel and activated alumina only moderately favorably, with some isotherms showing unfavorable sections. Equilibria for ion-exchange separations generally vary from moderately favorable to moderately unfavorable; depending on feed concentrations, alternates often exist for different steps of a regenerative cycle. Other factors in sorbent selection are mechanical and chemical stability, mass-transfer characteristics, and cost.

**Fixed-Bed Behavior** The number of transitions occurring in a fixed bed of initially uniform composition before it becomes saturated by a constant composition feed stream is generally equal to the variance of the system. This introductory discussion will be limited to single-transition systems.

Methods for analysis of fixed-bed transitions are shown in Table 16-2. Local equilibrium theory is based solely on stoichiometric concerns and system nonlinearities. A transition becomes a "simple wave" (a gradual transition), a "shock" (an abrupt transition), or a combination of the two. In other methods, mass-transfer resistances are incorporated.

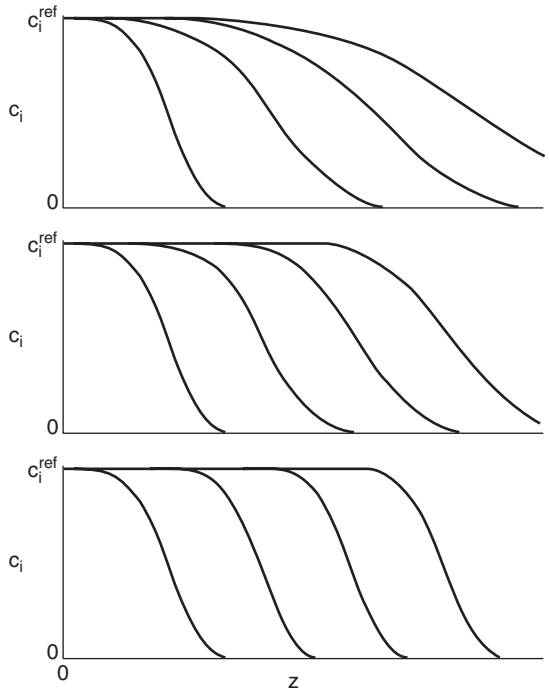

**FIG. 16-2** Limiting fixed-bed behavior: simple wave for unfavorable isotherm (*top*), square-root spreading for linear isotherm (*middle*), and constant pattern for favorable isotherm (*bottom*). [From LeVan in Rodrigues et al. (eds.), Adsorption: Science and Technology, *Kluwer Academic Publishers, Dordrecht, The Netherlands, 1989; reprinted with permission.*]

The asymptotic behavior of transitions under the influence of mass-transfer resistances in long, "deep" beds is important. The three basic asymptotic forms are shown in Fig. 16-2. With an unfavorable isotherm, the breadth of the transition becomes proportional to the depth of bed it has passed through. For the linear isotherm, the breadth becomes proportional to the square root of the depth. For the favorable isotherm, the transition approaches a constant breadth called a *constant pattern.*

Design of nonregenerative sorption systems and many regenerative ones often relies on the concept of the mass-transfer zone or MTZ, which closely resembles the constant pattern [Collins, *Chem. Eng. Prog. Symp. Ser. No. 74* **63:** 31 (1974); Keller, Anderson, and Yon (1987) in General References]. The length of this zone (depicted in Fig. 16-3) together with stoichiometry can be used to predict accurately how long a bed can be used before breakthrough.

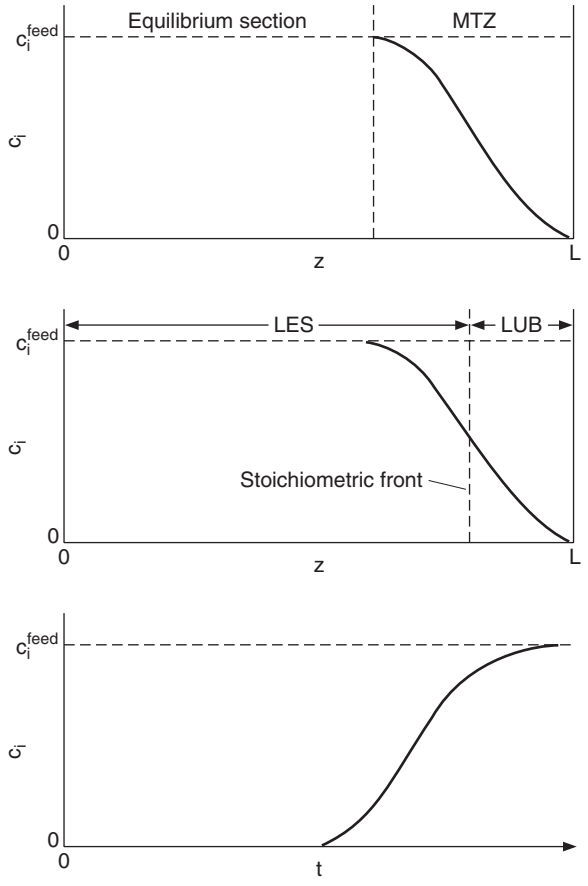

**FIG. 16-3** Bed profiles (*top* and *middle*) and breakthrough curve (*bottom*). The bed profiles show the mass-transfer zone (MTZ) and equilibrium section at breakthrough. The stoichiometric front divides the MTZ into two parts with contributions to the length of equivalent equilibrium section (LES) and the length of equivalent unused bed (LUB).

Upstream of the mass-transfer zone, the adsorbent is in equilibrium with the feed. Downstream, the adsorbent is in its initial state. Within the mass-transfer zone, the fluid-phase concentration drops from the feed value to the initial, presaturation state.

Equilibrium with the feed is not attained in this region. As a result, because an adsorption bed must typically be removed from service shortly after breakthrough begins, the full capacity of the bed is not used. Obviously, the broader the mass-transfer zone is, the greater will be the extent of unused capacity. Also shown in the figure are the length of the equivalent equilibrium section (LES) and the length of the equivalent unused bed (LUB). The length of the MTZ is divided between these two.

Adsorption with strongly favorable isotherms and ion exchange between strong electrolytes can usually be carried out until most of the stoichiometric capacity of the sorbent has been utilized, corresponding to a thin MTZ. Consequently, the total capacity of the bed is practically constant regardless of the composition of the solution being treated.

The effluent concentration history is the breakthrough curve, also shown in Fig. 16-3. The effluent concentration stays at or near zero or a low residual concentration until the transition reaches the column outlet. The effluent concentration then rises until it becomes unacceptable, this time being called the breakthrough time, which is typically much shorter than the time for the feed concentration to reach the column outlet. The feed step must stop and, for a regenerative system, the regeneration step begins.

Two dimensionless variables play key roles in the analysis of single-transition systems (and some multiple-transition systems). These are the *throughput parameter* [see Eq. (16-129)] and the *number of transfer units* (see Table 16-13). The former is time made dimensionless so that it equals unity at the stoichiometric center of a breakthrough curve. The latter is, as in packed tower calculations, a measure of mass-transfer resistance.

**Cycles** Design methods for cycles rely on mathematical modeling (or empiricism) and often extensive pilot plant experiments. Many cycles can be easily analyzed by applying the methods previously described to the collection of steps. In some cycles, however, especially those operated with short cycle times or in shallow beds, transitions may not be fully developed, even at a periodic state, and the complexity may be compounded by multiple sorbates.

A wide variety of complex process cycles have been developed. Systems with many beds incorporating multiple sorbents, possibly in layered beds, are in use. Mathematical models constructed to analyze such cycles can be complex. With a large number of variables and nonlinear equilibria involved, it is usually not beneficial to make all variables in such models dimensionless; doing so does not help appreciably in making comparisons with other largely dissimilar systems. If dimensionless variables are used, these usually begin with a dimensionless bed length and a dimensionless time, which is often different from the throughput parameter.

**Practical Aspects** A number of process-specific concerns are accounted for in good design. In regenerable systems, sorbents age, losing capacity because of fouling by heavy contaminants, loss of surface area or crystallinity, oxidation, and the like. Mass-transfer resistances may increase over time. Because of particle shape, size distribution, or column packing method, dispersion may be more pronounced than would normally be expected. The humidity of an entering stream will usually affect a solvent recovery application. Safety, including the possibility of a fire, may be a concern. For gas-phase adsorption, scale-up from an isothermal laboratory column to a nonisothermal pilot plant column to a largely adiabatic process column requires careful judgment. If the MTZ concept is utilized, the length of the MTZ cannot be reliably determined solely from knowledge on other systems. Experience plays the key role in accounting for these and other such factors.

# ADSORBENTS AND ION EXCHANGERS

## CLASSIFICATIONS AND CHARACTERIZATIONS

**Adsorbents** Table 16-3 classifies common adsorbents by structural type and water adsorption characteristics. Zeolite and silicalite adsorbents take advantage of their crystalline structure and/or their molecular sieving properties. The hydrophobic (nonpolar surface) or hydrophilic (polar surface) character may vary depending on the competing adsorbate. A large number of zeolites have been identified, and these include both synthetic and naturally occurring (e.g., mordenite and chabazite) varieties.

The classifications in Table 16-3 are intended only as a rough guide. For example, a carbon molecular sieve is truly amorphous but has been manufactured to have certain structural, rate-selective properties. Similarly, the extent of hydrophobicity of an activated carbon will depend on its ash content and its level of surface oxidation.

Zeolites are crystalline aluminosilicates. Zeolitic adsorbents have had their water of hydration removed by calcination to create a structure with well-defined openings into crystalline cages. The molecular sieving properties of zeolites are based on the sizes of these openings. Two crystal types are common: type A (with openings formed by four sodalite cages) and type X or Y (with openings formed by six sodalite cages). Cations balancing charge and their locations determine the size of opening into a crystal unit cell. Nominal opening sizes for the most common synthetic zeolites are 0.3 nm for KA, 0.4 nm for NaA, 0.5 nm for CaA, and 1.0 nm for NaX. Further details, including effective molecular diameters, are widely available [Barrer (1978); Breck (1974); Ruthven (1984); and Yang (1987) in General References].

Many adsorbents, particularly the amorphous adsorbents, are characterized by their pore size distribution. The distribution of small pores is usually determined by analysis, using one of several available methods, of a cryogenic nitrogen adsorption isotherm, although other probe molecules are also used. The distribution of large pores is usually determined by mercury porisimetry [Gregg and Sing (1982) in General References].

Table 16-4 shows the IUPAC classification of pores by size. Micropores are small enough that a molecule is attracted to both of the opposing walls forming the pore. The potential energy functions for these walls superimpose to create a deep well, and strong adsorption results. Hysteresis, that is, when the adsorption and the desorption branches of an isotherm are different, is generally not observed. (However, water vapor adsorbed in the micropores of activated carbon shows a large hysteresis loop, and the desorption branch is sometimes used with the Kelvin equation to determine the pore size distribution.) Capillary condensation occurs in mesopores, and a hysteresis loop is typically found. Macropores form important paths for molecules to diffuse into a particle; for gas-phase adsorption, they do not fill with adsorbate until the gas phase becomes saturated.

New adsorbents and ion-exchange materials are constantly under development. The class of microporous crystalline materials with molecular sieving properties is extensive and includes many metal silicates and phosphates, with the zeolites (aluminosilicates) being the most broadly useful. The titanosilicate ETS-4 is currently being implemented for separation of $CH_4$ and $N_2$. Among other classes of materials, the recently developed $\pi$-complexation sorbents are particularly promising; these use weak chemical bonds instead of purely physical interaction as the basis for separation [Yang (2003) in General References]. Two other adsorbent materials of considerable research interest, but which have not been implemented for commercial separations, are carbon nanotubes and the mesoporous silicas MCM-41 and SBA-15. Carbide-derived carbons (CDCs) are a new entry into

**TABLE 16-3 Classification of Common Adsorbents**

| | Amorphous | Structured |
|---|---|---|
| Hydrophobic | Activated carbon<br>Polymers | Carbon molecular sieves<br>Silicalite |
| Hydrophilic | Silica gel<br>Activated alumina | Common zeolites: 3A (KA), 4A (NaA), 5A (CaA), 13X (NaX), Mordenite, Chabazite, etc. |

**TABLE 16-4 Classification of Pore Sizes**

| Type | Slit width* ($w$) | Characteristic |
|---|---|---|
| Micropore† | $w < 2$ nm | Superimposed wall potentials |
| Mesopore | 2 nm $< w <$ 50 nm | Capillary condensation |
| Macropore | $w > 50$ nm | Effectively flat walled until $p \to P^s$ |

*Or pore diameter.
†Further subdivided into ultramicropores and supermicropores.
Gregg and Sing (1982) in General References; Thommes et al., *Pure Appl. Chem.* **87:** 1051 (2015).

the adsorbent field. They have surface areas ranging from 500 $m^2/g$ to 2000 $m^2/g$, depending on the starting precursor and smaller pore size distributions than typical activated carbons; adsorption studies are in early stages, as CDCs have been evaluated more often as electrochemical capacitors [Simon and Gogotsi, *Nature Materials* **7:** 845 (2008)]. Polymers with intrinsic microporosity (PIMs) are also under development as adsorbents, as are many other materials targeted for specific adsorbates.

Metal-organic frameworks (MOFs) are a new class of porous materials that entered the adsorbent literature in the late 1990s. Early research focused on their potential application in natural gas storage and hydrogen storage systems (Farrusseng, *Metal-Organic Frameworks: Applications from Catalysis to Gas Storage*, Wiley-VCH, Weinheim, 2011). The materials are now widely studied for applications to $CO_2$ capture, natural gas upgrading, and air purification but have yet to achieve commercial success [Li et al., *Chem. Reviews* **112:** 869 (2012)].

MOFs are synthesized by the self-assembly of metal ions coordinated to organic ligands most commonly through carboxylic acid groups or nitrogens. The resulting porous networks exhibit among the highest pore volumes and surface areas of any known adsorbents. They are also highly crystalline with distinct pore sizes and shapes. More than 20,000 structures have been discovered; these possess a large diversity of chemical composition, topology, and textural properties.

Among the most important examples, MOF-5 (or IRMOF-1) is one of the earliest porous MOFs. This structure is formed by 4-coordinated Zn-O tetrahedral [Eddaoudi et al., *Science* **295:** 469 (2002)]; this material has a surface area exceeding 1500 $m^2/g$ and pores sizes >1.2 nm but undergoes structural degradation in the presence of humidity or aqueous conditions. HKUST-1 (Cu-BTC) was the first permanently porous MOF assembled from the copper-paddlewheel building unit [Chui et al., *Science* **283:** 1148 (1999)]. The MOF possesses open metal sites (coordinatively unsaturated) that are available for interaction with adsorbate molecules. HKUST-1 has two types of pores: a larger center channel with diameter of 0.9 nm and smaller side pockets with diameter of 0.35 nm. This MOF displays improved water stability over MOF-5 and is currently produced at the kilogram scale by BASF and marketed as Basolite C300. The aluminum-based MOF MIL-53(Al), produced commercially as Basolite A100, is synthesized in water and comprised of $AlO_4(OH)_2$ corner-sharing octahedral chains connected by terephthalate groups to form a three-dimensional structure with 8.5 Å pores [Loiseau et al., *Chemistry-A European Journal* **10:** 1373 (2004)]. MIL-53(A1) is a stable structure with a surface area exceeding 1300 $m^2/g$. The zirconium-based MOF UiO-66 is synthesized from zirconium chloride and terephthalic acid in dimethyl formamide [Cavka et al., *J. Am. Chem. Soc.* **130:** 13850 (2008)]. UiO-66 possesses triangular-shaped pores with diameter of approximately 0.6 nm. The terephthalic acid ligand can be functionalized in a variety of ways with chemical groups such as $–NH_2$ and $–NO_2$ [Cmarik et al., *Langmuir* **28:** 15606 (2012)]. UiO-66 is one of the most robust and chemically stable MOFs in the literature.

MOFs have received intense attention in the scientific literature, but the materials have yet to find commercial application as adsorbents due to problems with chemical stability and synthesis scale-up. Of the thousands of known MOF structures, on the order of 50 structures exhibit high stability in the presence of water. Several hundred materials are "partially stable," with the remaining majority being unstable. For more details on MOF stability, a comprehensive review is available [Burtch et al., *Chemical Reviews* **114:** 10575 (2014)].

**Ion Exchangers** Ion exchangers are classified according to (1) their functionality and (2) the physical properties of the support matrix. Cation and anion exchangers are classified in terms of their ability to exchange positively or negatively charged species. Strongly acidic and strongly basic ion exchangers are ionized and thus are effective at nearly all pH values (e.g., pH 0–14). Weakly acidic exchangers are typically effective above pH 5. Weakly basic resins are effective below pH 9. Weakly acidic and weakly basic exchangers are often easier to regenerate, but leakage due to incomplete exchange may occur. Chelating resins containing iminodiacetic acid form specific metal complexes with metal ions with complex stability constants that follow the same order as those for EDTA. However, depending on pH, they also function as weak cation exchangers. The achievable ion-exchange capacity depends on the concentration of ionogenic groups and their availability as exchange sites. The latter is a function of the support matrix.

Polymer-based, synthetic ion exchangers known as resins are available commercially in gel type or truly porous forms. Gel-type resins are not porous in the usual sense of the word, since their structure depends on swelling in the solvent in which they are immersed. Removal of the solvent usually results in a collapse of the three-dimensional structure, and no significant surface area or pore diameter can be defined by the ordinary techniques available for truly porous materials. In their swollen state, gel-type resins approximate a true molecular-scale solution. Thus, an internal porosity $\varepsilon_p$ can be identified only in terms of the equilibrium uptake of water or other liquid. When cross-linked polymers are used as the support matrix, the internal porosity so defined varies approximately in inverse proportion to the degree of cross-linking, and swelling is typically more pronounced in solvents with a high dielectric constant. The ion held by the exchanger also influences the resin swelling. Thus, the size of the resin particles changes during the ion-exchange process as the resin is changed from one form to another, and this effect is more dramatic for resins with a lower degree of cross-linking. The choice of degree of cross-linking is dependent on several factors, including the extent of swelling, the exchange capacity, the intraparticle diffusivity, the ease of regeneration, and the physical and chemical stability of the exchanger under chosen operating conditions. The concentration of ionogenic groups determines the capacity of the resin. Although the capacity per unit mass of dry resin is insensitive to the degree of cross-linking, except for very highly cross-linked resins, the exchange capacity per unit volume of swollen resin increases significantly with degree of cross-linking, so long as the mesh size of the polymer network allows the ions free access to functional groups within the interior of the resin. The degree of cross-linking also affects the rate of ion exchange. The intraparticle diffusivity decreases nearly exponentially with the mesh size of the matrix. As a result, resins with a lower degree of cross-linking are normally required for the exchange of bulky species, such as organic ions with molecular weight in excess of 100. The regeneration efficiency is typically greater for resins with a lower degree of cross-linking. Finally, the degree of cross-linking also affects the long-term stability of the resin. Strongly acidic and strongly basic resins are subject to irreversible oxidative degradation of the polymer and thermal and oxidative decomposition of functional groups. Generally, more highly cross-linked resins are less prone to irreversible chemical degradation, but they may be subject to osmotic breakage caused by volume changes that occur during cyclic operations. In general, experience shows that an intermediate degree of cross-linking is often preferred. However, readers are referred to manufacturers' specifications for resin stability data at different operating conditions.

Truly porous, synthetic ion exchangers are also available. These materials retain their macroporosity even after removal of the solvent and have measurable surface areas and pore size. The term *macroreticular* is commonly used for resins prepared from a phase separation technique, where the polymer matrix is prepared with the addition of a liquid that is a good solvent for the monomers, but in which the polymer is insoluble. Matrices prepared in this way usually have the appearance of a conglomerate of gel-type microspheres held together to form an interconnected porous network. Macroporous resins possessing a more continuous gellular structure interlaced with a pore network have also been obtained with different techniques and are commercially available. Since higher degrees of cross-linking are typically used to produce truly porous ion-exchange resins, these materials tend to be more stable under highly oxidative conditions, more attrition-resistant, and more resistant to breakage due to osmotic shock than their gel-type counterparts. Moreover, since their porosity does not depend entirely on swelling, they can be used in solvents with low dielectric constant where gel-type resins can be ineffective. In general, compared to gel-type resins, truly porous resins typically have somewhat lower capacities and can be more expensive. Thus, for ordinary ion-exchange applications involving small ions under nonharsh conditions, gel-type resins are usually preferred.

Adsorbents for biomacromolecules such as proteins have special properties [see Carta and Jungbauer (2010) in General References]. First, these adsorbents need to have large pore sizes. A ratio of pore radius to molecule radius larger than 5 is desirable to prevent excessive diffusional hindrance (see the subsection Intraparticle Mass Transfer). Thus, for typical proteins, pore radii need to be in excess of 10–15 nm. Second, functional groups for interactions with proteins are usually attached to a matrix backbone via a spacer arm to provide accessibility. Third, hydrophilic matrices are preferred to limit nonspecific interactions with the backbone and prevent global unfolding or denaturation of the protein. Thus, if hydrophobic supports are used, their surfaces are usually rendered hydrophilic by incorporating hydrophilic coatings such as dextran or polyvinyl alcohol. Finally, materials stable in sodium hydroxide solutions or other solutions used for clean-in-place are preferred. Support matrices for protein adsorption can be classified into the following four broad groups: hydrophilic gels, including cross-linked agarose, cross-linked dextran, cross-linked polyacrylamide, and cellulose; rigid macroporous media, including silica/ceramic, alumina, polystyrene-DVB, and polymethacrylate; composite media, including agarose-dextran and ceramic-polyacrylamide; and monoliths, including polystyrene-DVB, polymethacrylate, and silica-based materials. Monoliths for biomacromolecule adsorption are generally synthesized in place in a column, resulting in a continuous random structure of linked, generally nonporous microparticles intercalated by a network of flow-through pores. The continuous structure allows independent control of microparticle size and flow-through pore sizes, resulting in rapid adsorption and moderate pressure drop. Although the adsorption capacity for proteins is smaller than for porous-particle-based adsorbents, they offer significant advantages for rapid high-resolution

separations and for adsorption of very large bioparticles such as plasmid DNA and viruses [see Josic et al., *J. Chrom. B.* **752:** 191 (2001)].

Functional groups or ligands incorporated in materials for biomacromolecule adsorption can be classified in the following four broad groups: cation exchange, including sulfopropyl (SP), methyl sulfonate (S), and carboxymethyl (CM); anion exchange, including quaternary ammonium ion (Q), quaternary aminoethyl (QAE), and diethylamino ethyl (DEAE); hydrophobic interaction, including ether, isopropyl, butyl, octyl, and phenyl ligands in order of increasing hydrophobicity; and biospecific interaction or affinity ligands, including amino acids, dyes, and proteins covalently bound to the base matrix and transition metals supported via complexing ligands. Among the affinity ligands, protein A is the most popular for the selective adsorption of antibodies. Hybrid or multimodal ligands, incorporating both charged and hydrophobic moieties, are also popular. Polystyrene-based particles and silica particles functionalized with hydrocarbon chains from C2 to C18 in length are also used for reversed-phase chromatographic separations. However, because of the limited stability of biomacromolecules, their process applications are limited. Inert, hydrophilic porous matrices and gels are used extensively for size exclusion chromatography (SEC). A useful general reference is Janson, *Protein Purification: Principles, High-Resolution Methods, and Applications*, 3d ed., Wiley, New York, 2011.

## PHYSICAL PROPERTIES

Selected data on some commercially available adsorbents and ion exchangers are given in Tables 16-5 and 16-6. The purpose of the tables is twofold: to assist the engineer or scientist in identifying materials suitable for a needed application, and to supply typical physical property values.

In addition to the particulate adsorbents listed in Table 16-5, some adsorbents are available in structured form for specific applications. Monoliths, papers, and paint formulations have been developed for zeolites, with these driven by the development of adsorbent wheels, adsorptive refrigeration, and other applications requiring low pressure drop across the column. Carbon monoliths are also available, as are activated carbon fibers, created from polymeric materials and sold in the form of fabrics, mats, felts, and papers for use in various applications, including in pleated form in filters. Zeolitic and carbon membranes are also available, with the latter developed for separation by "selective surface flow" [Rao and Sircar, *J. Membrane Sci.* **85:** 253 (1993)].

Excellent sources of information on the characteristics of adsorbents or ion-exchange products for specific applications are the manufacturers themselves. Additional information on adsorbents and ion exchangers is available in many of the General References [e.g., Yang (2003)] and in several articles in *Kirk-Othmer Encyclopedia of Chemical Technology.* A comprehensive summary of commercial ion exchangers, including manufacturing methods, properties, and applications, is given by Dorfner (1991).

Several densities and void fractions are commonly defined. For adsorbents, the *bulk density* $\rho_b$ denotes the mass of clean material per unit volume of a packed bed. The *extraparticle void fraction* $\varepsilon$ denotes the void volume outside the adsorbent particles per unit volume of a packed bed. The *intraparticle porosity* $\varepsilon_p$ denotes the void volume inside the adsorbent particles per unit volume of particle. Derived quantities are defined as follows. The dry *particle density* $\rho_p$ is

$$\rho_p = \rho_b/(1-\varepsilon) \tag{16-1}$$

The *skeletal density* $\rho_s$ of a particle (or crystalline density for a pure chemical compound) is

$$\rho_s = \rho_p/(1-\varepsilon_p) \tag{16-2}$$

For an adsorbent or ion exchanger, the *wet density* $\rho_w$ of a particle is related to the liquid density $\rho_f$ by

$$\rho_w = \rho_p + \varepsilon_p\rho_f \tag{16-3}$$

The *total void fraction* $\varepsilon_b$ in a packed bed (outside and inside particles) is

$$\varepsilon_b = \varepsilon + (1-\varepsilon)\varepsilon_p \tag{16-4}$$

†When two temperatures are shown, the first applies to H form for cation, or OH form for anion, exchanger; the second, to salt ion.

# SORPTION EQUILIBRIUM

The quantity of a solute adsorbed can be defined conveniently in terms of moles or volume ( for adsorption) or ion equivalents ( for ion exchange) per unit mass or volume (dry or wet) of sorbent. Common units for adsorption are mol/($m^3$ of fluid) for the fluid-phase concentration $c_i$ and mol/(kg of clean adsorbent) for adsorbed-phase concentration $n_i$. For gases, partial pressure may replace concentration.

Many models have been proposed for adsorption and ion exchange equilibria. The most important factor in selecting a model from an engineering standpoint is to have an accurate mathematical description over the entire range of process conditions. It is usually fairly easy to obtain correct capacities at selected points, but isotherm shape over the entire range is often a critical concern for a regenerable process.

## GENERAL CONSIDERATIONS

**Forces** Molecules are attracted to surfaces as the result of two types of forces: dispersion-repulsion forces (also called London or van der Waals forces) such as described by the Lennard-Jones potential for molecule–molecule interactions; and electrostatic forces, which exist as the result of a molecule or surface group having a permanent electric dipole or quadrupole moment or net electric charge.

Dispersion forces are always present and in the absence of any stronger force will determine equilibrium behavior, as with adsorption of molecules with no dipole or quadrupole moment on nonoxidized carbons and silicalite.

If a surface is polar, its resulting electric field will induce a dipole moment in a molecule with no permanent dipole and, through this polarization, increase the extent of adsorption. Similarly, a molecule with a permanent dipole moment will polarize an otherwise nonpolar surface, thereby increasing the attraction.

For a polar surface and molecules with permanent dipole moments, attraction is strong, as for water adsorption on a hydrophilic adsorbent. Similarly, for a polar surface, a molecule with a permanent quadrupole moment will be attracted more strongly than a similar molecule with a weaker moment; for example, nitrogen is adsorbed more strongly than oxygen on zeolites [Sherman and Yon (1991) in General References].

**Surface Excess** With a Gibbs dividing surface placed at the surface of the solid, the surface excess of component $i$, $\Gamma_i$ (mol/$m^2$), is the amount of that component per unit area of solid contained in the region near the surface, above that contained at the fluid-phase concentration far from the surface. This is depicted in Fig. 16-4. The quantity adsorbed per unit mass of adsorbent is

$$n_i = \Gamma_i A \tag{16-5}$$

where $A$ ($m^2$/kg) is the surface area of the solid.

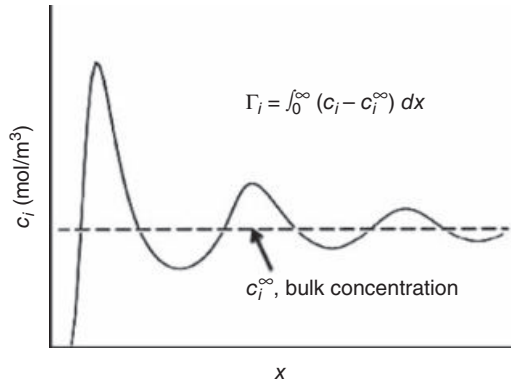

**FIG. 16-4** Depiction of surface excess $\Gamma_i$. The force field of the solid concentrates component $i$ near the surface; the concentration $c_i$ is low at the surface because of short-range repulsive forces between adsorbate and surface.

For a porous adsorbent, the amount adsorbed in the pore structure per unit mass of adsorbent, based on surface excess, is obtained by the difference

$$n_i = n_i^{\text{tot}} - V_p c_i^\infty \tag{16-6}$$

where $n_i^{\text{tot}}$ (mol/kg) is the total amount of component $i$ contained within the particle's pore volume $V_p$ (m$^3$/kg), and $c_i^\infty$ is the concentration outside of the particle. If $n_i$ differs significantly from $n_i^{\text{tot}}$ (as it will for weakly adsorbed species), then it is important to consider adsorbed-phase quantities in terms of surface excesses.

**Classification of Isotherms by Shape** Representative isotherms are shown in Fig. 16-5, as classified by Brunauer and coworkers. Curves that are concave downward throughout (type I) have historically been designated as "favorable," while those that are concave upward throughout (type III) are "unfavorable." Other isotherms (types II, IV, and V) have one or more inflection points. The designations favorable and unfavorable refer to fixed-bed behavior for the uptake step, with a favorable isotherm maintaining a compact wave shape. A favorable isotherm for uptake is unfavorable for the discharge step. This becomes particularly important for a regenerative process, in which a favorable isotherm may be too favorable for regeneration to occur effectively.

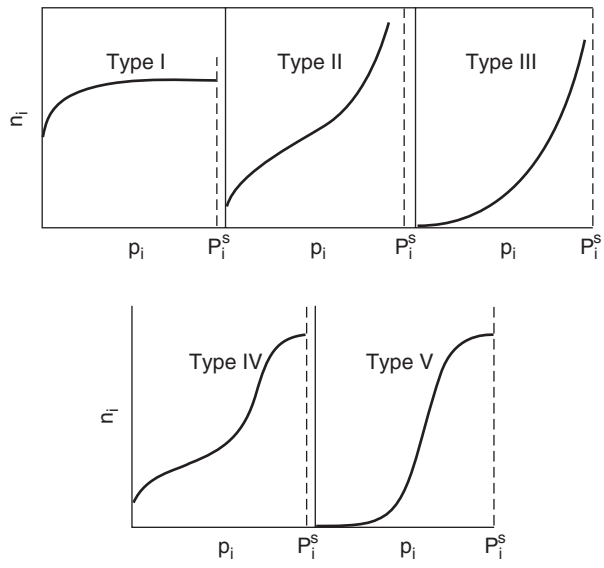

**FIG. 16-5** Representative isotherm types. $p_i$ and $P_i^s$ are pressure and vapor pressure of the solute. [Brunauer, *J. Am. Chem. Soc.* **62:** 1723 (1940); reprinted with permission; see also Thommes et al., *Pure Appl. Chem.* **87:** 1051 (2015).]

**Categorization of Equilibrium Models** Historically, sorption equilibrium has been approached from different viewpoints. For adsorption, many models for flat surfaces have been used to develop explicit equations and equations of state for pure components and mixtures, and many of the resulting equations are routinely applied to porous materials. Explicit equations for pore filling have also been proposed, generally based on the Polanyi potential theory. Ion exchange adds to these approaches concepts of absorption or dissolution and exchange reactions. Statistical mechanics and molecular dynamics contribute to our understanding of all of these approaches (Steele, *The Interaction of Gases with Solid Surfaces,* Pergamon, Oxford, 1974; Nicholson and Parsonage, *Computer Simulation and the Statistical Mechanics of Adsorption,* Academic Press, New York, 1982). Mixture models are often based on the adsorbed solution theory, which uses thermodynamic equations from vapor–liquid equilibria with volume replaced by surface area and pressure replaced by a two-dimensional spreading pressure. Other approaches include lattice theories and mass-action exchange equilibrium.

**Heterogeneity** Adsorbents and ion exchangers can be physically and chemically heterogeneous. Although exceptions exist, solutes generally compete for the same sites. Models for adsorbent heterogeneity have been developed for both discrete and continuous distributions of energies [Ross and Olivier, *On Physical Adsorption,* Interscience, New York, 1964; Jaroniec and Madey (1988); Rudzinski and Everett (1992) in General References].

**Isosteric Heat of Adsorption** The most useful heat of adsorption for fixed-bed calculations is the *isosteric heat of adsorption,* which is given by the Clausius-Clapeyron type relation

$$\lambda_i = \Re T^2 \left.\frac{\partial \ln p_i}{\partial T}\right|_{n_i, n_j} \tag{16-7}$$

where the $n_j$ can be dropped for single-component adsorption. $\lambda_i$ is positive by convention. If isosteres are straight lines when plotted as $\ln p_i$ versus $T^{-1}$ (see Fig. 16-1), then Eq. (16-7) can be integrated to give

$$\ln p_i = f(n_i) - \frac{\lambda_i}{\Re T} \tag{16-8a}$$

where $f(n_i)$ is an arbitrary function dependent only on $n_i$. Many other heats of adsorption have been defined, and their utility depends on the application [Ross and Olivier, *On Physical Adsorption,* Interscience, New York, 1964; Young and Crowell (1962) in General References].

From Eq. (16-8*a*), if a single isotherm is known in the pressure explicit form $p_i = p_i(n_i, T)$ and if $\lambda_i$ is known at least approximately, then equilibria can be estimated over a narrow temperature range using

$$\ln \frac{p_i}{p_i^{\text{ref}}} = \frac{\lambda_i}{\Re}\left(\frac{1}{T^{\text{ref}}} - \frac{1}{T}\right) \quad (\text{const } n_i) \tag{16-8b}$$

Similarly, Eq. (16-8*b*) can be used to calculate the isosteric heat of adsorption from two isotherms.

**Experiments** Sorption equilibria are measured using equipment and methods classified as volumetric, gravimetric, flow-through ( frontal analysis), and chromatographic. Equipment is discussed elsewhere [Yang (1987); Keller and Staudt (2005) in General References]. Heats of adsorption can be determined from isotherms measured at different temperatures or measured independently by calorimetric methods.

**Dimensionless Concentration Variables** Where appropriate, isotherms will be written here using the dimensionless system variables

$$c_i^* = \frac{c_i}{c_i^{\text{ref}}} \qquad n_i^* = \frac{n_i}{n_i^{\text{ref}}} \tag{16-9}$$

where the best choice of reference values depends on the operation.

In some cases, to allow for some preloading of the adsorbent, it will be more convenient to use the dimensionless transition variables

$$c_i^* = \frac{c_i - c_i'}{c_i'' - c_i'} \qquad n_i^* = \frac{n_i - n_i'}{n_i'' - n_i'} \tag{16-10}$$

where single and double primes indicate initial and final concentrations, respectively. Figure 16-6 shows $n_i$ plotted versus $c_i$ for a sample system. Superimposed are an upward transition (loading) and a downward transition (unloading), shown by the respective positions of $(c_i, n_i)$ and $(c_i', n_i')$ and $(c_i'', n_i'')$.

## SINGLE COMPONENT OR EXCHANGE

The simplest relationship between solid-phase and fluid-phase concentrations is the **linear isotherm**

$$n_i = K_i c_i \qquad \text{or} \qquad n_i = K_i' p_i \tag{16-11}$$

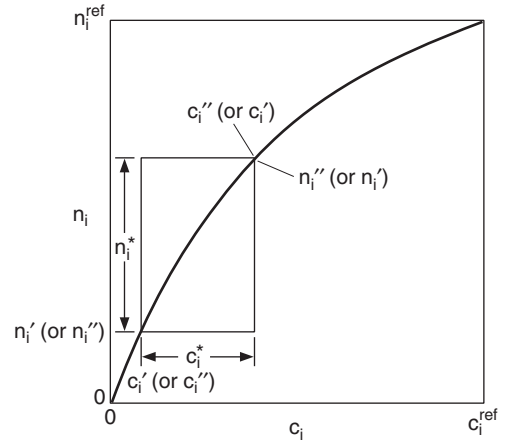

**FIG. 16-6** Isotherm showing concentration variables for a transition from $(c_i', n_i')$ to $(c_i'', n_i'')$.

Thermodynamics requires that a linear limit be approached in the Henry's law region for all isotherm equations.

**Flat-Surface Isotherm Equations** The classification of isotherm equations into two broad categories for flat surfaces and pore filling reflects their origin. This distinction does not restrict equations developed for flat surfaces from being applied successfully to describe data for porous adsorbents.

The classical isotherm for a homogeneous flat surface, and most popular of all nonlinear isotherms, is the *Langmuir isotherm*

$$n_i = \frac{n_i^s K_i c_i}{1 + K_i c_i} \tag{16-12}$$

where $n_i^s$ is the monolayer capacity approached at large concentrations and $K_i$ is an equilibrium constant. These parameters are often determined by plotting $1/n_i$ versus $1/c_i$. The derivation of the isotherm assumes negligible interaction between adsorbed molecules. For temperature-dependent adsorption equilibrium and a constant isosteric heat of adsorption, $K_i$ is given by

$$K_i = K_i^0 \exp(\lambda_i / \Re T) \tag{16-13}$$

where $K_i^0$ is a constant. Note that at low concentrations, the Langmuir isotherm approaches the linear limit ($n_i = n_i^s K_i c_i$). The Langmuir isotherm can also be written for two or more patches of differing energies to account for surface heterogeneity, with the total amount adsorbed being the sum of the patchwise contributions. A wide variety of gas adsorption equilibria on different adsorbents can be described using only two patches [Ritter et al., *Langmuir* **27:** 4700 (2011); Bhadra et al., *Langmuir* **28:** 6935 (2012)]. This dual process Langmuir (DPL) model is given by

$$n_i = \left(\frac{n_{1,i}^s K_{1,i} p_i}{1 + K_{1,i} p_i}\right)_{\text{Site 1}} + \left(\frac{n_{2,i}^s K_{2,i} p_i}{1 + K_{2,i} p_i}\right)_{\text{Site 2}} \tag{16-14}$$

where $n_{j,i}^s$ and $K_{j,i}$ are the saturation capacity and or equilibrium constant on site $j$. For temperature dependence, a form of Eq. (16-13) is applied to each site. Another variation on Eq. (16-12) is the multisite Langmuir isotherm [Nitta et al., *J. Chem. Eng. Japan* **17:** 39 (1984)], which is

$$K_i p_i = \frac{n_i / n_i^s}{(1 - n_i / n_i^s)^{a_i}} \tag{16-15}$$

where $a_i$ is a constant.

The classical isotherm for multilayer adsorption on a homogeneous, flat surface is the *BET isotherm* [Brunauer et al., *J. Am. Chem. Soc.* **60:** 309 (1938)]

$$n_i = \frac{n_i^s K_i p_i}{[1 + K_i p_i - (p_i / P_i^s)][1 - (p_i / P_i^s)]} \tag{16-16}$$

where $p_i$ is the pressure of the adsorbable component and $P_i^s$ is its vapor pressure. It is useful for gas–solid systems in which condensation is approached, fitting type II behavior.

For a heterogeneous flat surface, a classical isotherm is the *Freundlich isotherm*

$$n_i = K_i (c_i)^{m_i} \tag{16-17}$$

where $m_i$ is positive and generally not an integer. The isotherm corresponds approximately to an exponential distribution of heats of adsorption. Although it lacks the required linear behavior in the Henry's law region, it can often be used to correlate data on heterogeneous adsorbents over wide ranges of concentration.

Several isotherms combine aspects of both the Langmuir and Freudlich equations. One that has been shown to be effective in describing data mathematically for heterogeneous adsorbents is the *Tóth isotherm* [Toth, *Acta Chim. Acad. Sci. Hung.* **69:** 311 (1971)]

$$n_i = \frac{n_i^s p_i}{\left[(1/K_i) + p_i^{m_i}\right]^{1/m_i}} \tag{16-18}$$

This three-parameter equation behaves linearly in the Henry's law region and reduces to the Langmuir isotherm for $m_i = 1$. Other well-known isotherms include the *Langmuir-Freundlich isotherm* or *Sips isotherm* [Sips, *J. Chem. Phys.* **16:** 490 (1948); Koble and Corrigan, *Ind. Eng. Chem.* **44:** 383 (1952)] or *loading ratio correlation* with prescribed temperature dependence [Yon and Turnock, *AIChE Symp. Ser.* **67**(117): 75 (1971)]

$$n_i = \frac{n_i^s (K_i p_i)^{m_i}}{1 + (K_i p_i)^{m_i}} \tag{16-19}$$

Equations of state are also used. From an equation of state written in terms of the two-dimensional spreading pressure $\pi$, the corresponding isotherm is easily determined, as described later for adsorption of mixtures [see Eq. (16-43)]. The two-dimensional equivalent of an ideal gas is an ideal surface gas, which is described by

$$\pi A = n_i \Re T \tag{16-20}$$

which gives the linear isotherm, Eq. (16-11). Many more complicated equations of state are available, including two-dimensional analogs of the virial equation and equations of van der Waals, Redlich-Kwong, Peng-Robinson, etc. [Adamson (1990) in General References; Patrykiejewet et al., *Chem. Eng. J.* **15:** 147 (1978); Haydel and Kobayashi, *Ind. Eng. Chem. Fundam.* **6:** 546 (1967)].

**Pore-Filling Isotherm Equations** Most pore-filling models are grounded in the Polanyi potential theory. In Polanyi's model, an attracting potential energy field is assumed to exist adjacent to the surface of the adsorbent and concentrates vapors there. Adsorption takes place wherever the strength of the field, independent of temperature, is great enough to compress the solute to a partial pressure greater than its vapor pressure. The last molecules to adsorb form an equipotential surface containing the adsorbed volume. The strength of this field, called the adsorption potential $\varepsilon$ (J/mol), was defined by Polanyi to be equal to the work required to compress the solute from its partial pressure to its vapor pressure

$$\varepsilon = \Re T \ln(P_i^s / p_i) \tag{16-21}$$

The same result is obtained by considering the change in chemical potential. In the basic theory, $W$ ($m^3$/kg), the volume adsorbed as saturated liquid at the adsorption temperature, is plotted versus $\varepsilon$ to give a characteristic curve. Data measured at different temperatures for the same solute-adsorbent pair should fall on this curve. Using the method, it is possible to use data measured at a single temperature to predict isotherms at other temperatures. Data for additional, homologous solutes can be collapsed into a single "correlation curve" by defining a scaling factor $\beta$, the most useful of which has been $V/V^{ref}$, the adsorbate molar volume as saturated liquid at the adsorption temperature divided by that for a reference compound. Thus, by plotting $W$ versus $\varepsilon/\beta$ or $\varepsilon/V$ for data measured at various temperatures for various similar solutes and a single adsorbent, a single curve should be obtained. Variations of the theory are often used to evaluate properties for components near or above their critical points [Grant and Manes, *Ind. Eng. Chem. Fund.* **5:** 490 (1966)].

The most popular equations used to describe the shape of a characteristic curve or a correlation curve are the two-parameter *Dubinin-Radushkevich* (DR) equation

$$\frac{W}{W_0} = \exp\left[-k\left(\frac{\varepsilon}{\beta}\right)^2\right] \tag{16-22}$$

and the three-parameter *Dubinin-Astakhov* (DA) equation

$$\frac{W}{W_0} = \exp\left[-k\left(\frac{\varepsilon}{\beta}\right)^m\right] \tag{16-23}$$

where $W_0$ is micropore volume and $m$ is related to the pore size distribution [Gregg and Sing (1982)]. Neither of these equations has correct limiting behavior in the Henry's law regime.

**Ion Exchange** The *mass-action law* describes ion exchange equilibrium in fully ionized exchanger systems as

$$z_B A + z_A \overline{B} \rightleftharpoons z_B \overline{A} + z_A B$$

where overbars indicate the ionic species in the ion exchanger and $z_A$ and $z_B$ are the valences of counterions $A$ and $B$. The associated equilibrium relation is

$$K^c_{A,B} = K_{A,B}\left(\frac{\gamma_A}{\overline{\gamma}_A}\right)^{z_B}\left(\frac{\overline{\gamma}_B}{\gamma_B}\right)^{z_A} = \left(\frac{n_A}{c_A}\right)^{z_B}\left(\frac{c_B}{n_B}\right)^{z_A} \tag{16-24}$$

where $K^c_{A,B}$ is the apparent equilibrium constant or molar selectivity coefficient, $K_{A,B}$ is the thermodynamic equilibrium constant based on activities, and the $\gamma$s are activity coefficients. Often concentrations are represented in terms of equivalent ionic fractions based on solution normality $c_{\text{tot}}$ and ion exchanger capacity $n^s$ as $c^*_i = z_i c_i / c_{\text{tot}}$ and $n^*_i = z_i n_i / n_{\text{tot}}$, where $c_{\text{tot}} = \sum z_j c_j$ and $n_{\text{tot}} = \sum z_j n_j = n^s$ with the summations extended to all counter-ion species. A rational selectivity coefficient is then defined as

$$K'_{A,B} = K^c_{A,B}\left(\frac{n_{\text{tot}}}{c_{\text{tot}}}\right)^{z_A - z_B} = \left(\frac{n^*_A}{c^*_A}\right)^{z_B}\left(\frac{c^*_B}{n^*_B}\right)^{z_A} \tag{16-25}$$

For the exchange of ions of equal valence ($z_A = z_B$), $K^c_{A,B}$ and $K'_{A,B}$ are coincident and, to a first approximation, independent of solution normality. When $z_A > z_B$, $K^c_{A,B}$ decreases with solution normality. Thus, ion exchangers exhibit an increasing affinity for ions of lower valence as the solution normality increases.

An alternate form of Eq. (16-25) is

$$n^*_A = K^c_{A,B}\left(\frac{n_{\text{tot}}}{c_{\text{tot}}}\right)^{(z_A - z_B)/z_B}\left(\frac{1-n^*_A}{1-c^*_A}\right)^{z_A/z_B} c^*_A \tag{16-26}$$

When $B$ is in excess (that is $c^*_A, n^*_A \to 0$), this reduces to

$$n^*_A = K^c_{A,B}\left(\frac{n_{\text{tot}}}{c_{\text{tot}}}\right)^{(z_A - z_B)/z_B} c^*_A = K_A c^*_A \tag{16-27}$$

where the linear equilibrium constant $K_A = K^c_{A,B}(n_{\text{tot}}/c_{\text{tot}})^{(z_A/z_B)-1}$ decreases with solution normality $c_{\text{tot}}$ when $z_A > z_B$ or increases when $z_A < z_B$.

Table 16-7 gives equilibrium constants $K_{A,B}$ for cross-linked cation and anion exchangers for a variety of counterions. The values given for cation exchangers are based on ion $A$ replacing $Li^+$, and those given for anion exchangers are based on ion $A$ replacing $Cl^-$. The selectivity for a particular ion generally increases with decreasing hydrated ion size and increasing degree of cross-linking. The selectivity coefficient for any two ions $A$ and $D$ can be obtained from Table 16-7 from values of $K_{A,B}$ and $K_{D,B}$ as

$$K_{A,D} = K_{A,B}/K_{D,B} \tag{16-28}$$

The values given in this table are only approximate, but they are adequate for process screening purposes with Eqs. (16-24) and (16-25). Rigorous calculations generally require that activity coefficients be accounted for. However, for the exchange between ions of the same valence at solution concentrations of 0.1 N or less, or between any ions at 0.01 N or less, the solution-phase activity coefficients will be similar enough that they can be omitted.

Models for ion exchange equilibria based on the mass-action law taking into account solution and exchanger-phase nonidealities with equations similar to those for liquid mixtures have been developed by several authors [see Smith and Woodburn, *AIChE J.* **24:** 577 (1978); Mehablia et al., *Chem. Eng. Sci.* **49:** 2277 (1994)]. Thermodynamics-based approaches are also available [Soldatov in Dorfner (1991) in General References; Novosad and Myers, *Can J. Chem. Eng.* **60:** 500 (1982); Myers and Byington in Rodrigues, ed., *Ion Exchange Science and Technology,* NATO ASI Series, No. 107, Nijhoff, Dordrecht, 1986, pp. 119–145] as well as approaches for the exchange of macromolecules [see Carta and Jungbauer (2010)] also taking into account steric-hindrance effects [Brooks and Cramer, *AIChE J.* **38:** 12 (1992)].

***Example 16-3 Calculation of Useful Ion-Exchange Capacity*** An 8 percent cross-linked sulfonated resin is used to remove calcium from a solution containing 0.0007 mol/L $Ca^{+2}$ and 0.01 mol/L $Na^+$. The total resin ion-exchange capacity is 2.0 equiv/L. Estimate the resin capacity for calcium removal for the conditions given.

From Table 16-7, $K_{\text{Ca,Na}} = 5.16/1.98 = 2.6$. Since $n_{\text{tot}} = 2$ equiv/L and $c_{\text{tot}} = 2 \times 0.0007 + 0.01 = 0.011$ equiv/L, $K'_{\text{Ca,Na}} = 2.6 \times 2/0.011 = 470$. Thus, with $C^*_{\text{Ca}} = 2 \times 0.0007/0.011 = 0.13$, Eq. (16-25) gives $470 = (n^*_{\text{Ca}}/0.13)[(1-0.13)/(1-n^*_{\text{Na}})]^2$ or $n^*_{\text{Ca}} = 0.9$. The available capacity for calcium is $n_{\text{Ca}} = 0.9 \times 2.0/2 = 0.9$ mol/L.

**Donnan Uptake** The uptake of an electrolyte as a neutral ion pair of a salt is called Donnan uptake. It is generally negligible at low ionic concentrations. Above 0.5 g·equiv/L with strongly ionized exchangers (or at lower concentrations with those more weakly ionized), the resin's fixed ion-exchange capacity is measurably exceeded as a result of electrolyte invasion. With only one coion species $Y$ (matching the charge sign of the fixed groups in the resin), its uptake $n_Y$ equals the total excess uptake of the counterion.

**TABLE 16-7 Equilibrium Constants for Polystyrene DVB Cation and Anion Exchangers**

Strong acid sulfonated cation exchangers ($Li^+$ reference ion)

| | Degree of cross-linking | | | | Degree of cross-linking | | |
|---|---|---|---|---|---|---|---|
| Counterion | 4% DVB | 8% DVB | 16% DVB | Counterion | 4% DVB | 8% DVB | 16% DVB |

*Trimethylamine.
†Dimethyl-hydroxyethylamine.
Data from Bonner and Smith, *J. Phys. Chem.* **61:** 326 (1957) and Wheaton and Bauman, *Ind. Eng. Chem.* **43:** 1088 (1951).

Equilibrium is described by the mass-action law. For the case of a resin in *A*-form in equilibrium with a salt *AY,* the excess counterion uptake is given by [Helfferich (1962), pp. 133–147, in General References].

$$z_Y n_Y = \left[ \frac{n^{s2}}{4} + (z_Y c_Y)^2 \left( \frac{\gamma_{AY}}{\overline{\gamma}_{AY}} \right)^2 \left( \frac{\overline{a}_w}{a_w} \right)^{\hat{v}_{AY}/\hat{v}_w} \right]^{1/2} - \frac{n^s}{2} \tag{16-29}$$

where γs are activity coefficients, *a*s are water activities, and νs are partial molar volumes. For dilute conditions, Eq. (16-29) predicts a squared dependence of $n_Y$ on $c_Y$. Thus, the electrolyte sorption isotherm has a strong positive curvature. Donnan uptake is more pronounced for resins of lower degree of cross-linking and for counterions of low valence.

**Separation Factor** By analogy with the mass-action case and appropriate for both adsorption and ion exchange, a *separation factor r* can be defined based on dimensionless system variables [Eq. (16-9)] by

$$r = \frac{c_i^*(1-n_i^*)}{n_i^*(1-c_i^*)} \quad \text{or} \quad r = \frac{n_B^*/c_B^*}{n_A^*/c_A^*} \tag{16-30}$$

This term is analogous to relative volatility or its reciprocal (or to an equilibrium selectivity). Similarly, the assumption of a constant separation factor is a useful assumption in many sorptive operations. [It is constant for the Langmuir isotherm, as described below, and for mass-action equilibrium with $z_a = z_b$ in Eq. (16-24).] This gives the constant separation factor isotherm

$$n_i^* = \frac{c_i^*}{r + (1-r)c_i^*} \tag{16-31}$$

The separation factor *r* identifies the equilibrium increase in $n_i^*$ from 0 to 1, which accompanies an increase in $c_i^*$ from 0 to 1. For a concentration change over only part of the isotherm, a separation factor *R* can be defined for the dimensionless transition variables [Eq. (16-10)]. This separation factor is

$$R = \frac{n_i''/c_i''}{n_i'/c_i'} = \frac{c_i^*(1-n_i^*)}{n_i^*(1-c_i^*)} \tag{16-32}$$

and gives an equation identical to Eq. (16-31) with *R* replacing *r*.

Figure 16-7 shows constant separation factor isotherms for a range of *r* (or *R*) values. The isotherm is linear for $r = 1$, favorable for $r < 1$, rectangular (or irreversible) for $r = 0$, and unfavorable for $r > 1$. As a result of symmetry properties, if *r* is defined for adsorption of component *i* or exchange of ion *A* for *B*, then the reverse process is described by $1/r$.

The Langmuir isotherm, Eq. (16-12), corresponds to the constant separation factor isotherm with

$$r = 1/\left(1 + K_i c_i^{\text{ref}}\right) \tag{16-33}$$

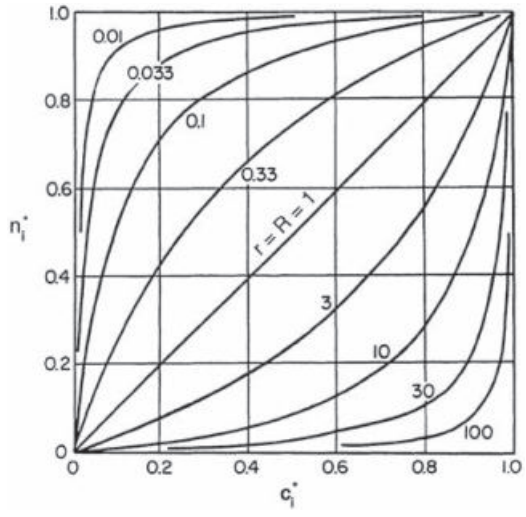

**FIG. 16-7** Constant separation factor isotherm as a function of the separation factor *r* (or interchangeably *R*). Each isotherm is symmetric about the perpendicular line connecting (0,1) and (1,0). Isotherms for *r* and $1/r$ are symmetric about the 45° line.

for system variables [Eq. (16-9)] or

$$R = \frac{r + (1-r)\left(c_i'/c_i^{\text{ref}}\right)}{r + (1-r)\left(c_i''/c_i^{\text{ref}}\right)} \tag{16-34}$$

for transition variables [Eq. (16-10)]. Vermeulen et al. (1984) give additional properties of constant separation factor isotherms.

***Example 16-4 Application of Isotherms*** Thomas [*Ann. N.Y. Acad. Sci.* **49:** 161 (1948)] provides the following Langmuir isotherm for the adsorption of anthracene from cyclohexane onto alumina:

$$n_i = \frac{22 c_i}{1 + 375 c_i}$$

with $n_i$ in mol anthracene/kg alumina and $c_i$ in mol anthracene/L liquid.

*a.* What are the values of $K_i$ and $n_i^s$ according to Eq. (16-12)?

$$K_i = 375 \text{ L/mol}$$

$$n_i^s = \frac{22}{K_i} = 0.0587 \text{ mol/kg}$$

*b.* For a feed concentration of $8.11 \times 10^{-4}$ mol/L, what is the value of *r*?

$$r = \frac{1}{1 + K_i(8.11 \times 10^{-4})} = 0.766 \qquad \text{[from Eq. (16-33)]}$$

*c.* If the alumina is presaturated with liquid containing $2.35 \times 10^{-4}$ mol/L and the feed concentration is $8.11 \times 10^{-4}$ mol/L, what is the value of *R*?

$$R = 0.834 \qquad \text{[from Eq. (16-32) or (16-34)]}$$

## MULTICOMPONENT ADSORPTION OR ION EXCHANGE

When more than one adsorbed species or more than two ion-exchanged species interact in some manner, equilibrium becomes more complicated. Usually, thermodynamics provides a sound basis for prediction.

**Adsorbed-Solution Theory** The common thermodynamic approach to multicomponent adsorption treats adsorption equilibrium in a way analogous to fluid-fluid equilibrium. The theory has as its basis the Gibbs adsorption isotherm [Young and Crowell (1962) in General References], which is

$$A d\pi = \sum_i n_i d\mu_i \qquad (\text{const } T) \tag{16-35}$$

where $\mu_i$ is chemical potential. For an ideal gas ($d\mu_i = \Re T d \ln p_i$), if it is assumed that an adsorbed solution is defined with a pure-component standard state (as is common for a liquid solution), then Eq. (16-35) can be integrated to give [Rudisill and LeVan, *Chem. Eng. Sci.* **47:** 1239 (1992)]

$$p_i = \gamma_i x_i P_i^{\text{ref}}(T, \pi) \tag{16-36}$$

where $\gamma_i$ and $x_i$ are the adsorbed-phase activity coefficient and mole fraction of component *i* and $P_i^{\text{ref}}$ is the standard state, specified to be at the temperature and spreading pressure of the mixture.

Equation (16-36) with $\gamma_i = 1$ provides the basis for the ideal adsorbed-solution theory [Myers and Prausnitz, *AIChE J.* **11:** 121 (1965)]. The spreading pressure for a pure component is determined by integrating Eq. (16-35) for a pure component to obtain

$$\frac{\pi A}{\Re T} = \int_0^{P_i^{\text{ref}}} \frac{n_i}{p_i} dp_i \tag{16-37}$$

where $n_i$ is given by the pure-component isotherm. Also, since $\sum x_i = 1$, Eq. (16-36) with $\gamma_i = 1$ gives $\sum (p_i/P_i^{\text{ref}}) = 1$. With no area change on mixing for the ideal solution, the total number of moles adsorbed per unit weight of adsorbent is determined using a two-dimensional form of Amagat's law:

$$\frac{1}{n_{\text{tot}}} = \sum \frac{x_i}{n_i^{\text{ref}}} \tag{16-38}$$

where $n_{\text{tot}} = \sum n_i$ and $n_i^{\text{ref}}$ is given by the pure-component isotherm at $P_i^{\text{ref}}$. Adsorbed-phase concentrations are calculated using $n_i = x_i n_{\text{tot}}$. Generally, different values of $\pi$ [or $\pi A/(\Re T)$] must be tried until one is found that satisfies Eq. (16-37) and $\sum x_i = 1$.

***Example 16-5 Application of Ideal Adsorbed-Solution Theory*** Consider a binary adsorbed mixture for which each pure component obeys the Langmuir equation, Eq. (16-12). Let $n_1^s = 4$ mol/kg, $n_2^s = 3$ mol/kg, $K_1p_1 = K_2p_2 = 1$. Use the ideal adsorbed-solution theory to determine $n_1$ and $n_2$.

Substituting the pure component Langmuir isotherm

$$n_i = \frac{n_i^s K_i p_i}{1 + K_i p_i}$$

into Eq. (16-37) and integrating gives

$$\frac{\pi A}{\Re T} = n_i^s \ln(1 + K_i P_i^{\text{ref}})$$

which can be solved explicitly for $K_iP_i^{\text{ref}}$. Values are guessed for $\pi A/(\Re T)$, values of $K_iP_i^{\text{ref}}$ are calculated from the preceding equation, and $\Sigma x_i = \Sigma K_i p_i/(K_iP_i^{\text{ref}}) = 1$ is checked to see if it is satisfied. Trial and error gives $\pi A/(\Re T) = 3.8530$ mol/kg, $K_1P_1^{\text{ref}} = 1.6202$, $K_2P_2^{\text{ref}} = 2.6123$, and $x_1 = 0.61720$. Evaluating the pure-component isotherms at the reference pressures and using Eq. (16-38) gives $n_{\text{tot}} = 2.3475$ mol/kg, and finally $n_i = x_i n_{\text{tot}}$ gives $n_1 = 1.4489$ mol/kg and $n_2 = 0.8986$ mol/kg.

Other approaches to account for various effects have been developed. Negative deviations from Raoult's law (i.e., $\gamma_i < 1$) are often found due to adsorbent heterogeneity [e.g., Myers, *AIChE J.* **29:** 691 (1983)]. Thus, contributions include accounting for adsorbent heterogeneity [Valenzuela et al., *AIChE J.* **34:** 397 (1988)] and excluded pore-volume effects [Myers, in Rodrigues, LeVan, and Tondeur (1989) in General References]. Several activity coefficient models have been developed to account for nonideal adsorbate–adsorbate interactions, including a spreading pressure-dependent activity coefficient model [e.g., Talu and Zwiebel, *AIChE J.* **32:** 1263 (1986)] and a vacancy solution theory [Suwanayuen and Danner, *AIChE J.* **26:** 68–76 (1980)].

**Langmuir-Type Relations** For systems composed of solutes that individually follow Langmuir isotherms, the traditional multicomponent Langmuir equation, obtained via a kinetic derivation, is

$$n_i = \frac{n_i^s K_i p_i}{1 + \sum_j K_j p_j} \tag{16-39}$$

where $j$ is summed over all components. This equation has been criticized on thermodynamic grounds because it does not satisfy the Gibbs adsorption isotherm unless all monolayer capacities $n_i^s$ are equal.

To satisfy the Gibbs adsorption isotherm for unequal monolayer capacities, explicit isotherms can be obtained in the form of a series expansion [LeVan and Vermeulen, *J. Phys. Chem.* **85:** 3247 (1981)]. A two-term form is

$$n_1 = \frac{(n_1^s + n_2^s)K_1p_1}{2(1 + K_1p_1 + K_2p_2)} + \frac{(n_1^s - n_2^s)K_1p_1K_2p_2}{(K_1p_1 + K_2p_2)^2}\ln(1 + K_1p_1 + K_2p_2) \tag{16-40}$$

where the subscripts may be interchanged. Multicomponent forms are also available [Frey and Rodrigues, *AIChE J.* **40:** 182 (1994)].

A variation of Eq. (16-39) follows from an extension of the DPL model Eq. (16-14) to gas mixture adsorption equilibria and is given by [Ritter et al., *Langmuir* **27:** 4700 (2011)]

$$n_i = \sum_{j=1}^{2}\left(\frac{n_{j,i}^s K_{j,i} p_i}{1 + \sum_{k=1}^{N} K_{n,k} p_k}\right)_{\text{Site}\,j} \tag{16-41}$$

where $n_i$ is the total amount of component $i$ adsorbed on both sites $j$ from an $N$ component mixture. Since there are two different free energies for each component in the mixture, that is, one for each site, this leads to perfect positive (PP) or perfect negative (PN) correlation. When a pair of components both see site 1 as the high-energy site and site 2 as the low-energy site, then their energies correlate in a PP fashion, and $K_{n,k} = K_{j,k}$. When one component sees site 1 as the high-energy site and another component sees site 1 as the low-energy site, then their energies correlate in a PN fashion, and $K_{n,k} = K_{1,k}$ if $j = 2$ and $K_{n,k} = K_{2,k}$ if $j = 1$. This PP and PN behavior allows the DPL model to predict very nonideal behavior, including azeotropes using only single component parameters.

***Example 16-6 Comparison of Binary Langmuir Isotherms*** Use the numerical values in Example 16-5 to evaluate the binary Langmuir isotherms given by Eqs. (16-39) and (16-40) and compare results with the exact answers given in Example 16-5.

Equation (16-39) gives $n_1 = 1.3333$ mol/kg and $n_2 = 1.0000$ mol/kg for an average deviation from the exact values of approximately 10 percent. Equation (16-40) gives $n_1 = 1.4413$ mol/kg and $n_2 = 0.8990$ mol/kg for an average deviation of about 0.6 percent.

**Freundlich-Type Relations** A binary Freundlich isotherm, obtained from the ideal adsorbed solution theory in loading-explicit closed form [Crittenden et al., *Environ. Sci. Technol.* **19:** 1037 (1985)], is

$$c_i = \frac{n_i}{\sum_{j=1}^{N} n_j}\left(\frac{\sum_{j=1}^{N}(n_j/m_j)}{K_i/m_i}\right)^{1/m_i} \tag{16-42}$$

**Equations of State** If an equation of state is specified for a multicomponent adsorbed phase of the form $\pi A/(\Re T) = f(n_1, n_2, \ldots)$, then the isotherms are determined using [Van Ness, *Ind. Eng. Chem. Fundam.* **8:** 464–473 (1969)]

$$\ln\left(\frac{k_i p_i}{n_i/M_s}\right) = \int_A^{\infty}\left[\left.\frac{\partial[\pi A/(\Re T)]}{\partial n_i}\right|_{T,A,n_j} - 1\right]\frac{dA}{A} \tag{16-43}$$

where, because integration is over $A$, $M_s$ is mass of adsorbent, units for $n$ and $A$ are mol and $m^2$ (rather than mol/kg and $m^2$/kg), and $K_ip_i/(n_i/M_s) = 1$ is the linear lower limit approached for the ideal surface gas [see Eqs. (16-12) and (16-20)].

**Ion Exchange—Stoichiometry** In most applications, except for some weak-electrolyte and some concentrated-solution cases, the following summations apply:

$$\sum_i z_i c_i = c_{\text{tot}} = \text{const} \qquad \sum_i z_i n_i = n_{\text{tot}} = \text{const} \tag{16-44a}$$

In equivalent-fraction terms, the sums become

$$\sum_i c_i^* = 1 \qquad \sum_i n_i^* = 1 \tag{16-44b}$$

**Mass Action** Here the equilibrium relations, consistent with Eq. (16-25), are

$$K'_{ij} = \left(\frac{n_i^*}{c_i^*}\right)^{z_j}\left(\frac{c_j^*}{n_j^*}\right)^{z_i} \tag{16-45}$$

For an $N$-species system, with $N$ values of $c^*$ (or $n^*$) known, the $N$ values of $n^*$ (or $c^*$) can be found by simultaneous solution of the $N - 1$ independent $i,j$ combinations for Eq. (16-45) using Eq. (16-44*a*); one $n_j^*/c_j^*$ is assumed, the other values can be calculated using Eq. (16-45), and the sum of the trial $n^*$ values (or $c^*$ values) is compared with Eq. (16-44*b*).

Because an $N$-component system has $N - 1$ independent concentrations, a three-component equilibrium can be plotted in a plane and a four-component equilibrium in a three-dimensional space. Figure 16-8 shows a triangular plot of $c^*$ contours in equilibrium with the corresponding $n^*$ coordinates.

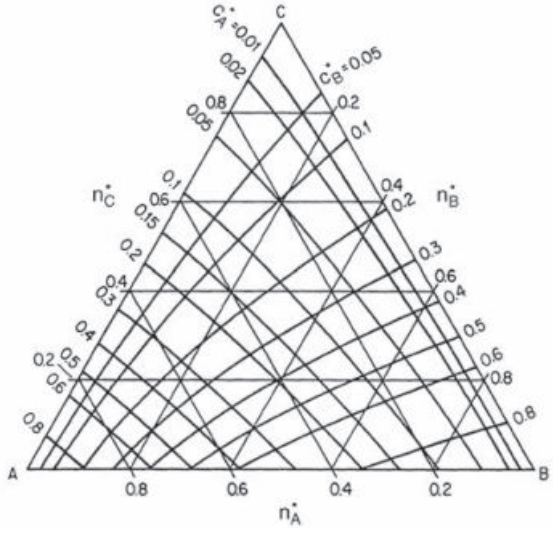

**FIG. 16-8** Ideal mass-action equilibrium for three-component ion exchange with unequal valences. $K'_{A,C} = 8.06$; $K'_{B,C} = 3.87$. Duolite C-20 polystyrenesulfonate resin, with Ca as A, Mg as B, and Na as C. [Klein et al., *Ind. Eng. Chem. Fund.* **6:** 339 (1967); reprinted with permission.]

Improved models for ion-exchange equilibria are in Smith and Woodburn [*AIChE J.* **24:** 577 (1978)]; Mehablia et al. [*Chem. Eng. Sci.* **49:** 2277 (1994)]; Soldatov [in Dorfner (1991) in General References]; Novosad and Myers, [*Can J. Chem. Eng.* **60:** 500 (1982)]; and Myers and Byington [in Rodrigues, ed., *Ion Exchange: Science and Technology,* NATO ASI Series, No. 107, Nijhoff, Dordrecht, 1986, pp. 119–145].

**Constant Separation-Factor Treatment** If the valences of all species are equal, the separation factor $\alpha_{ij}$ applies, where

$$\alpha_{ij} = k_{ij} = \frac{n_i^* c_j^*}{c_i^* n_j^*} \tag{16-46}$$

For a binary system, $r = \alpha_{BA} = 1/\alpha_{AB}$. The symbol $r$ applies primarily to the process, while $\alpha$ is oriented toward interactions between pairs of solute species. For each binary pair, $r_{ij} = \alpha_{ji} = 1/\alpha_{ij}$.

Equilibrium then is given explicitly by

$$n_i^* = \frac{c_i^*}{\sum_j \alpha_{ji} c_j^*} = \frac{\alpha_{iN} c_i^*}{\sum_j \alpha_{jN} c_j^*} \tag{16-47}$$

and

$$c_i^* = \frac{n_i^*}{\sum_j \alpha_{ij} n_j^*} = \frac{\alpha_{Ni} n_i^*}{\sum_j \alpha_{Nj} n_j^*} \tag{16-48}$$

For the constant separation factor case, the $c^*$ contours in a plot like Fig. 16-8 are linear.

# CONSERVATION EQUATIONS

Material balances, often an energy balance, and occasionally a momentum balance are needed to describe an adsorption process. These are written in various forms depending on the specific application and the desire for simplicity or rigor. Reasonably general material balances for various processes are given next. An energy balance is developed for a fixed bed for gas-phase application and simplified for liquid-phase application. Momentum balances for pressure drop in packed beds are given in Sec. 6.

## MATERIAL BALANCES

At the nanoscale, a sorbable component exists at three locations—in a sorbed phase, in pore fluid, and in fluid outside particles. As a consequence, in material balances, time derivatives must include terms involving $n_i$, $c_{pi}$ (the pore concentration), and $c_i$ (the extraparticle concentration). Let $\overline{n}_i$ represent $n_i$ averaged over particle volume, and let $\overline{c}_{pi}$ represent $c_{pi}$ averaged over pore fluid volume.

For batch or stirred tank processes, in terms of the mass of adsorbent $M_s$ (kg), extraparticle volume of fluid $V_f$ ($m^3$), and volumetric flow rates $F_v$ ($m^3$/s) in and out of a tank, the material balance on component $i$ is

$$M_s \frac{d\hat{n}_i}{dt} + \frac{d(V_f c_i)}{dt} = F_{\text{v,in}}\, c_{\text{in},i} - F_{\text{v,out}}\, c_i \tag{16-49}$$

with

$$\hat{n}_i = \overline{n}_i + (\varepsilon_p/\rho_p)\overline{c}_{pi} = \overline{n}_i + [(1-\varepsilon)\varepsilon_p/\rho_b]\,\overline{c}_{pi} \tag{16-50}$$

where $\rho_p$ and $\rho_b$ are particle and bulk densities, and $\varepsilon$ and $\varepsilon_p$ are void fraction (extraparticle volume fraction) and particle porosity, respectively.

For a fixed-bed process, the material balance for component $i$ is

$$\rho_b \frac{\partial \hat{n}_i}{\partial t} + \varepsilon \frac{\partial c_i}{\partial t} + \varepsilon \frac{\partial (v c_i)}{\partial z} = \varepsilon D_L \frac{\partial}{\partial z}\left( c \frac{\partial y_i}{\partial z} \right) \tag{16-51}$$

where $v$ is interstitial fluid velocity, $D_L$ is a Fickian axial dispersion coefficient, and $y_i = c_i/c$ is the fluid-phase mole fraction of component $i$. $v$ is related to the superficial velocity $u$ by $v = u/\varepsilon$, where $u$ is equal to the volumetric flow rate divided by the cross-sectional area of the fixed bed. In certain applications, the group $\rho_b \hat{n}_i$ in the first term of Eq. (16-51) is replaced by $(1-\varepsilon)\hat{n}_i$, where $\hat{n}_i$ has units of mol/($m^3$ of adsorbent). An alternative form, grouping together fluid-phase concentrations rather than intraparticle concentrations, is

$$\rho_b \frac{\partial \overline{n}_i}{\partial t} + \varepsilon_b \frac{\partial \hat{c}_i}{\partial t} + \varepsilon \frac{\partial (v c_i)}{\partial z} = \varepsilon D_L \frac{\partial}{\partial z}\left( c \frac{\partial y_i}{\partial z} \right) \tag{16-52}$$

where, noting Eq. (16-4), $\hat{c}_i$ is defined by

$$\varepsilon_b \hat{c}_i = \varepsilon c_i + (1-\varepsilon)\varepsilon_p \overline{c}_{pi} \tag{16-53}$$

For moving-bed processes, a term is added to Eq. (16-51) to obtain

$$\rho_b \left[ \frac{\partial \hat{n}_i}{\partial t} + v_s \frac{\partial \hat{n}_i}{\partial z} \right] + \varepsilon \left[ \frac{\partial c_i}{\partial t} + \frac{\partial (v c_i)}{\partial z} - D_L \frac{\partial}{\partial z}\left( c \frac{\partial y_i}{\partial z} \right) \right] = 0 \tag{16-54}$$

where $v_s$ is the solid-phase velocity (opposite in sign to $v$ for a countercurrent process).

## ENERGY BALANCE

Many different forms of the energy balance have been used in fixed-bed adsorption studies. The form chosen for a particular study depends on the process considered (e.g., temperature-swing adsorption or pressure-swing adsorption) and on the degree of approximation that is appropriate [see Walton and LeVan, *Ind. Eng. Chem. Res.* **42:** 6938 (2003); **44:** 7474 (2005)].

An energy balance for a fixed-bed process, ignoring dispersion, is

$$\rho_b \frac{\partial u_s}{\partial t} + \frac{\partial (\varepsilon_b \hat{c} u_f)}{\partial t} + \frac{\partial (\varepsilon v c h_f)}{\partial z} = -\frac{2h_w (T - T_w)}{T_c} \tag{16-55}$$

where $h_w$ is a heat transfer coefficient for energy transfer with the column wall and $r_c$ is the radius of the column. The second term of Eq. (16-55) combines contributions from both pore and extraparticle fluid.

Thermodynamic paths are necessary to evaluate the enthalpy (or internal energy) of the fluid phase and the internal energy of the stationary phase. For gas-phase processes at low and modest pressures, the enthalpy departure function for pressure changes can be ignored and a reference state for each pure component chosen to be ideal gas at temperature $T^{\text{ref}}$, and a reference state for the stationary phase (adsorbent plus adsorbate) chosen to be adsorbate-free solid at $T^{\text{ref}}$. Thus, for the gas phase

$$h_f = \sum_t y_i h_{fi} = \sum_t y_i \left[ h_{fi}^{\text{ref}} + \int_{T^{\text{ref}}}^{T} C_{pfi}^{\circ}\, dT \right] \tag{16-56}$$

$$u_f = h_f - P/c \tag{16-57}$$

and for the stationary phase

$$u_s = u_{\text{sol}} + n u_a \approx u_{\text{sol}} + n h_a \tag{16-58}$$

$$u_{\text{sol}} = u_{\text{sol}}^{\text{ref}} + \int_{T^{\text{ref}}}^{T} C_s\, dT \tag{16-59}$$

The enthalpy of the adsorbed phase $h_a$ is evaluated along a path for which the gas-phase components undergo temperature change from $T_{\text{ref}}$ to $T$ and then are adsorbed isothermally, giving

$$h_a = \sum_i x_i h_{fi} - \left( \frac{1}{n} \right) \sum_i \int_0^{n_i} q_i^{st}(n_i, n_j, T)\, dn_i \tag{16-60}$$

The isosteric heat of adsorption $q_i^{st}$ is composition-dependent, and the sum of integrals in Eq. (16-60) is difficult to evaluate for multicomponent adsorption if the isosteric heats indeed depend on loading. Because each isosteric heat depends on the loadings of all components, the sum must be evaluated

for a path beginning with clean adsorbent and ending with the proper loadings of all components. If the isosteric heat of adsorption is constant, as is commonly assumed, then the energy balance [Eq. (16-55)] becomes

$$\left[\rho_b\left(C_s+\sum_i n_i C_{pfi}^{\circ}\right)+\varepsilon_b c C_{pf}^{\circ}\right]\frac{\partial T}{\partial t}-\rho_b\sum_i q_i^{st}\frac{\partial n_i}{\partial t}-\frac{\partial(\varepsilon_b P)}{\partial t}+\varepsilon v C_{pf}^{\circ}\frac{\partial T}{\partial z}=-\frac{2h_w(T-T_w)}{r_c} \tag{16-61}$$

where Eq. (16-52) with $D_L = 0$ has been used. Equation (16-61) is a popular form of the energy balance for fixed-bed adsorption calculations. Often the first summation on the left-hand side, which involves gas-phase heat capacities, is neglected, or the gas-phase heat capacities are replaced by adsorbed-phase heat capacities. It is also possible to estimate the adsorbed-phase heat capacities from thermodynamic paths given gas-phase heat capacities and temperature-dependent adsorption equilibrium [Walton and LeVan, *Ind. Eng. Chem. Res.* **44:** 178 (2005)].

Nonisothermal liquid-phase processes may be driven by changes in feed temperature or heat addition or withdrawal through a column wall. For these, heats of adsorption and pressure effects are generally of less concern. For this case, a suitable energy balance is

$$\left(\rho_b C_s+\varepsilon_b c C_{pf}^{\circ}\right)\frac{\partial T}{\partial t}+\varepsilon v C_{pf}^{\circ}\frac{\partial T}{\partial z}=-\frac{2h_w(T-T_w)}{r_c} \tag{16-62}$$

# RATE AND DISPERSION FACTORS

The performance of adsorption processes results in general from the combined effects of equilibrium or thermodynamic factors and rate factors. It is convenient to consider first *thermodynamic factors*. These determine the process performance in a limit where the system behaves ideally, that is, without mass transfer and kinetic limitations and with the fluid phase in perfect plug flow. *Rate factors* determine the efficiency of the real process in relation to the ideal process performance. Rate factors include heat- and mass-transfer limitations, reaction kinetic limitations, and hydrodynamic dispersion resulting from the velocity distribution across the bed and from mixing and diffusion in the interparticle void space.

## TRANSPORT AND DISPERSION MECHANISMS

Figure 16-9 depicts porous adsorbent particles in an adsorption bed with sufficient generality to illustrate the nature and location of individual transport and dispersion mechanisms. Each mechanism involves a different driving force and, in general, gives rise to a different form of mathematical result.

**Intraparticle Transport Mechanisms** Intraparticle transport may be limited by *pore diffusion, solid diffusion, reaction kinetics*, or by two or more of these mechanisms together.

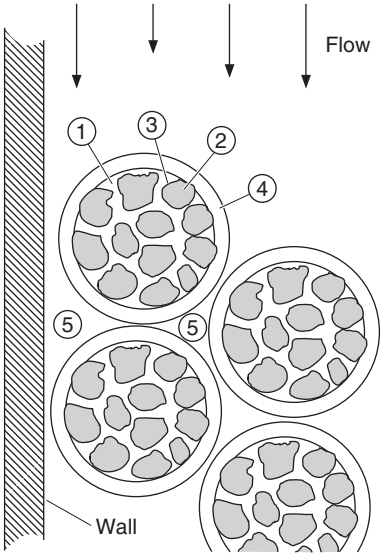

**FIG. 16-9** General scheme of adsorbent particles in a packed bed showing the locations of mass transfer and dispersive mechanisms. Numerals correspond to numbered paragraphs in the text: 1, pore diffusion; 2, solid diffusion; 3, reaction kinetics at phase boundary; 4, external mass transfer; 5, fluid mixing.

1. *Pore diffusion* denotes transport in fluid-filled pores sufficiently large that the adsorbing molecules escape the force field of the adsorbent surface. Thus, this process is often referred to as *macropore diffusion.* The driving force for such a diffusion process can be approximated by the gradient in mole fraction or, if the molar concentration is constant, by the gradient in concentration of the diffusing species within the pores.

2. *Solid diffusion* denotes transport in the adsorbed phase for conditions where the diffusing molecules never escape the force field of the adsorbent surface. Solid diffusion may occur along a surface by an activated process involving jumps between adsorption sites, which is referred to as *surface diffusion*, in small pores, such as in activated carbon, which is referred to as *micropore diffusion* or *nanopore diffusion,* within a crystal, as in the case of zeolites, which is referred to as *intracrystalline diffusion*, or in gel-type ion-exchange resins, which is referred to as *gel* or *homogenous diffusion.* The common feature is that, in general, the driving force for solid diffusion can be approximated by the gradient in concentration of the species in the adsorbed state.

3. *Reaction kinetics* denotes a kinetic resistance to binding at a fluid–adsorbent interface or on a functional ligand. Rates of adsorption and desorption in porous adsorbents are generally controlled by mass transfer within the pore network rather than by the kinetics of sorption at the fluid–solid interface. Exceptions are the cases of chemisorption and affinity-adsorption systems used for biological separations, where the kinetics of bond formation can be exceedingly slow.

Intraparticle convection can also occur in packed beds when the adsorbent particles have very large and well-connected pores. Although, in general, bulk flow through the pores of the adsorbent particles is only a small fraction of the total flow, intraparticle convection can affect the transport of very slowly diffusing species such as macromolecules. The driving force for convection, in this case, is the pressure drop across each particle that is generated by the frictional resistance to flow experienced by the fluid as this flows through the packed bed [Rodrigues et al., *Chem. Eng. Sci.* **46:** 2765 (1991); Carta et al., *Sep. Technol.* **2:** 62 (1992); Frey et al., *Biotechnol. Progr.* **9:** 273 (1993); Liapis and McCoy, *J. Chromatogr.* **599:** 87 (1992)]. Intraparticle convection can also be significant when there is a total pressure difference between the center of the particle and the outside, such as is experienced in pressurization and depressurization steps of pressure-swing adsorption or when more gas is drawn into an adsorbent to equalize pressure as adsorption occurs from the gas phase within a porous particle [Lu et al., *AIChE J.* **38:** 857 (1992); Lu et al., *Gas Sep. Purif.* **6:** 89 (1992); Taqvi et al., *Adsorption* **3:** 127 (1997)].

**Extraparticle Transport and Dispersion Mechanisms** Extraparticle mechanisms are affected by the design of the contacting device and depend on the hydrodynamic conditions outside the particles.

4. *External mass transfer* denotes transport in the boundary layer at the external surfaces of the adsorbent particles. The driving force is the concentration difference across the boundary layer, which, in turn, is affected by the hydrodynamic conditions outside the particles.

5. *Dispersion* denotes mixing or lack of mixing in the fluid phase surrounding the adsorbent particles. Examples include the existence of a radial velocity distribution or dead zones in a packed bed column, diffusion in the extraparticle fluid, or inefficient mixing in an agitated contactor. In packed-bed adsorbers, dispersion is often described in terms of an *axial dispersion coefficient* whereby all mechanisms contributing to dispersion in the fluid phase are lumped together in a single effective coefficient.

**Heat Transfer** Since adsorption is generally accompanied by the evolution of heat, the rate of heat transfer between the adsorbent particles and the fluid phase may be important. In addition, heat transfer can occur across the column wall in small-diameter beds and is important in energy applications of adsorption. In gas adsorption systems, even with highly porous particles, the controlling heat transfer resistance is generally associated with extraparticle transport [Lee and Ruthven, *Can. J. Chem. Eng.* **57:** 65 (1979)], so the temperature within the particles is essentially uniform. In liquid-phase adsorption, intraparticle and extraparticle heat transfer resistances are generally comparable. However, in this case the heat capacity of the fluid phase is sufficiently high that temperature effects may be negligible except in extreme cases. General discussions of heat-transfer effects in adsorbents and adsorption beds are found in Suzuki (1990), pp. 187–208 and pp. 275–290, and in Ruthven (1984), pp. 189–198 and pp. 215–219 in General References.

## INTRAPARTICLE MASS TRANSFER

Diffusional mass transfer in adsorption systems can be described phenomenologically in terms of Fick's first law:

$$J_i = -D_i(c_i)\frac{\partial c_i}{\partial x} \tag{16-63}$$

This expression can be used to describe both pore and solid diffusion so long as the driving force is expressed in terms of the appropriate concentrations. Although the driving force should be more correctly expressed in terms of chemical potentials, Eq. (16-63) provides a qualitatively and quantitatively correct representation of adsorption systems so long as the diffusivity is allowed to be a function of the adsorbate concentration. The diffusivity will be constant only for a limited number of adsorption systems.

**Pore Diffusion** When transport occurs through a network of fluid-filled pores inside the particles, the diffusion flux can be expressed in terms of a pore diffusion coefficient $D_{pi}$ as:

$$J_i = -\varepsilon_p D_{pi}\frac{\partial c_{pi}}{\partial r} \tag{16-64}$$

$D_{pi}$ is smaller than the molecular diffusivity $D_i$ as a result of the random orientation of the pores, which gives a longer diffusion path, and the variation in the pore diameter. Both effects are commonly accounted for by a tortuosity factor $\tau_p$ such that $D_{pi} = D_i/\tau_p$. In principle, predictions of the tortuosity factor can be made if the pore structure, pore size, and shape distributions are known (see Dullien, *Porous Media: Fluid Transport and Pore Structure,* Academic Press, New York, 1979). In some cases, approximate prediction can be obtained from the following equations.

Mackie and Meares, *Proc. Roy. Soc.* **A232:** 498 (1955):

$$\tau_p = (2-\varepsilon_p)^2/\varepsilon_p \tag{16-65a}$$

Wakao and Smith, *Chem. Eng. Sci.* **17:** 825 (1962):

$$\tau_p = 1/\varepsilon_p \tag{16-65b}$$

Suzuki and Smith, *Chem. Eng. J.* **3:** 256 (1972):

$$\tau_p = \varepsilon_p + 1.5(1-\varepsilon_p) \tag{16-65c}$$

The predictive value of these equations is limited, and vastly different results are obtained from each. All of them, on the other hand, predict that $\tau_p$ increases as the porosity decreases.

For catalyst particles, Satterfield (*Heterogeneous Catalysis in Practice,* McGraw-Hill, 1980) recommends the use of a value of $\tau_p = 4$ when no other information is available, and this can be used for many adsorbents. In general, however, it is more reliable to treat the tortuosity as an empirical constant that is determined experimentally for any particular adsorbent.

For adsorbent materials, experimental tortuosity factors generally fall in the range 2–6 and generally decrease as the particle porosity is increased. Higher apparent values may be obtained when transport is affected by other resistances, while values much lower than 2 generally indicate that solid diffusion either occurs in parallel or controls the process.

Ruthven (1984) summarizes methods for the measurement of effective pore diffusivities that can be used to obtain tortuosity factors by comparison with the estimated pore diffusion coefficient of the adsorbate. Molecular diffusivities can be estimated with the methods in Sec. 6.

For gas-phase diffusion in small pores at low pressure, the molecular mean free path may be larger than the pore diameter, giving rise to Knudsen diffusion. Satterfield (*Mass Transfer in Heterogeneous Catalysis,* MIT, Cambridge, MA, 1970, p. 43) gives the following expression for the pore diffusivity:

$$D_{pi} = \frac{1}{\tau_p}\left[\frac{3}{4r_{\text{pore}}}\left(\frac{\pi M_{ri}}{2\Re T}\right)^{1/2} + \frac{1}{D_i}\right]^{-1} \tag{16-66}$$

where $r_{\text{pore}}$ is the average pore radius, $T$ the absolute temperature, and $M_{ri}$ the molecular weight.

For liquid-phase diffusion of large adsorbate molecules, when the ratio $\lambda_m = r_m/r_{\text{pore}}$ of the molecule radius $r_m$ to the pore radius is significantly greater than zero, the pore diffusivity is reduced by steric interactions with the pore wall and hydrodynamic resistance. When $\lambda_m < 0.2$, the following expressions derived by Brenner and Gaydos [*J. Coll. Int. Sci.* **58:** 312 (1977)] for a hard sphere molecule diffusing in a long cylindrical pore can be used

$$D_{pi} = \frac{D_i}{\tau_p}(1-\lambda_m)^{-2}\left[1+\frac{9}{8}\lambda_m \ln \lambda_m - 1.539\lambda_m\right] \tag{16-67}$$

$r_m$ is the Stokes-Einstein radius of the solute that can be determined from the free diffusivity as

$$r_m = \frac{\kappa T}{6\pi\mu D_i} \tag{16-68}$$

where $\kappa$ is the Boltzmann constant. When $\lambda_m > 0.2$, the centerline approximation [Anderson and Quinn, *Biophys. J.* **14:** 130, (1974)] can be used instead of Eq. (16-67)

$$D_{pi} = \frac{D_i}{\tau_p}(1-2.1044\lambda_m + 2.089\lambda_m^3 - 0.984\lambda_m^5)\times 0.865 \tag{16-69}$$

The 0.865 factor is used to match this equation to the Brenner and Gaydos expression for $\lambda_m = 0.2$. In these cases, the pore concentration $c_{pi}$ is related to the external concentration $c_i$ by the partition ratio $(1-\lambda_m)^2$.

**Solid Diffusion** In the case of pore diffusion just discussed, transport occurs within the fluid phase contained inside the particle; here the solute concentration is generally similar in magnitude to the external fluid concentration. A solute molecule transported by pore diffusion may attach to the sorbent and detach many times along its path. In other cases, attachment can be essentially permanent, but in both cases, only detached molecules undergo transport. In contrast, the following four instances illustrate cases where diffusion of adsorbate molecules occurs in their adsorbed state within phases that are distinct from the pore fluid:

1. Movement of mobile adsorbed solute molecules along pore surfaces, without detaching
2. Transport in a homogeneously dissolved state, as for a neutral molecule inside a sorbent gel or in a pore filled with a liquid that is immiscible with the external fluid
3. Ion transport in charged ion-exchange resins
4. Advance of an adsorbate molecule from one cage to another within a zeolite crystal

In these cases, the diffusion flux may be written in terms of the adsorbed solute concentration as

$$J_i = -\rho_p D_{si}\frac{\partial n_i}{\partial r} \tag{16-70}$$

The diffusion coefficient in these phases $D_{si}$ is usually considerably smaller than that in fluid-filled pores; however, the adsorbate concentration is often much larger. Thus, the diffusion rate can be smaller or larger than can be expected for pore diffusion, depending on the magnitude of the fluid/solid partition coefficient.

Numerical values for solid diffusivities $D_{si}$ in adsorbents are sparse and vary greatly. Moreover, they may be strongly dependent on the adsorbed phase concentration of solute. Hence, locally conducted experiments and interpretation must be used to a great extent. Summaries of available data for surface diffusivities in activated carbon and other adsorbent materials and for micropore diffusivities in zeolites are given in Ruthven (1984), Yang (1987), Suzuki (1990), and Karger and Ruthven (1992); see General References.

Surface diffusivities are generally strongly dependent on the fractional surface coverage and increase rapidly at surface coverage greater than 80 percent [see, for example, Yang et al., *AIChE J.* **19:** 1052 (1973)]. For estimation purposes, the correlation of Sladek et al. [*Ind. Eng. Chem. Fundam.* **13:** 100 (1974)] can be used to predict surface diffusivities for gas-phase adsorption on a variety of adsorbents.

Zeolite crystallite diffusivities for sorbed gases range from $10^{-7}$ to $10^{-14}$ cm$^2$/s. These diffusivities generally show a strong increase with the adsorbate concentration that is accounted for by the Darken thermodynamic correction factor

$$D_{si} = D_{0i}\frac{d\ln a_i}{d\ln n_i} = D_{0i}\frac{n_i/p_i}{dn_i/dp_i} \tag{16-71}$$

where $D_{0i}$ is the corrected diffusivity and $a_i$ is the thermodynamic activity of the species in the adsorbed phase. Corrected diffusivities $D_{0i}$ calculated according to this equation are often found to be essentially independent of concentration. If the adsorption equilibrium isotherm obeys the Langmuir equation [Eq. (16-12)], Eq. (16-71) yields:

$$D_{si} = D_{0i}\left(1-\frac{n_i}{n_i^s}\right)^{-1} \tag{16-72}$$

The effect of temperature on diffusivities in zeolite crystals can be expressed in terms of the Eyring equation [see Ruthven (1984) in General References).

In ion-exchange resins, diffusion is further complicated by electrical coupling effects. In a system with $M$ counterions, diffusion rates are described by the Nernst-Planck equations [Helfferich (1962) in General References]. Assuming complete Donnan exclusion, these equations can be written as:

$$J_i = -\rho_p\frac{1}{z_i}\sum_{j=1}^{M-1}\bar{D}_{i,j}\frac{\partial z_j n_j}{\partial r} \tag{16-73}$$

with

$$\bar{D}_{i,j} = -\frac{\bar{D}_i(\bar{D}_j-\bar{D}_M)z_i^2 n_i}{\sum_{k=1}^{M}\bar{D}_k z_k^2 n_k} \tag{16-74a}$$

$$\bar{D}_{i,i} = \bar{D}_i - \frac{\bar{D}_i(\bar{D}_i-\bar{D}_M)z_i^2 n_i}{\sum_{k=1}^{M}\bar{D}_k z_k^2 n_k} \tag{16-74b}$$

which are dependent on the *ionic self diffusivities* $\bar{D}_i$ of the individual species. As a qualitative rule, ionic diffusivities of inorganic species in cross-linked polystyrene-DVB ion-exchange resins compared with those in water are 1:10 for monovalent ions, 1:100 for divalent ions, and 1:1000 for trivalent ions. Table 16-8 shows typical ionic diffusivities of inorganic ions in cation and anion-exchange resins; larger organic ions, however, can have ionic diffusivities much smaller than inorganic ions of the same valence [see, for example, Jones and Carta, *Ind. Eng. Chem. Res.* **32:** 117 (1993)].

For mixtures of unlike ions (the usual case), the apparent diffusivity will be intermediate between these values because of the electrical coupling effect. For a system with two counterions $A$ and $B$, with charge $z_A$ and $z_B$, Eqs. (16-73) and (16-74) reduce to:

$$J_A = -\rho_p\bar{D}_{A,B}\frac{\partial n_A}{\partial r} = -\rho_p\frac{\bar{D}_A\bar{D}_B\left[z_A^2 n_A + z_B^2 n_B\right]}{z_A^2\bar{D}_A n_A + z_B^2\bar{D}_B n_B}\frac{\partial n_A}{\partial r} \tag{16-75}$$

which shows that the apparent diffusivity $\bar{D}_{A,B}$ varies between $\bar{D}_A$ when the ionic fraction of species $A$ in the resin is very small and $\bar{D}_B$ when the ionic fraction of $A$ in the resin approaches unity, indicating that the ion present in smaller concentration has the stronger effect on the local interdiffusion rate.

**Combined Pore and Solid Diffusion** In porous adsorbents and ion-exchange resins, intraparticle transport can occur with pore and solid diffusion in parallel. The dominant transport process is the faster one, and this depends on the relative diffusivities and concentration gradients in the pore fluid and in the adsorbed phase. Often, equilibrium between the pore fluid and the solid phase can be assumed to exist locally at each point within a particle. In this case, the mass-transfer flux is expressed in terms of an apparent diffusivity $D_{\text{app},i}$ by:

$$J_i = -\left[\varepsilon_p D_{pi} + \rho_p D_{si}\frac{dn_i^e}{dc_i}\right]\frac{\partial c_{pi}}{\partial r} = -D_{\text{app},i}(c_{pi})\frac{\partial c_{pi}}{\partial r} \tag{16-76}$$

where $dn_i^e/dc_i$ is the derivative of the adsorption isotherm and it has been assumed that at equilibrium $c_{pi} = c_i$. This equation suggests that in such an adsorbent, pore and solid diffusivities can be obtained by determining the apparent diffusivity $D_{\text{app},i}$ for conditions of no adsorption ($dn_i^e/dc_i = 0$) and for conditions of strong adsorption, where $dn_i^e/dc_i$ is large. If the adsorption isotherm is linear over the range of experimental measurement, then

$$D_{\text{app},i} = \varepsilon_p D_{pi} + \rho_p K_i D_{si} \tag{16-77}$$

Thus, a plot of the apparent diffusivity versus the linear adsorption equilibrium constant $K_i$ should be linear so long as $D_{pi}$ and $D_{si}$ remain constant.

In a particle having a *bidispersed pore structure* comprising spherical adsorptive subparticles of radius $r_s$ forming a macroporous aggregate, separate flux equations can be written for the macroporous network in terms of Eq. (16-64) and for the subparticles themselves in terms of Eq. (16-70) if solid diffusion occurs.

## EXTERNAL MASS TRANSFER

Because of the complexities encountered with a rigorous treatment of the hydrodynamics around particles in practical solid-fluid systems, mass transfer to and from the adsorbent is described in terms of a mass-transfer coefficient $k_f$. The flux at the particle surface is:

$$J_i = k_f(c_i - c_i^s) \tag{16-78}$$

where $c_i$ and $c_i^s$ are the solute concentrations in the bulk fluid and at the particle surface, respectively. $k_f$ can be estimated from available correlations

in terms of the Sherwood number $Sh = k_f d_p/D_i$, the Reynolds number, $Re = \varepsilon v \rho_f d_p/\mu$, and the Schmidt number $Sc = \mu/\rho_f D_i$. For packed-bed operations, the correlations in Table 16-9 are recommended. A plot of these equations is given in Fig. 16-10 for representative ranges of Re and Sc with $\varepsilon = 0.4$.

External mass-transfer coefficients for particles suspended in agitated contactors can be estimated from equations in Levins and Glastonbury [*Trans. Instn. Chem. Eng.* **50:** 132 (1972)] and Armenante and Kirwan [*Chem. Eng. Sci.* **44:** 2871 (1989)].

## AXIAL DISPERSION IN PACKED BEDS

The axial dispersion coefficient in a packed bed [cf. Eq. (16-51)] lumps together all mechanisms leading to dispersion in the fluid phase, including molecular diffusion, convective mixing, and nonuniformities in the fluid velocity across the packed bed. As such, the axial dispersion coefficient is best determined experimentally for each specific system.

The effects of *flow nonuniformities*, in particular, can be severe in gas systems when the ratio of bed-to-particle diameters is small; in liquid systems when viscous fingering occurs as a result of large viscosity gradients in the adsorption bed; when very small particles (<10 μm) are used, such as in high-performance liquid chromatography systems; and in large-diameter beds. A lower bound of the axial dispersion coefficient can be estimated for well-packed beds from correlations that follow.

Neglecting flow nonuniformities, the contributions of molecular diffusion and turbulent mixing arising from stream splitting and recombination around the sorbent particles can be considered additive [Langer et al., *Int. J. Heat Mass Trans.* **21:** 751 (1978)]; thus, the axial dispersion coefficient $D_L$ can be expressed as:

$$\frac{D_L}{D_i} = \gamma_1 + \gamma_2 \frac{d_p v}{D_i} = \gamma_1 + \gamma_2 \frac{ReSc}{\varepsilon} \tag{16-79}$$

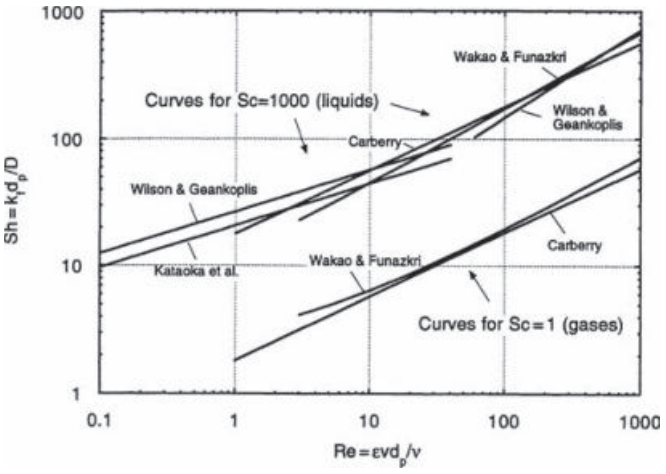

**FIG. 16-10** Sherwood number correlations for external mass-transfer coefficients in packed beds for $\varepsilon = 0.4$. [*Adapted from Suzuki (1990) in General References.*]

or, in terms of a particle-based Peclet number ($Pe = d_p v/D_L$), as:

$$\frac{1}{Pe} = \frac{\gamma_1 \varepsilon}{ReSc} + \gamma_2 \tag{16-80}$$

The first term in Eqs. (16-79) and (16-80) accounts for molecular diffusion, and the second term accounts for mixing. For the first term, Wicke [*Ber. Bunsenges* **77:** 160 (1973)] has suggested:

$$\gamma_1 = 0.45 + 0.55\varepsilon \tag{16-81}$$

which, for typical void fractions, $\varepsilon = 0.35 - 0.45$ gives $\gamma_1 = 0.64 - 0.70$ [Ruthven (1984) in General References]. Expressions for the axial mixing term $\gamma_2$ in Eq. (16-79) are given in Table 16-10. The expression of Wakao and Funazkri includes an axial diffusion term, $\gamma_1$, that varies from 0.7 for nonporous particles to $20/\varepsilon$, depending on the intraparticle mass-transfer mechanism. For strongly adsorbed species, Wakao and Funazkri suggest that the effective axial dispersion coefficient is much larger than that predicted on the basis of nonporous, nonadsorbing particles. The Gunn expression includes a term $\sigma_v^2$ accounting for deviations from plug flow, which is defined as the dimensionless variance of the distribution of the ratio of velocity to average velocity over the cross section of the bed. The parameter values included in this equation are valid for spherical particles. Values for nonspherical particles can be found in the original reference.

Figure 16-11 compares predicted values of $D_L/D_i$ for $\sigma_v = 0$ and $\varepsilon = 0.4$ with Sc = 1 (gases at low pressure), and Sc = 1000 (small molecules in liquids), based on the equations in Table 16-10.

Correlations for axial dispersion in beds packed with very small particles (<10 μm) that take into account the holdup of liquid in the bed are discussed by Horvath and Lin [*J. Chromatogr.* **126:** 401 (1976)].

## RATE EQUATIONS

Rate equations are used to describe interphase mass transfer in batch systems, packed beds, and other contacting devices for sorptive processes and are formulated in terms of fundamental transport properties of adsorbent and adsorbate.

**General Component Balance** For a spherical adsorbent particle:

$$\varepsilon_p \frac{\partial c_{pi}}{\partial t} + \rho_p \frac{\partial n_i}{\partial t} = \frac{1}{r^2} \frac{\partial}{\partial r}(-r^2 N_i) \tag{16-82}$$

For particles that have no macropores, such as gel-type ion-exchange resins, or when the adsorption capacity is high, the first term on the left side of this equation, representing solute hold up in the pore fluid, may be neglected. Ignoring bulk flow terms, the fluxes $N_i$ and $J_i$ are equal. In this case, coupling the component balance with the flux expressions previously introduced gives the rate equations in Table 16-11. Typical boundary conditions are also included in this table. Generally, these equations apply to particles that can be approximated as spherical and of a uniform size and properties. An appropriately chosen mean particle size must be used in these equations when dealing with adsorbents having a broad particle size distribution. The appropriate average depends on the controlling mass-transfer mechanism. For intraparticle mass-transfer mechanisms, the volume or mass-average particle size usually provides the best prediction.

**TABLE 16-10 Coefficients for Axial Dispersion Correlations in Packed Beds Based on Eq. (16-79)**

**TABLE 16-11 Rate Equations for Description of Mass Transfer in Spherical Adsorbent Particles**

| Mechanism | Flux equation | Rate equation |
|---|---|---|
| A. Pore diffusion | 16-64 | $\varepsilon_p\frac{\partial c_{pi}}{\partial t}+\rho_p\frac{\partial n_i}{\partial t}=\frac{1}{r^2}\frac{\partial}{\partial r}\left(\varepsilon_p D_{pi} r^2\frac{\partial c_{pi}}{\partial r}\right)$<br>$(\partial c_{pi}/\partial r)_{r=0}=0,\ (\varepsilon_p D_{pi}\partial c_{pi}/\partial r)_{r=r_p}=k_f(c_i-c_{pi\mid r=r_p})$<br>or $(c_{pi})_{r=r_p}=c_i$ for no external resistance |
| B. Solid diffusion | 16-70 | $\frac{\partial n_i}{\partial t}=\frac{1}{r^2}\frac{\partial}{\partial r}\left(D_{si} r^2\frac{\partial n_i}{\partial t}\right)$<br>$(\partial n_i/\partial r)_{r=0}=0,\ (\rho_p D_{si}\partial n_i/\partial r)_{r=r_p}=k_f(c_i-c_i^e)$<br>or $(n_i)_{r=r_p}=n_i^e(c_i)$ for no external resistance |
| C. Parallel pore and solid diffusion<br>(local equilibrium between pore and adsorbed phase) | 16-76 | $\left(\varepsilon_p+\rho_p\frac{dn_i^e}{dc_i}\right)\frac{\partial c_{pi}}{\partial t}=\frac{1}{r^2}\frac{\partial}{\partial r}\left[r^2\left(\varepsilon_p D_{pi}+\rho_p D_{si}\frac{dn_i^e}{dc_i}\right)\frac{\partial c_{pi}}{\partial r}\right]$<br>$(\partial c_{pi}/\partial r)_{r=0}=0,\ [(\varepsilon_p D_{pi}+\rho_p D_{si} dn_i^e/dc_i)\partial c_{pi}/\partial r]_{r=r_p}=k_f(c_i-c_{pi\mid r=r_p})$<br>or $(c_{pi})_{r=r_p}=c_i$ for no external resistance |
| D. Diffusion in bidispersed particles<br>(no external resistance) | 16-64 and 16-70 | $\frac{\partial n_i}{\partial t}=\frac{1}{\rho^2}\frac{\partial}{\partial\rho}\left(D_{si}\rho^2\frac{\partial n_i}{\partial\rho}\right),\ (\partial n_i/\partial\rho)_{\rho=0}=0,\ (n_i)_{\rho=r_s}=n_i^e(c_{pi})$<br>$\bar{n}_i(r,t)=\frac{3}{r_s^3}\int_0^{r_s}\rho^2 n_i\,d\rho$<br>$\varepsilon_p\frac{\partial c_{pi}}{\partial t}+\rho_p\frac{\partial\bar{n}_i}{\partial t}=\frac{1}{r^2}\frac{\partial}{\partial r}\left(\varepsilon_p D_{pi} r^2\frac{\partial c_{pi}}{\partial r}\right),\ (\partial c_{pi}/\partial r)_{r=0}=0,\ (c_{pi})_{r=r_p}=c_i$ |

**Linear Driving Force Approximation** Simplified expressions can also be used for an approximate description of adsorption in terms of rate coefficients for both extraparticle and intraparticle mass transfer controlling. As an approximation, the rate of adsorption on a particle can be written as:

$$\frac{\partial \hat{n}_i}{\partial t} = k\, f(n_i, c_i) \tag{16-83}$$

where $k$ is a rate coefficient, and the function $f(n_i, c_i)$ is a driving force relationship. The variables $k_c$ and $k_n$ are used to denote rate coefficients based on fluid-phase and adsorbed-phase concentration driving forces, respectively.

Commonly used forms of this rate equation are given in Table 16-12, where $\Lambda = \rho_b n_i^{\text{ref}}/c_i^{\text{ref}}$ is the partition ratio based on the feed concentration as a reference [cf. Eq. (16-125)]. For adsorption bed calculations with constant separation factor systems, somewhat improved predictions are obtained using correction factors $\psi_s$ and $\psi_p$ defined in Table 16-12.

The linear driving force (LDF) approximation is obtained when the driving force is expressed as a concentration difference. This approximation was originally developed to describe packed-bed dynamics under linear equilibrium conditions [Glueckauf, *Trans. Far. Soc.* **51:** 1540 (1955)]. This form is exact for a nonlinear isotherm only when external mass transfer is controlling. However, this expression can also be used for nonlinear systems with pore or solid diffusion mechanisms as an approximation, since it provides qualitatively correct results.

Alternate driving force approximations, item 2B in Table 16-12 for solid diffusion, and item 3B in Table 16-12 for pore diffusion, provide somewhat more accurate results in constant pattern packed-bed calculations with pore or solid diffusion controlling for constant separation factor systems.

The reaction kinetics approximation is mechanistically correct for systems where the reaction step at pore surfaces or other fluid-solid interfaces is controlling. This may occur in the case of chemisorption on porous catalysts and in affinity adsorbents that involve very slow binding steps. In these cases, the mass-transfer parameter $k$ is replaced by a second-order reaction rate constant $k_a$. The corresponding driving force for a constant separation factor isotherm is given in column 4 of Table 16-12. When diffusion controls the process, it is still possible to describe the system by its apparent second-order kinetic behavior, since it usually provides a good approximation to a more complex exact form for single-transition systems (see the subsection Fixed-Bed Transitions).

**Combined Intraparticle Resistances** When solid diffusion and pore diffusion operate in parallel, the effective rate is the sum of these two rates. When solid diffusion predominates, mass transfer can be represented approximately in terms of the LDF approximation, replacing $k_n$ in column 2 of Table 16-12 with

$$k_n^c = \frac{15\psi_s D_{si}}{r_p^2} + \frac{15(1-\varepsilon)\psi_p \varepsilon_p D_{pi}}{\Lambda r_p^2} \tag{16-84}$$

When pore diffusion predominates, use of column 3 in Table 16-12 is preferable, with $k_n^c$ replacing $k_n$.

For particles with a *bidispersed pore structure*, the mass-transfer parameter $k_n$ in the LDF approximation (column 2 in Table 16-12) can be approximated by the series-combination of resistances as:

$$\frac{1}{k_n^c} = \frac{1}{b_s}\left[\frac{\Lambda r_p^2}{15(1-\varepsilon)\psi_p \varepsilon_p D_{pi}} + \frac{r_s^2}{15\psi_s D_{si}}\right] \tag{16-85}$$

where $b_s$ is a correction to the driving force that is described next. In the limiting cases where the controlling resistance is diffusion through the particle pores or diffusion within the subparticles, the rate coefficients $k_n = 15(1-\varepsilon)\psi_p \varepsilon_p D_{pi}/\Lambda r_p^2$ and $k_n = 15\psi_s D_{si}/r_s^2$ are obtained.

**Overall Resistance** With a linear isotherm ($R = 1$), the overall mass transfer resistance is the sum of intraparticle and extraparticle resistances. Thus, the overall LDF coefficient for use with a particle-side driving force (column 2 in Table 16-12) is:

$$\frac{1}{k_n^o} = \frac{\Lambda r_p}{3(1-\varepsilon)k_f} + \frac{1}{k_n^c} \tag{16-86}$$

or

$$\frac{1}{k_c^o} = \frac{\rho_p r_p}{3(1-\varepsilon)k_f} + \frac{\rho_b}{\Lambda k_n^c} \tag{16-87}$$

for use with a fluid-phase driving force (column 1 in Table 16-12).

In either equation, $k_n^c$ is given by Eq. (16-84) for parallel pore and surface diffusion or by Eq. (16-85) for a bidispersed particle. For nearly linear isotherms ($0.7 < R < 1.5$), the same linear addition of resistance can be used as a good approximation to predict the adsorption behavior of packed beds, since solutions for all mechanisms are nearly identical. With a highly favorable isotherm ($R \to 0$), however, the rate at each point is controlled by the resistance that is locally greater, and the principle of additivity of resistances breaks down. For approximate calculations with intermediate values of $R$, an overall transport parameter for use with the LDF approximation can be

**TABLE 16-12 Expressions for Rate Coefficient *k* and Driving Force Relationships for Eq. (16-83)**

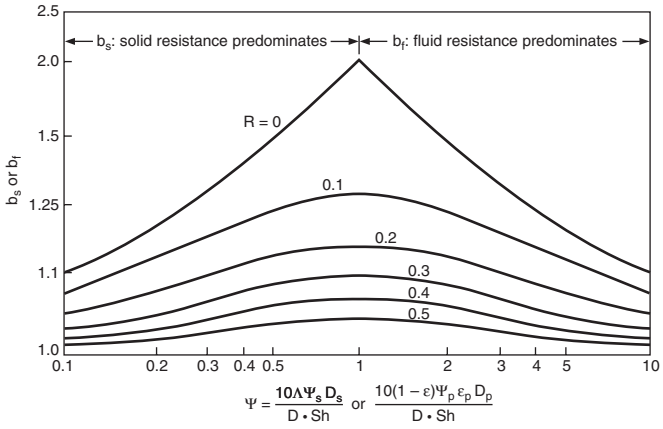

**FIG. 16-12** Correction factors for addition of mass-transfer resistances, relative to effective overall solid phase or fluid phase rates, as a function of the mechanism parameter. Each curve corresponds to both $b_s$ and $b_f$ over its entire range.

calculated from the following relationship for solid diffusion and film resistance in series:

$$\frac{\Lambda r_p}{3(1-\varepsilon)k_f}+\frac{r_p^2}{15\psi_s D_{si}}=\frac{b_s}{k_n^o}=\frac{b_f\Lambda}{\rho_b k_c^o} \tag{16-88}$$

$b_s$ and $b_f$ are correction factors that are given by Fig. 16-12 as a function of the separation factor $R$ and the mechanism parameter

$$\Psi=\frac{10\psi_s D_{si}\Lambda}{D_i}\frac{1}{\mathrm{Sh}} \tag{16-89}$$

**Axial Dispersion Effects** In adsorption bed calculations, axial dispersion effects are typically accounted for by the axial diffusion–like term in the bed conservation equations [Eqs. (16-51) and (16-52)]. For nearly linear isotherms ($0.5 < R < 1.5$), the combined effects of axial dispersion and mass-transfer resistances on the adsorption behavior of packed beds can be expressed approximately in terms of an apparent rate coefficient $k_c$ for use with a fluid-phase driving force (column 1, Table 16-12):

$$\frac{1}{k_c}=\frac{\rho_b}{\varepsilon}\frac{D_L}{v^2}+\frac{1}{k_c^o} \tag{16-90}$$

which extends the linear addition principle to combined axial dispersion and mass-transfer resistances. Even for a highly nonlinear isotherm (e.g., $R = 0.33$), the linear addition principle expressed by this equation provides a useful approximation except in the extreme case of low mass-transfer resistance and large axial dispersion, when $D_L\rho_p k_c^o/v^2\varepsilon >> 5$ [Garg and Ruthven, *Chem. Eng. Sci.* **30:** 1192 (1975)]. However, when the isotherm is irreversible ($R \to 0$), the linear addition principle breaks down, and axial dispersion has to be taken into account by explicit models (see the subsection Fixed-Bed Transitions).

**Rapid Adsorption-Desorption Cycles** For rapid cycles with particle diffusion controlling, when the cycle time $t_c$ is much smaller than the time constant for intraparticle transport, the LDF approximation becomes inaccurate. The generalized expression

$$\frac{\partial\hat{n}_i}{\partial t}=\Omega k_n(n_i^e-\bar{n}_i) \tag{16-91}$$

can be used for packed-bed calculations when the parameter $\Omega$ is defined to be a function of the cycle time such that the amount of solute adsorbed and desorbed during a cycle is equal to that obtained by solution of the complete particle diffusion equations. Graphical and analytical expressions for $\Omega$ in the case of a single particle, usable for very short beds, are given by Nakao and Suzuki [*J. Chem. Eng. Japan* **16:** 114 (1983)] and Carta [*Chem. Eng. Sci.* **48:** 622 (1993)]. With equal adsorption and desorption times, $t_a = t_d = t_c/2$, $\Omega$ approaches the value $\pi^2/15$ for long cycle times and the asymptote $\Omega = 1.877/\sqrt{t_c k_n}$ for short cycle times [Alpay and Scott, *Chem. Eng. Sci.* **47:** 499 (1992)]. However, other results by Raghavan et al. [*Chem. Eng. Sci.* **41:** 2787 (1986)] indicate that a limiting constant value of $\Omega$ (larger than 1) is obtained for very short cycles, when calculations are carried out for beds of finite length.

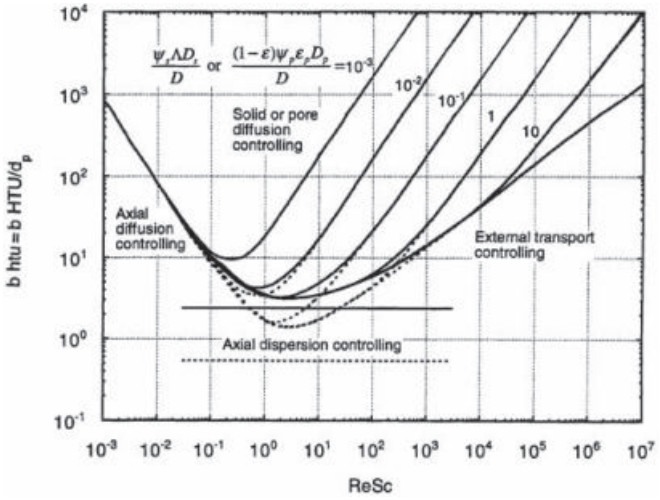

**FIG. 16-13** Effect of ReSc group, distribution ratio, and diffusivity ratio on height of a transfer unit. Dotted lines for gas and solid lines for liquid-phase systems.

**Determination of Controlling Rate Factor** The most important physical variables determining the controlling rate factor are particle size and structure, flow rate, fluid- and solid-phase diffusivities, partition ratio, and fluid viscosity. When multiple resistances and axial dispersion can potentially affect the rate, the spreading of a concentration wave in a fixed bed can be represented approximately in terms of the single LDF rate parameter $k$. In customary separation-process calculations, the height of an adsorption bed can be calculated approximately as the product of the number of transfer units times the height of one fluid-phase transfer unit (HTU). The HTU is related to the LDF rate parameters $k_c$ and $k_n$ by:

$$\mathrm{HTU}=\frac{\varepsilon v}{\rho_b k_c}=\frac{\varepsilon v}{\Lambda k_n} \tag{16-92}$$

Figure 16-13 is a plot of the dimensionless HTU (htu = HTU/$d_p$) multiplied times the correction factor $b_f$ (between 1 and 2) as a function of the dimensionless velocity ReSc = $\varepsilon v d_p/D$ and a ratio of the controlling diffusivity to the fluid-phase diffusivity, generated on the basis of results of Vermeulen et al. (1984) using typical values of the individual physical factors likely to be found in adsorption beds. This figure can be used to determine the controlling rate factor from a knowledge of individual physical parameters. If fluid-side effects control, the dimensionless HTU is given by the bottom curve (dotted for gas and solid for liquid-phase systems). If intraparticle diffusion controls, the dimensionless HTU is given by a point above the lower envelope on the appropriate diffusional contour (through the $\psi_s$, the contour value depends slightly on the separation factor $R$). If pore and solid diffusion occur in parallel, the reciprocal of the HTU is the sum of the reciprocals of the HTU values for the two mechanisms. Near the intersections of the diffusional contours with the envelope, the dimensionless HTU is the sum of the HTU values for fluid-side and particle-side resistances.

***Example 16-7 Estimation of Rate Coefficient for Gas Adsorption*** An adsorption bed is used to remove methane from a methane–hydrogen mixture at 10 atm (abs.) (10.1 bar) and 25°C (298 K), containing 10 mol% methane. Activated carbon particles having a mean diameter $d_p = 0.17$ cm, a surface area $A = 1.1 \times 10^7$ cm$^2$/g, a bulk density $\rho_b = 0.509$ g/cm$^3$, a particle density $\rho_p = 0.777$ g/cm$^3$, and a skeletal density $\rho_s = 2.178$ g/cm$^3$ are used as the adsorbent. Based on data of Grant et al. [*AIChE J.* **8:** 403 (1962)], adsorption equilibrium is represented by $n = 2.0 \times 10^{-3} K_A p_A/(1 + K_A p_A)$ mol/g adsorbent, with $K_A = 0.346$ atm$^{-1}$. Estimate the rate coefficient and determine the controlling rate factor for a superficial velocity of 30 cm/s.

1. The intraparticle void fraction is $\varepsilon_p = (0.777^{-1} - 2.178^{-1})/(0.777^{-1}) = 0.643$ and the extraparticle void fraction is $\varepsilon = (0.509^{-1} - 0.777^{-1})/(0.509^{-1}) = 0.345$. The pore radius is estimated from $r_p = 2\varepsilon_p/(A\rho_p) = 1.5 \times 10^{-7}$ cm.
2. The fluid phase diffusivity is $D = 0.0742$ cm$^2$/s. The pore diffusivity is estimated from Eq. (16-66) with a tortuosity factor $\tau_p = 4$; $D_p = 1.45 \times 10^{-3}$ cm$^2$/s.
3. The fluid-side mass transfer coefficient is estimated from Fig. 16-10. For these conditions, the kinematic viscosity is $\nu = \mu/\rho_f = 0.108$ cm$^2$/s, Re = $30 \times 0.17/0.108 = 47$, and Sc = $0.108/0.0742 = 1.5$. From Fig. 16-10 or equations in Table 16-9, Sh ~ 13.
4. The isotherm parameters based on the feed concentration are $R = 1/(1 + K_A p_A) = 0.4$ and $\Lambda = 0.509 \times 7.68 \times 10^{-4}/4.09 \times 10^{-5} = 9.56$. For pore diffusion, $\psi_p = 0.961$ from item 3A in Table 16-12. Thus, $(1-\varepsilon)\psi_p\varepsilon_p D_p/D = (1 - 0.345) \times 0.961 \times 0.643 \times 1.45 \times 10^{-3}/0.0742 = 7.9 \times 10^{-3}$. From Fig. 16-13 at ReSc = 69, $b$ htu ~ 150. $b$ is found from Fig. 16-12. However, since the mechanism parameter $\Psi$ is very small, $b \sim 1$. Thus, $k_n = \varepsilon\nu/(\mathrm{htu}\, d_p\Lambda) = 0.12$ s$^{-1}$.

This value applies to the driving force $n_i^e - \bar{n}_i$. Since pore diffusion is dominant, this value is very close to the value $k_n = 15(1-\varepsilon)\psi_p\varepsilon_p D_p/(r_p^2\Lambda) = 0.13\ s^{-1}$ obtained directly from Table 16-12. It should be noted that surface diffusion is neglected in this estimation. Its occurrence could significantly affect the overall mass transfer rate [see Suzuki (1990), pp. 70–85 in General References].

***Example 16-8 Estimation of Rate Coefficient for Ion Exchange*** Estimate the rate coefficient for flow of a 0.01-M water solution of NaCl through a bed of cation exchange particles in hydrogen form with $\varepsilon = 0.4$. The superficial velocity is 0.2 cm/s and the temperature is 25°C. The particles are 600 μm in diameter, and the diffusion coefficient of sodium ion is $1.2\times10^{-5}$ cm$^2$/s in solution and $9.4\times10^{-7}$ cm$^2$/s inside the particles (cf. Table 16-8). The bulk density is 0.7 g dry resin/cm$^3$ of bed, and the capacity of the resin is 4.9 mequiv/g dry resin. The mass action equilibrium constant is 1.5. The fluid kinematic viscosity is $\nu = 0.913$ cm$^2$/s.

1. Estimate the fluid-side mass-transfer coefficient; $\mathrm{Re} = \varepsilon v d_p/\nu = 0.2\times0.06/0.00913 = 1.3$, $\mathrm{Sc} = \nu/D = 0.00913/1.2\times10^{-5} = 761$. From Fig. 16-10 or Table 16-9, Sh ~ 23. Thus, $k_f = D\,\mathrm{Sh}/d_p = 4.5\times10^{-3}$ cm/s.

2. From the equilibrium constant, $R = 1/K_{\mathrm{Na,H}} = 0.67$. Thus, from Table 16-12, item 2A, $\psi_s = 0.979$. Using $n^{\mathrm{ref}} = 4.9$ mequiv/g and $c^{\mathrm{ref}} = 0.01$ mmole/cm$^3$, $\Lambda = \rho_b n^{\mathrm{ref}}/c^{\mathrm{ref}} = 343$. Thus, $\psi_s D_s\Lambda/D = 26$ and the external mass-transfer resistance is controlling (cf. Fig. 16-13).

3. The rate coefficient for use with a fluid-phase driving force is $k_c = 3(1-\varepsilon)k_f/(\rho_b r_p) = 0.39$ cm$^3$/(g·s).

***Example 16-9 Estimation of Rate Coefficient for Protein Adsorption*** Estimate the rate coefficient for the adsorption of an antibody ($M_r = 150{,}000$) from a 1 mg/cm$^3$ aqueous solution ($\mu = 1$ mPa s) in a column with $\varepsilon = 0.4$ operated at 0.05 cm/s and 25°C. The adsorbent particles have diameter $d_p = 100$ μm, porosity $\varepsilon_p = 0.5$, and pore radius $r_{\mathrm{pore}} = 30$ nm. The adsorption isotherm is $n = 500c/(1 + 9.0c)$, where $n$ is in mg/cm$^3$ particle volume and $c$ in mg/cm$^3$.

1. Estimate $k_f$. $\mathrm{Re} = \varepsilon v d_p/\nu = 0.05\times100\times10^{-4}/0.01 = 0.05$. For a 150,000 molecular mass globular protein in water, $D \sim 4\times10^{-7}$ cm$^2$/s [Tyn and Gusek, *Biotechnol. Bioeng.* **35:** 327 (1990)], $\mathrm{Sc} = \nu/D = 25{,}000$. From Table 16-9, $\mathrm{Sh} = (1.09/0.4)(0.05)^{0.33}(25{,}000)^{0.33} = 29$. Thus, $k_f = D\mathrm{Sh}/d_p = 1.1\times10^{-3}$ cm/s.

2. Determine the controlling resistance. From the isotherm, $n^{\mathrm{ref}} = (500\times1)/(1+9.0\times1) = 50$ mg/cm$^3$ particle. Thus, $\Lambda = (1-\varepsilon)n^{\mathrm{ref}}/c^{\mathrm{ref}} = (1-0.4)\times50/1 = 30$ and $R = 1/(1+9.0\times1) = 0.1$ [cf. Eqs. (16-33) and (16-34)]. From Eq. (16-68), $r_m = \kappa T/6\pi\mu D = (1.38\times10^{-16}\times298)/(6\pi\times0.01\times4\times10^{-7}) = 5.5$ nm. Thus, $\lambda_m = r_m/r_{\mathrm{pore}} = 5.5/30 = 0.18$. From Eq. (16-67) with $\tau_p = 4$, obtain $D_p = 5.8\times10^{-8}$ cm$^2$/s. From Table 16-12, item 3A, $\psi_p = 0.83$, giving $10(1-\varepsilon)\psi_p\varepsilon_p D_p/(D\times\mathrm{Sh}) = 0.012$. Thus, from Fig. 16-13, the intraparticle pore diffusion resistance is dominant. For these conditions, from Table 16-12, $k_n = 15\psi_p(1-\varepsilon)\varepsilon_p D_p/\Lambda r_p^2 = 2.8\times10^{-4}$ s$^{-1}$. A similar approximate result is obtained directly from Fig. 16-13 with $\mathrm{ReSc} = 0.05\times25{,}000 = 1250$ and $(1-\varepsilon)\psi_p\varepsilon_p D_p/D \sim 0.04$, giving $\mathrm{HTU}/d_p \sim 1000$. $k_n \sim 2\times10^{-4}$ s$^{-1}$ is obtained by using the HTU value in Eq. (16-92). These calculations assume that intraparticle transport is by pore diffusion alone, which is typically limiting for protein adsorption in porous adsorbents.

# BATCH ADSORPTION

In this section, the transient adsorption of a solute from a dilute solution in a constant-volume, well-mixed batch system or, equivalently, adsorption of a pure gas is considered. The solutions provided can approximate the response of a stirred vessel containing suspended adsorbent particles, or that of a very short adsorption bed. Uniform, spherical particles of radius $r_p$ are assumed. These particles, initially of uniform adsorbate concentration, are assumed to be exposed to a step change in concentration of the external fluid.

In general, solutions are obtained by coupling the basic conservation equation for the batch system, Eq. (16-49), with the appropriate rate equation. Rate equations are summarized in Tables 16-11 and 16-12 for different controlling mechanisms.

Solutions are provided for external mass-transfer control, intraparticle diffusion control, and mixed resistances for the case of constant $V_f$ and $F_{v,\mathrm{in}} = F_{v,\mathrm{out}} = 0$. The results are in terms of the fractional approach to equilibrium $F = (\hat{n}_i - \hat{n}_i^{0'})/(\hat{n}_i^{\infty} - \hat{n}_i^{0'})$, where $\hat{n}_i^{0'}$ and $\hat{n}_i^{\infty}$ are the initial and ultimate solute concentrations in the adsorbent. The solution concentration is related to the amount adsorbed by the material balance $c_i = c_i^0 - (\hat{n}_i - \hat{n}_i^{0'})M_s/V_f$.

Two general cases are considered: (1) adsorption under conditions of constant or nearly constant external solution concentration (equivalent to infinite fluid volume); and (2) adsorption in a batch with finite volume. In the latter case, the fluid concentration varies from $c_i^0$ to $c_i^{\infty}$ when equilibrium is eventually attained. $\Lambda^{\infty} = (c_i^0 - c_i^{\infty})/c_i^0 = M_s(\hat{n}_i^{\infty} - \hat{n}_i^0)/(V_f c_i^0)$ represents the fraction of adsorbate that is ultimately adsorbed and determines which general case should be considered in the analysis of experimental systems. Generally, when $\Lambda^{\infty} \ge 0.1$, solutions for the second case (finite batch volume) are required.

## EXTERNAL MASS-TRANSFER CONTROL

The intraparticle concentration is uniform, and the rate equation is given by column 1 in Table 16-12.

For a *Langmuir isotherm* with negligible solute accumulation in the particle pores, the solution for an infinite fluid volume is:

$$(1-R)\left(1-n_i^{0'}/n_i^0\right)F - R\ln(1-F) = (3k_f t/r_p)\left(c_i^0/\rho_p n_i^0\right) \qquad (16\text{-}93)$$

where $n_i^0 = n_i^{\infty} = n_i^S K_i c_i^0/(1+K_i c_i^0)$ is the adsorbate concentration in the particle at equilibrium with the fluid concentration. The predicted behavior is shown in Fig. 16-14 for $n_i^{0'} = 0$. In the *irreversible limit* ($R = 0$), $F$ increases linearly with time while in the *linear limit* ($R = 1$), $1 - F$ decreases exponentially with time.

For a finite fluid volume ($\Lambda^{\infty} > 0$), the fractional approach to equilibrium is given by:

$$\left[1 - \frac{b'(1-R^{\infty})}{2c'}\right]\frac{1}{q'}\ln\frac{(2c'F - b' - q')(-b' + q')}{(2c'F - b' + q')(-b' - q')} - \frac{1-R^{\infty}}{2c'}\ln(1 - b'F + c'F^2) = \frac{3k_f t}{r_p}\frac{c_i^0}{\rho_p n_i^{\infty}} \qquad (16\text{-}94)$$

where

$$b' = \frac{1-R^{\infty}}{1-R^0} + \Lambda^{\infty} \qquad (16\text{-}95a)$$

$$c' = \Lambda^{\infty}(1-R^{\infty}) \qquad (16\text{-}95b)$$

$$q' = (b'^2 - 4c')^{0.5} \qquad (16\text{-}95c)$$

$$R^0 = \frac{1}{1+K_i c_i^o} \qquad (16\text{-}95d)$$

$$R^{\infty} = \frac{1}{1+K c_i^{\infty}} \qquad (16\text{-}95e)$$

The predicted behavior is shown in Fig. 16-15 for $R^0 = 0.5$ with different values of $\Lambda^{\infty}$.

## SOLID DIFFUSION CONTROL

For a constant diffusivity and an infinite fluid volume, the solution is:

$$F = 1 - \frac{6}{\pi^2}\sum_{n=1}^{\infty}\frac{1}{n^2}\exp\left(-\frac{n^2\pi^2 D_{si} t}{r_p^2}\right) \qquad (16\text{-}96)$$

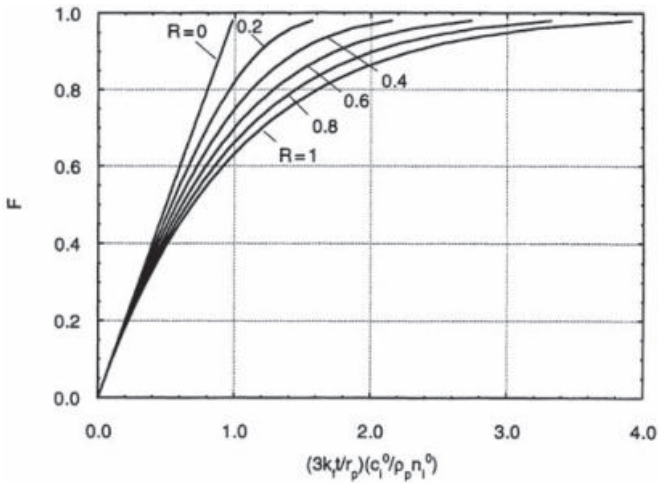

**FIG. 16-14** Constant separation factor batch adsorption curves for external mass-transfer control with an infinite fluid volume and $n_i^0 = 0$.

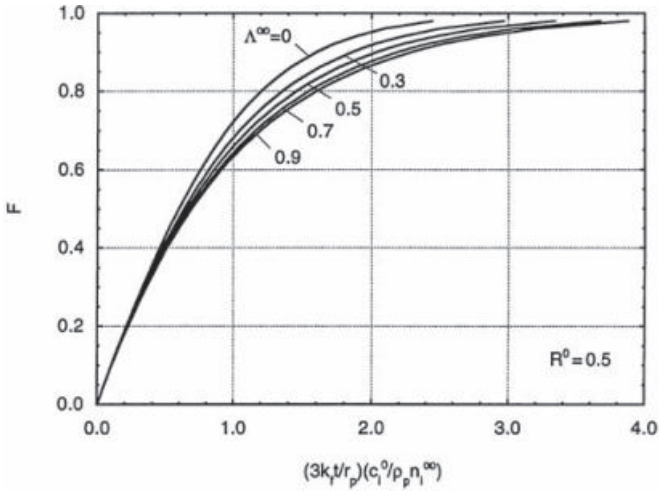

**FIG. 16-15** Constant separation factor batch adsorption curves for external mass-transfer control with a finite fluid volume, $n_i^{0'} = 0$ and $R^0 = 0.5$.

For short times, this equation does not converge rapidly. The following approximations can be used instead [Helfferich and Hwang, in Dorfner (1991), pp. 1277–1309 in General References]:

$$F = \frac{6}{r_p}\left(\frac{D_{si}t}{\pi}\right)^{0.5} \qquad F < 0.2 \tag{16-97}$$

$$F = \frac{6}{r_p}\left(\frac{D_s t}{\pi}\right)^{0.5} - \frac{3D_{si}t}{r_p^2} \qquad F < 0.8 \tag{16-98}$$

For values of $F > 0.8$, the first term ($n = 1$) in Eq. (16-96) is generally sufficient. If the controlling resistance is diffusion in the subparticles of a bidispersed adsorbent, Eq. (16-96) applies with $r_s$ replacing $r_p$.

For a finite fluid volume, the solution is:

$$F = 1 - 6\sum_{n=1}^{\infty} \frac{\exp(-p_n^2 D_{si}t/r_p^2)}{9\Lambda^{\infty}/(1-\Lambda^{\infty}) + (1-\Lambda^{\infty})p_n^2} \tag{16-99}$$

where the $p_n$s are the positive roots of

$$\frac{\tan p_n}{p_n} = \frac{3}{3 + (1/\Lambda^{\infty} - 1)p_n^2} \tag{16-100}$$

The predicted behavior is shown in Fig. 16-16. $F$ is calculated from Eq. (16-96) for $\Lambda^{\infty} = 0$ and from Eq. (16-99) for $\Lambda^{\infty} > 0$. Significant deviations from the $\Lambda^{\infty} = 0$ curve exist for $\Lambda^{\infty} > 0.1$.

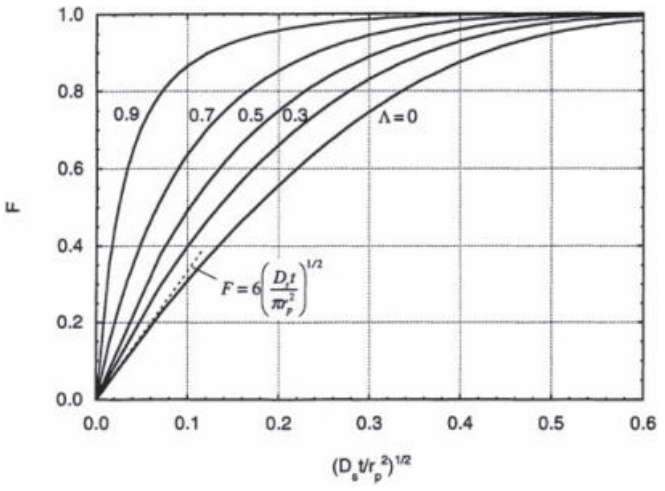

**FIG. 16-16** Batch adsorption curves for solid diffusion control. The curve for $\Lambda^{\infty} = 0$ corresponds to an infinite fluid volume. [*Adapted from Ruthven (1984) in General References, with permission.*]

For nonconstant diffusivity, a numerical solution of the conservation equations is generally required. In molecular sieve zeolites, when equilibrium is described by the Langmuir isotherm, the concentration dependence of the intracrystalline diffusivity can often be approximated by Eq. (16-72). The relevant rate equation is:

$$\frac{\partial n_i}{\partial t} = \frac{D_{0i}}{r^2}\frac{\partial}{\partial r}\left(\frac{r^2}{1 - n_i/n_i^s}\frac{\partial n_i}{\partial r}\right) \tag{16-101}$$

A numerical solution of this equation for a constant surface concentration (infinite fluid volume) is given by Garg and Ruthven [*Chem. Eng. Sci.* **27:** 417 (1972)]. The solution depends on the value of $\lambda = (n_i^0 - n_i^{0'})/(n_i^s - n_i^{0'})$. Because of the effect of adsorbate concentration on the effective diffusivity, for large concentration steps, adsorption is faster than desorption, while for small concentration steps, when $D_s$ can be taken to be essentially constant, adsorption and desorption curves are mirror images of each other as predicted by Eq. (16-96); see Ruthven (1984), p. 175.

In binary ion exchange, intraparticle mass transfer is described by Eq. (16-75) and is dependent on the ionic self diffusivities of the exchanging counterions. A numerical solution of the corresponding conservation equation for spherical particles with an infinite fluid volume is given by Helfferich and Plesset [*J. Chem. Phys.* **66**(28): 418 (1958)]. The numerical results for the case of two counterions of equal valence where a resin bead, initially partially saturated with $A$, is completely converted to the $B$ form, is expressed by:

$$F = \left\{1 - \exp\left[\pi^2\left(f_1(\alpha')\tau_D + f_2(\alpha')\tau_D^2 + f_3(\alpha')\tau_D^3\right)\right]\right\}^{1/2} \tag{16-102}$$

with

$$f_1(\alpha') = -(0.570 + 0.430\alpha'^{0.775})^{-1} \tag{16-103a}$$

$$f_2(\alpha') = (0.260 + 0.782\alpha')^{-1} \tag{16-103b}$$

$$f_3(\alpha') = -(0.165 + 0.177\alpha')^{-1} \tag{16-103c}$$

where $\tau_D = \bar{D}_A t/r_p^2$ and $\alpha' = 1 + (\bar{D}_A/\bar{D}_B - 1)n_A^{0'}/n^s$ for $0.1 \le \alpha' \le 10$. The predicted behavior is shown in Fig. 16-17. When $\alpha' = 1$ (equal ion diffusivities or $n_A^{0'} \sim 0$), Eq. (16-102) coincides with Eq. (16-96). For $\alpha' \ne 1$, the exchange rate is faster or slower, depending on which counterion is initially present in the ion exchanger and on the initial level of saturation.

For an initially fully saturated particle, the exchange rate is faster when the faster counterion is initially in the resin, with the difference in rate becoming more important as conversion from one form to the other progresses. Helfferich (1962, pp. 270–271) gives explicit expressions for the exchange of ions of unequal valence.

## PORE DIFFUSION CONTROL

The rate equation is given by item A in Table 16-11. With pore fluid and adsorbent at equilibrium at each point within the particle and for a constant diffusivity, the rate equation can be written as:

$$\frac{\partial c_{pi}}{\partial t} = \frac{\varepsilon_p D_{pi}}{\varepsilon_p + \rho_p dn_i^e/dc_i}\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial c_{pi}}{\partial r}\right) \tag{16-104}$$

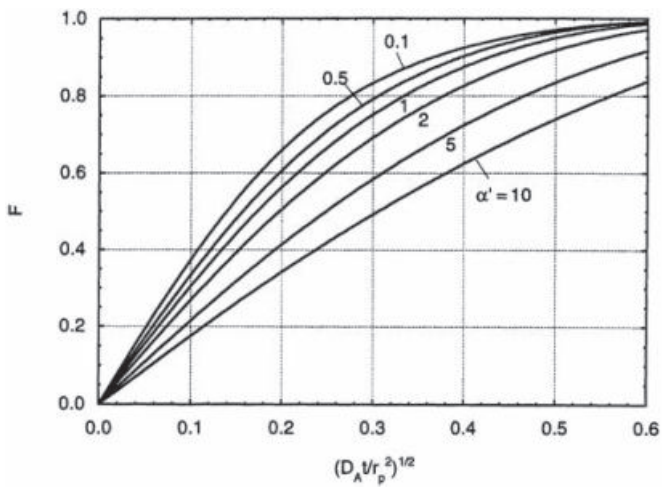

**FIG. 16-17** Batch ion exchange for two equal-valence counterions. The exchanger is initially uniformly loaded with ion $A$ in concentration $n_A^{0'}$ and is completely converted to the $B$ form. $\alpha' = 1 + (\bar{D}_A/\bar{D}_B - 1)n_A^{0'}/n^s$.

For a *linear isotherm* ($n_i = K_i c_i$), this equation is identical to the conservation equation for solid diffusion, except that the solid diffusivity $D_{si}$ is replaced by the expression $\varepsilon_p D_{pi}/(\varepsilon_p + \rho_p K_i)$. Thus, Eqs. (16-96) and (16-99) can be used for pore diffusion control with infinite and finite fluid volumes simply by replacing $D_{si}$ with this expression.

When the adsorption isotherm is nonlinear, a numerical solution is generally required. For a *Langmuir system* with negligible solute holdup in the pore fluid, item A in Table 16-11 gives:

$$\frac{\partial n_i}{\partial t} = \frac{\varepsilon_p D_{pi}}{\rho_p n_i^s K_i}\frac{1}{r^2}\frac{\partial}{\partial r}\left[\frac{r^2}{(1-n_i/n_i^s)^2}\frac{\partial n_i}{\partial r}\right] \tag{16-105}$$

This equation has the same form as that obtained for solid diffusion control with $D_{si}$ replaced by the expression $\varepsilon_p D_{pi}/[\rho_p n_i^s K_i (1-n_i/n_i^s)^2]$. Numerical results for the case of adsorption on an initially clean particle are given in Fig. 16-18 for different values of $\lambda = n_i^0/n_i^s = 1-R$. The uptake curves become increasingly steeper, as the nonlinearity of the isotherm, measured by the parameter $\lambda$, increases. The desorption curve shown for a particle with $n_i^{0'}/n_i^s = 0.9$ shows that for the same step in concentration, adsorption occurs much more quickly than desorption. This difference, however, becomes smaller as the value of $\lambda$ is reduced, and in the linear region of the adsorption isotherm ($\lambda \to 0$), adsorption and desorption curves are mirror images. The solution in Fig. 16-18 is applicable to a nonzero initial adsorbent loading by redefining $\lambda$ as $(n_i^0 - n_i^{0'})/(n_i^s - n_i^{0'})$ and the dimensionless time variable in the abscissa as $[\varepsilon_p D_{pi} t/\rho_p (1-n_i^{0'}/n_i^s)^2 n_i^s K_i r_p^2]^{1/2}$ [Ruthven (1984) in General References].

In the *irreversible limit* ($R < 0.1$), the adsorption front within the particle approaches a sharp transition separating an inner core into which the adsorbate has not yet penetrated from an outer layer in which the adsorbed phase concentration is uniform at the saturation value. The dynamics of this process is described approximately by the shrinking-core model [Yagi and Kunii, *Chem. Eng. (Japan)* **19:** 500 (1955)]. For an infinite fluid volume, the solution is:

$$\frac{\varepsilon_p D_{pi} t}{r_p^2}\frac{c_i^0}{\rho_p n_i^s} = \frac{1}{2} - \frac{1}{3}F - \frac{1}{2}(1-F)^{2/3} \tag{16-106}$$

or, in explicit form [Brauch and Schlunder, *Chem. Eng. Sci.* **30:** 540 (1975)]:

$$F = 1 - \left\{\frac{1}{2} + \cos\left[\frac{\pi}{3} + \frac{1}{3}\cos^{-1}\left(1 - \frac{12\varepsilon_p D_{pi} t}{r_p^2}\frac{c_i^0}{\rho_p n_i^s}\right)\right]\right\}^3 \tag{16-107}$$

For a finite fluid volume with $0 < \Lambda^\infty \le 1$, the solution is [Teo and Ruthven, *Ind. Eng. Chem. Process Des. Dev.* **25:** 17 (1986)]:

$$\frac{\varepsilon_p D_{pi} t}{r_p^2}\frac{c_i^0}{\rho_p n_i^s} = I_2 - I_1 \tag{16-108}$$

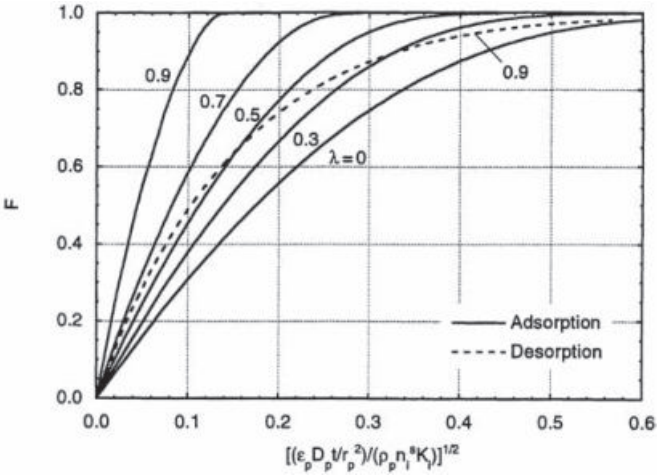

**FIG. 16-18** Constant separation factor batch adsorption curves for pore diffusion control with an infinite fluid volume. $\lambda$ is defined in the text.

where

$$I_1 = \frac{1}{\lambda'\Lambda^\infty\sqrt{3}}\left[\tan^{-1}\frac{2\eta-\lambda'}{\lambda'\sqrt{3}} - \tan^{-1}\frac{2-\lambda'}{\lambda'\sqrt{3}}\right] + \frac{1}{6\lambda'\Lambda^\infty}\ln\left[\frac{\lambda'^3+\eta^3}{\lambda'^3+1}\left(\frac{\lambda'+1}{\lambda'+\eta}\right)^3\right] \tag{16-109a}$$

$$I_2 = \frac{1}{3\Lambda^\infty}\ln\frac{\lambda'^3+\eta^3}{\lambda'^3+1} \tag{16-109b}$$

$$\eta = (1-F)^{1/3} \tag{16-109c}$$

$$\lambda' = \left(\frac{1}{\Lambda^\infty} - 1\right)^{1/3} \tag{16-109d}$$

Solutions for $R = 0$ analogous to Eqs. (16-107) and (16-108) but accounting explicitly for a distribution of particle sizes are available in Carta and Ubiera, *AIChE J.* **49:** 3066 (2003).

## COMBINED RESISTANCES

In general, exact analytic solutions are available only for the linear ($R = 1$) and irreversible limits ($R \to 0$). Intermediate cases require numerical solution or the use of approximate driving force expressions (see the subsection Rate and Dispersion Factors).

**Parallel Pore and Solid Diffusion Control** With a *linear isotherm*, assuming equilibrium between the pore fluid and the solid adsorbent, batch adsorption is described by Eqs. (16-96) and (16-99), replacing $D_{si}$ with the expression $(\varepsilon_p D_{pi} + \rho_p D_{si})/(\varepsilon_p + \rho_p K_i)$.

**External Mass Transfer and Intraparticle Diffusion Control** With a linear isotherm, the solution for combined external mass transfer and pore diffusion control with an infinite fluid volume is (Crank, *Mathematics of Diffusion,* 2d ed., Clarendon Press, 1975):

$$F = 1 - \sum_{n=1}^{\infty}\frac{6\mathrm{Bi}^2\exp\left[-\left(p_n^2\varepsilon_p D_{pi} t/r_p^2\right)/(\varepsilon_p + \rho_p K_i)\right]}{p_n^2\left[p_n^2 + \mathrm{Bi}(\mathrm{Bi}-1)\right]} \tag{16-110}$$

where $\mathrm{Bi} = k_f r_p/\varepsilon_p D_{pi}$ is the *Biot number* and the $p_n$s are the positive roots of

$$p_n \cot p_n = 1 - \mathrm{Bi} \tag{16-111}$$

For a finite fluid volume, the solution is:

$$F = 1 - 6\sum_{n=1}^{\infty}\frac{\exp\left[-\left(p_n^2\varepsilon_p D_{pi} t/r_p^2\right)/(\varepsilon_p + \rho_p K_i)\right]}{\dfrac{9\Lambda^\infty}{1-\Lambda^\infty} + (1-\Lambda^\infty)p_n^2 - (5\Lambda^\infty+1)\dfrac{p_n^2}{\mathrm{Bi}} + (1-\Lambda^\infty)\dfrac{p_n^4}{\mathrm{Bi}^2}} \tag{16-112}$$

where the $p_n$s are the positive roots of

$$\frac{\tan p_n}{p_n} = \frac{3 - \dfrac{1-\Lambda^\infty}{\Lambda^\infty}\dfrac{p_n^2}{\mathrm{Bi}}}{3 + \dfrac{1-\Lambda^\infty}{\Lambda^\infty}\dfrac{(\mathrm{Bi}-1)p_n^2}{\mathrm{Bi}}} \tag{16-113}$$

These expressions can also be used for the case of external mass transfer and solid diffusion control by substituting $D_{si}$ for $\varepsilon_p D_{pi}/(\varepsilon_p + \rho_p K_i)$ and $k_f r_p/(\rho_p K_i D_{si})$ for the Biot number.

In the *irreversible limit*, the solution for combined external resistance and pore diffusion with infinite fluid volume is [Yagi and Kunii, *Chem. Eng. (Japan)* **19:** 500 (1955)]:

$$\frac{\varepsilon_p D_{pi} t}{r_p^2}\frac{c_i^0}{\rho_p n_i^s} = \frac{1}{2} - \frac{1}{3}\left(1 - \frac{1}{\mathrm{Bi}}\right)F - \frac{1}{2}(1-F)^{2/3} \tag{16-114}$$

For a finite fluid volume, the solution is [Teo and Ruthven, *Ind. Eng. Chem. Process Des. Dev.* **25:** 17 (1986)]:

$$\frac{\varepsilon_p D_{pi} t}{r_p^2}\frac{c_i^0}{\rho_p n_i^s} = \left(1 - \frac{1}{\mathrm{Bi}}\right)I_2 - I_1 \tag{16-115}$$

where $I_1$ and $I_2$ are given by Eqs. (16-109*a*) and (16-109*b*).

**Bidispersed Particles** For particles of radius $r_p$ comprising adsorptive subparticles of radius $r_s$ that define a macropore network, conservation equations are needed to describe transport both within the macropores and within the subparticles and are given in Table 16-11, item D. Detailed equations and solutions for a linear isotherm are given in Ruthven (1984, p. 183)

and Ruckenstein et al. [*Chem. Eng. Sci.* **26:** 1306 (1971)]. The solution for a linear isotherm with no external resistance and an infinite fluid volume is:

$$F = 1 - \frac{18}{\beta + 3\alpha} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \left( \frac{n^2\pi^2}{p_{n,m}^4} \right) \times \frac{\exp(-p_{n,m}^2 D_{si} t / r_s^2)}{\alpha + \frac{\beta}{2}\left[ 1 + \frac{\cot p_{n,m}}{p_{n,m}} (p_{n,m} \cot p_{n,m} - 1) \right]} \quad (16\text{-}116)$$

where the $p_{n,m}$ values are the roots of the equation

$$\alpha p_{n,m}^2 - n^2\pi^2 = \beta(p_{n,m} \cot p_{n,m} - 1) \quad (16\text{-}117)$$

and

$$\alpha = \frac{D_{si}/r_s^2}{D_{pi}/r_p^2} \quad (16\text{-}118a)$$

$$\beta = \frac{3\alpha\rho_p K_i}{\varepsilon_p} \quad (16\text{-}118b)$$

In these equations, $D_{si}$ is the diffusivity in the subparticles, and $D_{pi}$ is the diffusivity in the pore network formed by the subparticles.

For large $K_i$ values, the uptake curve depends only on the value of the parameter $\beta$ representing the ratio of characteristic time constants for diffusion in the pores and in the subparticles. For small $\beta$ values, diffusion in the subparticles is controlling, and the solution coincides with Eq. (16-96) with $r_s$ replacing $r_p$. For large $\beta$ values, pore diffusion is controlling, and the solution coincides with Eq. (16-96) with $\varepsilon_p D_{pi}/(\varepsilon_p + \rho_p K_i)$ replacing $D_{si}$.

Lee [*AIChE J.* **24:** 531 (1978)] gives the solution for batch adsorption with bidispersed particles for the case of a finite fluid volume.

### MULTICOMPONENT SYSTEMS

Describing the kinetics of competitive adsorption in multicomponent systems requires, in general, a numerical solution of the relevant conservation equations. Approximate analytical solutions, neglecting solute holdup in the pore fluid, are available for the case where the isotherms are highly favorable and sharp fronts are formed within the particles when pore diffusion controls [Martin et al., *J. Chromatogr. A* **1079:** 105 (2005)].

## FIXED-BED TRANSITIONS

As discussed in the subsection Design Concepts, a large fraction of adsorption and ion-exchange processes takes place in fixed beds. Two classical methods for analyzing fixed-bed transitions are described here. First, local equilibrium theory is presented. In this theory, all mass-transfer resistances are ignored to focus on the often-dominating role of isotherm shape. Second, results of constant pattern analysis are presented. This gives the maximum breadth to which a mass-transfer zone will spread for various rate mechanisms. It is therefore conservative for design purposes. Both of these methods pertain to behavior in deep beds. For shallow beds, the equations that follow must be solved for the particular case of interest.

### DIMENSIONLESS SYSTEM

For both methods, Eq. (16-52) is considered, that is, the material balance for a fixed bed, written in the form

$$\rho_b \frac{\partial \bar{n}_i}{\partial t} + \varepsilon_b \frac{\partial c_i}{\partial t} + \varepsilon \frac{\partial (v c_i)}{\partial z} = \varepsilon D_L \frac{\partial}{\partial z}\left( c \frac{\partial y_i}{\partial z} \right) \quad (16\text{-}119)$$

where it has been assumed that $D_L$ is constant and that $\hat{c}_i \approx c_i$.

Dimensionless variables can be defined for time, the axial coordinate, and velocity:

$$\tau = \frac{\varepsilon v^{\text{ref}} t}{L} \quad (16\text{-}120)$$

$$\zeta = \frac{z}{L} \quad (16\text{-}121)$$

$$v^* = \frac{v}{v^{\text{ref}}} \quad (16\text{-}122)$$

respectively, where $L$ is the bed length, $v^{\text{ref}}$ is the interstitial velocity at the bed inlet, and $\tau$ is equal to the number of empty bed volumes of feed passed into the bed. Accordingly, the material balance becomes

$$\rho_b \frac{\partial \bar{n}_i}{\partial \tau} + \varepsilon_b \frac{\partial c_i}{\partial \tau} + \frac{\partial (v^* c_i)}{\partial \zeta} = \frac{1}{N_{\text{Pe}}} \frac{\partial}{\partial \zeta}\left( c \frac{\partial y_i}{\partial \zeta} \right) \quad (16\text{-}123)$$

where $N_{\text{Pe}} = v^{\text{ref}} L / D_L$ is a Peclet number for the bed or a number of dispersion units. Equation (16-123) or a similar equation is often the material balance used in nonisothermal problems, in problems involving adsorption of nontrace components, and in calculations of cycles.

For a trace, isothermal system, $v^* = 1$, and using the dimensionless system variables for concentrations [Eq. (16-10)], Eq. (16-123) becomes

$$\Lambda \frac{\partial \bar{n}_i^*}{\partial \tau} + \varepsilon_b \frac{\partial c_i^*}{\partial \tau} + \frac{\partial c_i^*}{\partial \zeta} = \frac{1}{N_{\text{Pe}}} \frac{\partial^2 c_i^*}{\partial \zeta^2} \quad (16\text{-}124)$$

where $\Lambda$ is the partition ratio, defined by

$$\Lambda = \rho_b n_i^{\text{ref}} / c_i^{\text{ref}} \quad (16\text{-}125)$$

This important dimensionless group is the volumetric capacity of the bed for the sorbable component divided by the concentration of the sorbable component in the feed. The stoichiometric capacity of the bed for solute is exactly equal to $\Lambda$ empty bed volumes of feed (to saturate the sorbent at the feed concentration) plus a fraction of a bed volume of feed to fill the voids outside and inside the particles. Alternatively, Eq. (16-124) is also obtained using the dimensionless transition variables for concentrations [Eq. (16-11)], but now the partition ratio in the first term of Eq. (16-124) pertains to the transition and is given by

$$\Lambda = \rho_b \frac{n_i'' - n_i'}{c_i'' - c_i'} \quad (16\text{-}126)$$

Equation (16-124) is a commonly used form of material balance for a fixed-bed adsorber.

If the system under consideration involves the use of the sorbent for only a single feed step or reuse after uniform regeneration, as in many applications with activated carbons and ion exchangers, then one of two paths is often followed at this point to simplify Eq. (16-124) further. The second term on the left-hand side of the equation is often assumed to be negligibly small (usually a good assumption), and time is redefined as

$$\tau_1 = \tau / \Lambda \quad (16\text{-}127)$$

to give

$$\frac{\partial \bar{n}_i^*}{\partial \tau_1} + \frac{\partial c_i^*}{\partial \zeta} = \frac{1}{N_{\text{Pe}}} \frac{\partial^2 c_i^*}{\partial \zeta^2} \quad (16\text{-}128)$$

Alternatively, in the absence of axial dispersion, a variable of the form

$$\tau_1 = \frac{\tau - \varepsilon_b \zeta}{\Lambda} \quad (16\text{-}129)$$

can be defined to reduce Eq. (16-124) directly to

$$\frac{\partial \bar{n}_i^*}{\partial \tau_1} + \frac{\partial c_i^*}{\partial \zeta} = 0 \quad (16\text{-}130)$$

The variable $\tau_1$ defined by Eq. (16-127) or (16-129) is a throughput parameter, equal to unity (hence, the 1 subscript) at the time when the stoichiometric center of the concentration wave leaves the bed. This important group, in essence a dimensionless time variable, determines the location of the stoichiometric center of the transition in the bed at any time.

### LOCAL EQUILIBRIUM THEORY

In local equilibrium theory, fluid and sorbed phases are assumed to be in local equilibrium with one another at every axial position in the bed. Thus, because of uniform concentrations, the overbar on $n_i^*$ is not necessary, and we have $\hat{c}_i \approx c_i$ [note Eqs. (16-52) and (16-119)].

**Single-Transition System** For a system described by a single material balance, Eq. (16-130) gives

$$\frac{\partial \tau_1}{\partial \zeta} = -\frac{\partial c_i^* / \partial \zeta}{\partial c_i^* / \partial \tau_1} = \frac{dn_i^*}{dc_i^*} \quad (16\text{-}131)$$

where $d\tau_1/d\zeta$ is the reciprocal of a concentration velocity. Equation (16-131) is the equation for a *simple wave* (or gradual transition or proportionate pattern). If a bed is initially uniformly saturated, then $d\tau_1/d\zeta = \tau_1/\zeta$. Thus, for the dimensionless system, the reciprocal of the velocity of a concentration is equal to the slope of the isotherm at that concentration. Furthermore, from Eq. (16-131), the depth of penetration of a given concentration into the bed is directly proportional to time, so the breadth of a simple wave increases in direct proportion to the depth of its penetration into the bed (or to time). Thus, for the simple wave, the length of the MTZ is proportional to the depth of the bed through which the wave has passed. Consideration of isotherm shape indicates that a simple wave occurs for an unfavorable dimensionless isotherm ($d^2n_i^*/dc_i^{*2} > 0$), for which low concentrations will go faster than high concentrations. Equation (16-131) also pertains to a linear isotherm, in which case the wave is called a *contact discontinuity* because it has neither a tendency to spread nor to sharpen. If a mass-transfer resistance is added to the consideration of wave character for unfavorable isotherms, the wave will still asymptotically approach the simple wave result given by Eq. (16-131).

For a favorable isotherm ($d^2n_i^*/dc_i^{*2} < 0$), Eq. (16-131) gives the impossible result that three concentrations can coexist at one point in the bed (see Example 16-10). The correct solution is a *shock* (or abrupt transition) and not a simple wave. Mathematical theory has been developed for this case to give "weak solutions" to conservation laws. The form of the solution is

$$\text{Shock speed} = \frac{\text{change in flux}}{\text{change in accumulated quantity}}$$

where the changes are jump discontinuities across the shock. The reciprocal of this equation, using Eq. (16-130), is

$$\frac{d\tau_1}{d\zeta} = \frac{\Delta n_i^*}{\Delta c_i^*} \tag{16-132}$$

where the differences are taken across the shock.

It is also possible to have a *combined wave*, which has both gradual and abrupt parts. The general rule for an isothermal, trace system is that in passing from the initial condition to the feed point in the isotherm plane, the slope of the path must not decrease. If it does, then a shock chord is taken for part of the path. Referring to Fig. 16-19, for a transition from (0,0) to (1,1), the dashes indicate shock parts, which are connected by a simple wave part between points $P_1$ and $P_2$.

***Example 16-10 Transition Types*** For the constant separation-factor isotherm given by Eq. (16-31), determine breakthrough curves for $r = 2$ and $r = 0.5$ for transitions from $c_i^* = 0$ to $c_i^* = 1$.

Using Eq. (16-131), we obtain

$$\frac{\tau_1}{\zeta} = \frac{r}{[r + (1-r)c_i^*]^2}$$

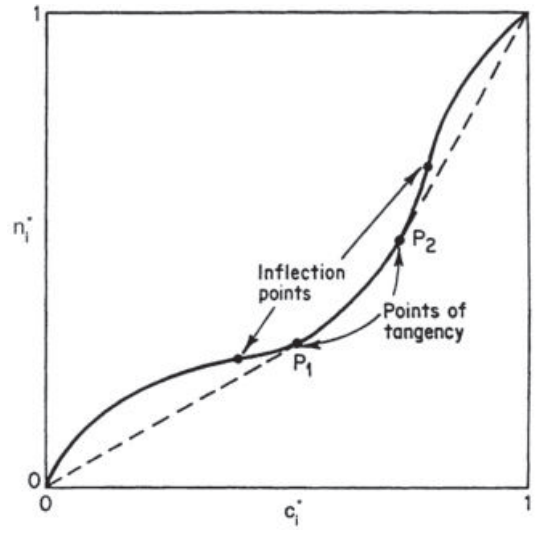

**FIG. 16-19** Path in isotherm plane for a combined wave. [After Tudge, *Can. J. Phys.* **39:** 1611 (1961).]

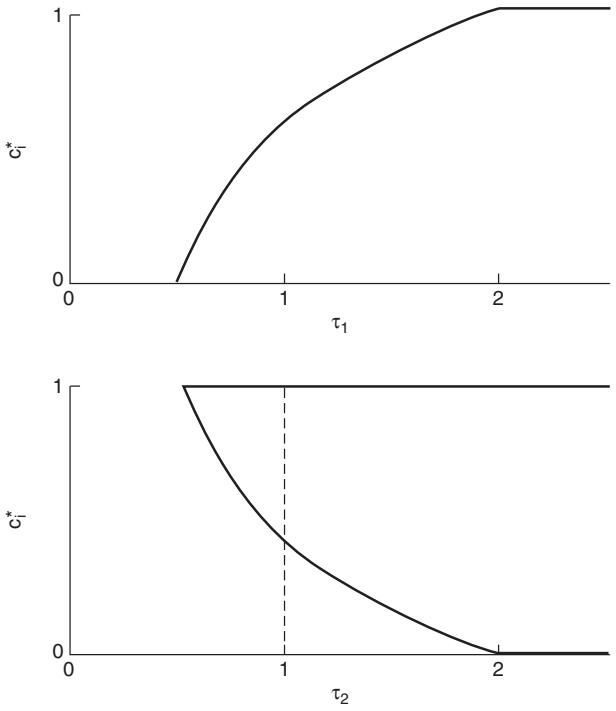

**FIG. 16-20** Breakthrough curves for $r = 2$ (*top*) and $r = 0.5$ (*bottom*) for Example 16-9.

This equation, evaluated at $\zeta = 1$, is plotted for $r = 2$ and $r = 0.5$ in Fig. 16-20. Clearly, the solution for $r = 0.5$ is not physically correct. Equation (16-132), with $d\tau_1/d\zeta = \tau_1/\zeta$, is applied to this case to give the shock indicated by the dashed line. Alternatively, bed profiles can be obtained by evaluating equations at $\tau_1 = \text{const}$.

**Multiple-Transition System** Local equilibrium theory for multiple transitions begins with some combination of material and energy balances, written

$$\rho_b \frac{\partial n_i}{\partial \tau} + \varepsilon_b \frac{\partial c_i}{\partial \tau} + \frac{\partial(\nu^* c_i)}{\partial \zeta} = 0 \qquad (i = 1,2,\ldots) \tag{16-133}$$

$$\rho_b \frac{\partial u_s}{\partial \tau} + \varepsilon_b \frac{\partial(cu_f)}{\partial \tau} + \frac{\partial(\nu^* c h_f)}{\partial \zeta} = 0 \tag{16-134}$$

which are Eq. (16-123) written with no axial dispersion and Eq. (16-55) written for an adiabatic bed.

For a simple wave, application of the method of characteristics (hodograph transformation) gives

$$\frac{d\tau}{d\zeta} = \frac{d(\rho_b n_1 + \varepsilon_b c_1)}{d(\nu^* c_1)} = \frac{d(\rho_b n_2 + \varepsilon_b c_2)}{d(\nu^* c_2)} = \cdots = \frac{d(\rho_b u_s + \varepsilon_b c u_f)}{d(\nu^* c h_f)} \tag{16-135}$$

where the derivatives are taken along the path of a transition (i.e., directional derivatives).

If a simple wave is not possible on physical grounds, then it (or part of it) is replaced by a shock, given by

$$\frac{d\tau}{d\zeta} = \frac{\Delta(\rho_b n_1 + \varepsilon_b c_1)}{\Delta(\nu^* c_1)} = \frac{\Delta(\rho_b n_2 + \varepsilon_b c_2)}{\Delta(\nu^* c_2)} = \cdots = \frac{\Delta(\rho_b u_s + \varepsilon_b c u_f)}{\Delta(\nu^* c h_f)} \tag{16-136}$$

**Extensions** When more than two conservation equations are to be solved simultaneously, matrix methods for eigenvalues and left eigenvectors are efficient [Jeffrey and Taniuti, *Nonlinear Wave Propagation,* Academic Press, New York, 1964; Jacob and Tondeur, *Chem. Eng. J.* **22:** 187 (1981), **26:** 41 (1983); Davis and LeVan, *AIChE J.* **33:** 470 (1987); Rhee, Aris, and Amundson (1986, 1989) in General References].

Nontrace isothermal systems give the "adsorption effect" (i.e., significant change in fluid velocity because of loss or gain of solute). Criteria for the existence of simple waves, contact discontinuities, and shocks are changed somewhat [Peterson and Helfferich, *J. Phys. Chem.* **69:** 1283 (1965); LeVan et al., *AIChE J.* **34:** 996 (1988); Frey, *AIChE J.* **38:** 1649 (1992)].

Local equilibrium theory also pertains to adsorption with axial dispersion, since this mechanism does not disallow the existence of equilibrium between stationary and fluid phases across the cross section of the bed [Rhee et al., *Chem. Eng. Sci.* **26:** 1571 (1971)]. This will be discussed in further detail from the standpoint of the constant pattern.

***Example 16-11 Two-Component Isothermal Adsorption*** Two components present at low mole fractions are adsorbed isothermally from an inert fluid in an initially clean bed. The system is described by $\rho_b = 500$ kg/m$^3$, $\varepsilon_b = 0.7$, and the binary Langmuir isotherm

$$n_i = \frac{n_i^s K_i c_i}{1 + K_1 c_1 + K_2 c_2} \qquad (i = 1,2)$$

with $n_1^s = n_2^s = 6$ mol/kg, $K_1 = 40$ m$^3$/mol, and $K_2 = 20$ m$^3$/mol. The feed is $c_1 = c_2 = 0.5$ mol/m$^3$. Find the bed profile.

Using the isotherm to calculate loadings in equilibrium with the feed gives $n_1 = 3.87$ mol/kg and $n_2 = 1.94$ mol/kg. An attempt to find a simple wave solution for this problem fails because of the favorable isotherms (as in the bottom figure of Fig. 16-20). To obtain the two shocks, Eq. (16-136) is written

$$\frac{d\tau}{d\zeta} = \frac{\Delta(\rho_b n_1 + \varepsilon_b c_1)}{\Delta c_1} = \frac{\Delta(\rho_b n_2 + \varepsilon_b c_2)}{\Delta c_2}$$

The concentration of one of the components will drop to zero in the shock nearest the bed inlet. If it is component 1, then using feed values and the preceding equation, that shock would be at

$$\frac{\tau}{\zeta} = \frac{\rho_b n_1 + \varepsilon_b c_1}{c_1} \approx \frac{\rho_b n_1}{c_1} = 3870$$

Similarly, if the second component were to disappear in the first shock, $\tau/\zeta = 1940$. Material balance considerations require that the shorter distance is accepted, so component 1 disappears in the first shock.

The concentrations of component 2 on the plateau downstream of the first shock are then calculated from

$$\frac{\tau}{\zeta} = \frac{\Delta(\rho_b n_2 + \varepsilon_b c_2)}{\Delta c_2} \approx \frac{\rho_b \Delta n_2}{\Delta c_2} = 3870$$

and its pure component isotherm, giving $c_2 = 0.987$ mol/m$^3$ and $n_2 = 5.71$ mol/kg. The location of this shock is determined using these concentrations and

$$\frac{\tau}{\zeta} = \frac{\rho_b n_2 + \varepsilon_b c_2}{c_2} \approx \frac{\rho_b n_2}{c_2}$$

which gives $\tau/\zeta = 2890$. The bed profile is plotted in Fig. 16-21 using $\zeta/\tau$ as the abscissa. This example can also be worked with the *h*-transformation and can be extended to adiabatic adsorption and thermal regeneration as shown elsewhere [LeVan and Carta (2008) in General References].

## CONSTANT PATTERN BEHAVIOR FOR FAVORABLE ISOTHERMS

With a favorable isotherm and a mass-transfer resistance or axial dispersion, a transition approaches a *constant pattern*, which is an asymptotic shape beyond which the wave will not spread. The wave is said to be "self-sharpening." (If a wave is initially broader than the constant pattern, it will sharpen to approach the constant pattern.) Thus, for an initially uniformly loaded bed, the constant pattern gives the maximum breadth of the MTZ. As bed length is increased, the constant pattern will occupy an increasingly smaller fraction of the bed. (Square-root spreading for a linear isotherm gives this same qualitative result.)

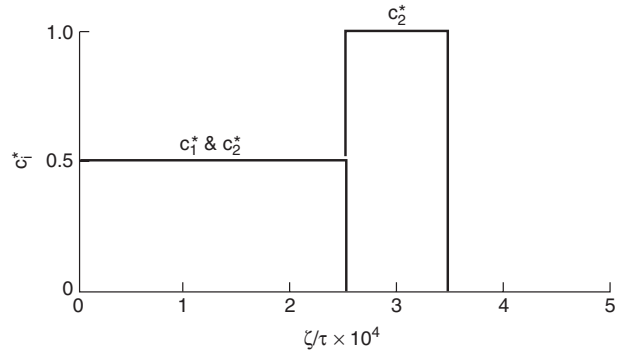

**FIG. 16-21** Bed profiles for two-component isothermal adsorption, Example 16-10.

The treatment here is restricted to the Langmuir or constant separation factor isotherm, single-component adsorption, dilute systems, isothermal behavior, and mass-transfer resistances acting alone. References to extensions are given later in this discussion. Different isotherms have been considered, and the theory is well developed for general isotherms.

**Asymptotic Solution** Rate equations for the various mass-transfer mechanisms are written in dimensionless form in Table 16-13 in terms of a number of transfer units, $N = L/\text{HTU}$, for particle-scale mass-transfer resistances, a number of reaction units for the reaction kinetics mechanism, and a number of dispersion units, $N_{\text{Pe}}$, for axial dispersion. For pore and solid diffusion, $\xi = r/r_p$ is a dimensionless radial coordinate, where $r_p$ is the radius of the particle. If a particle is bidisperse, then $r_p$ can be replaced by $r_s$, the radius of a subparticle. For preliminary calculations, Fig. 16-13 can be used to estimate $N$ for use with the LDF approximation when more than one resistance is important.

In constant pattern analysis, equations are transformed into a new coordinate system that moves with the wave. Variables are changed from $(\zeta, \tau_1)$ to $(\zeta - \tau_1, \tau_1)$. The new variable $\zeta - \tau_1$ is equal to zero at the stoichiometric center of the wave. Equation (16-130) for a bed with no axial dispersion, when transformed to the $(\zeta - \tau_1, \tau_1)$ coordinate system, becomes

$$-\frac{\partial \bar{n}_i^*}{\partial(\zeta - \tau_1)} + \frac{\partial \bar{n}_i^*}{\partial \tau_1} + \frac{\partial c_i^*}{\partial(\zeta - \tau_1)} = 0 \qquad (16\text{-}137)$$

The constant pattern is approached as the $\tau_1$ dependence in this equation disappears. Thus, discarding the derivative with respect to $\tau_1$ and integrating, using the condition that $\bar{n}_i^*$ and $c_i^*$ approach zero as $N(\zeta - \tau_1) \to \infty$ [or approach unity as $N(\zeta - \tau_1) \to -\infty$], gives simply

$$\bar{n}_i^* = c_i^* \qquad (16\text{-}138)$$

For adsorption with axial dispersion, the material balance transforms to

$$-\frac{\partial n_i^*}{\partial(\zeta - \tau_1)} + \frac{\partial n_i^*}{\partial \tau_1} + \frac{\partial c_i^*}{\partial(\zeta - \tau_1)} = \frac{1}{N_{\text{Pe}}} \frac{\partial^2 c_i^*}{\partial(\zeta - \tau_1)^2} \qquad (16\text{-}139)$$

The partial derivative with respect to $\tau_1$ is discarded and the resulting equation integrated once to give

$$-n_i^* + c_i^* = \frac{1}{N_{\text{Pe}}} \frac{dc_i^*}{d(\zeta - \tau_1)} \qquad (16\text{-}140)$$

After eliminating $n_i^*$ or $c_i^*$ using the adsorption isotherm, Eq. (16-140) can be integrated directly to obtain the constant pattern.

For other mechanisms, the particle-scale equation must be integrated. Equation (16-138) is used to advantage. For example, for external mass transfer acting alone, the dimensionless rate equation in Table 16-13 would be transformed into the $(\zeta - \tau_1, \tau_1)$ coordinate system and derivatives with respect to $\tau_1$ discarded. Equation (16-138) is then used to replace $c_i^*$ with $\bar{n}_i^*$ in the transformed equation. Furthermore, for this case there are assumed to be no gradients within the particles, so $\bar{n}_i^* = n_i^*$. After making this substitution, the transformed equation can be rearranged to

$$-\frac{dn_i^*}{n_i^* - c_i^*} = d(\zeta - \tau_1) \qquad (16\text{-}141)$$

Since $n_i^*$ and $c_i^*$ are related by the adsorption isotherm, Eq. (16-141) can be integrated.

The integration of Eq. (16-140) or (16-141) as an indefinite integral will give an integration constant that must be evaluated to center the transition properly. The material balance depicted in Fig. 16-22 is used. The two shaded regions must be of equal area if the stoichiometric center of the transition is located where the throughput parameter is unity. Thus,

$$\int_{-\infty}^{0} (1 - n_i^*)\, d(\zeta - \tau_1) = \int_{0}^{\infty} n_i^*\, d(\zeta - \tau_1) \qquad (16\text{-}142)$$

Integrating Eq. (16-142) by parts gives

$$\int_0^1 (\zeta - \tau_1)\, dn_i^* = 0 \qquad (16\text{-}143)$$

For all mechanisms except axial dispersion, the transition can be centered just as well using $c_i^*$ because of Eq. (16-138). For axial dispersion, the

**TABLE 16-13 Constant Pattern Solutions for Constant Separation Factor Isotherm ($R < 1$)**

transition should be centered using $n_i^*$ provided the fluid-phase accumulation term in the material balance, Eq. (16-124), can be neglected. If fluid-phase accumulation is important, then the transition for axial dispersion can be centered by taking into account the relative quantities of solute held in the fluid and adsorbed phases.

Constant pattern solutions for the individual mechanisms and constant separation factor isotherm are given in Table 16-13. The solutions all have the expected dependence on $R$—the more favorable the isotherm, the sharper the profile.

Figure 16-23 compares the various constant pattern solutions for $R = 0.5$. The curves are of a similar shape. The solution for reaction kinetics is perfectly symmetrical. The curves for the axial dispersion fluid-phase concentration profile and the linear driving force approximation are identical except that the latter occurs one transfer unit further down the bed. The curve for external mass transfer is exactly that for the linear driving force approximation turned upside down [i.e., rotated 180° about $c_i^* = n_i^* = 0.5$, $N(\zeta - \tau_1) = 0$]. The linear driving force approximation provides a good approximation for both pore diffusion and surface diffusion.

Because of the close similarity in shape of the profiles shown in Fig. 16-23 (as well as likely variations in parameters; e.g., concentration-dependent surface diffusion coefficient), a controlling mechanism cannot be reliably determined from transition shape. If reliable correlations are not available and rate parameters cannot be measured in independent experiments, then particle diameters, velocities, and other factors should be varied, and the observed impact should be considered in relation to the definitions of the numbers of transfer units.

***Example 16-12 Estimation of Breakthrough Time*** With reference to Example 16-9, determine the 10 percent breakthrough time and the column dynamic binding capacity if the column is 20 cm long.

1. From Example 16-9, $\Lambda = 30$, $R = 0.1$, and $D_p = 5.8 \times 10^{-8}$ cm$^2$/s. For pore diffusion control (Table 16-13, item A), $N = 15(1-\varepsilon)\varepsilon_p D_p L/(\varepsilon v r_p^2) = 4.2$. Based on the numerical solution of Hall et al. [*Ind. Eng. Chem. Fundam.* **5:** 212 (1966)], $N(1-\tau_1) \sim 1.3$ with $c_i^* = 0.1$, giving $\tau_1 = 0.69$. The corresponding time is $t = (L/\varepsilon v)(\varepsilon + \Lambda\tau_1) = (20/0.05)(0.4 + 30 \times 0.69) \sim 8400$ s. The column dynamic binding capacity ($DBC_{10\%}$) is the amount of adsorbate retained in the column per unit column volume when the outlet concentration reaches 10 percent of the feed. As a fraction of equilibrium capacity, $DBC_{10\%}$ is equal to $\tau_1$, neglecting the adsorbate held in the pore volume and the leakage prior to 10 percent of breakthrough.

2. From Example 16-9, the rate coefficient for the linear driving-force approximation (Table 16-13, item E) is $k_n = 2.8 \times 10^{-4}$ s$^{-1}$. Thus, $N = k_n \Lambda L/\varepsilon v = 2.8 \times 10^{-4} \times 30 \times 20/0.05 = 3.4$ and

$$N(1-\tau_1) = \frac{1}{1-0.1}\ln\left(\frac{1-0.1}{0.1^{0.1}}\right) + 1 = 1.1$$

with $c_i^* = 0.1$, giving $\tau_1 = 0.67$. The corresponding breakthrough time $t = 8200$ s.

3. If the isotherm is approximated as irreversible ($R = 0$), from Table 16-13, item B, $N(1-\tau_1) \sim 1.03$ with $c_i^* = 0.1$, giving $\tau_1 = 0.75$ with a corresponding breakthrough time $t = 9100$ s.

**Breakthrough Behavior for Axial Dispersion** Breakthrough behavior for adsorption with axial dispersion in a deep bed is not adequately described by the constant pattern profile for this mechanism. Equation (16-128), the partial differential equation of the second order Fickian model, requires two boundary conditions for its solution. The constant pattern pertains to a bed of infinite depth—in obtaining the solution the downstream boundary condition $c_i^* \to 0$ as $N_{Pe}\zeta \to \infty$ is applied. Breakthrough behavior presumes the existence of a bed outlet, and a boundary condition must be applied there.

The full mathematical model for this problem is Eq. (16-128) with boundary conditions

$$c_i^* - \frac{1}{N_{Pe}}\frac{\partial c_i^*}{\partial \zeta} = 1 \quad \text{at} \quad \zeta = 0 \tag{16-144}$$

$$\frac{\partial c_i^*}{\partial \zeta} = 0 \quad \text{at} \quad \zeta = 1 \tag{16-145}$$

and an initial condition. Equation (16-144) specifies a constant flux at the bed inlet, and Eq. (16-145), the Danckwerts-type boundary condition at the bed outlet, is appropriate for fixed-bed adsorption, provided that the partition ratio is large.

The solution to this model for a deep bed indicates an increase in velocity of the fluid-phase concentration wave during breakthrough. This is most dramatic for the rectangular isotherm—the instant the bed becomes saturated, the fluid-phase profile jumps in velocity from that of the adsorption transition to that of the fluid, and a near shocklike breakthrough curve is observed [Coppola and LeVan, *Chem. Eng. Sci.* **36:** 967 (1981)].

**Extensions** Existence, uniqueness, and stability criteria have been developed for the constant pattern [Cooney and Lightfoot, *Ind. Eng. Chem. Fundam.* **4:** 233 (1965); Rhee et al., *Chem. Eng. Sci.* **26:** 1571 (1971); Rhee and Amundson, *Chem. Eng. Sci.* **26:** 1571 (1971), **27:** 199 (1972), **29:** 2049 (1974)].

The rectangular isotherm has received special attention. For this, many of the constant patterns are developed fully at the bed inlet, as shown for external mass transfer [Klotz, *Chem. Revs.* **39:** 241 (1946)], pore diffusion [Vermeulen, *Adv. Chem. Eng.* **2:** 147 (1958); Hall et al., *Ind. Eng. Chem. Fundam.* **5:** 212 (1966)], pore diffusion with film resistance in series [Weber and Chakraborti, *AIChE J.* **20:** 228 (1974)], the linear driving force approximation [Cooper, *Ind. Eng. Chem. Fundam.* **4:** 308 (1965)], reaction kinetics [Hiester and Vermeulen, *Chem. Eng. Progress* **48:** 505 (1952); Bohart and Adams, *J. Amer. Chem. Soc.* **42:** 523 (1920)], and axial dispersion [Coppola and LeVan, *Chem. Eng. Sci.* **38:** 991 (1983)].

Multiple mass-transfer resistances have been considered in many studies [Vermeulen, *Adv. in Chem. Eng.* **2:** 147 (1958); Vermeulen et al. (1984) and Ruthven (1984) in General References; Fleck et al., *Ind. Eng. Chem. Fundam.* **12:** 95 (1973); Yoshida et al., *Chem. Eng. Sci.* **39:** 1489 (1984)].

Treatments of constant pattern behavior have been carried out for multicomponent adsorption [Vermeulen, *Adv. in Chem. Eng.* **2:** 147 (1958); Vermeulen et al. (1984) and Ruthven (1984) in General References; Rhee and Amundson, *Chem. Eng. Sci.* **29:** 2049 (1974); Cooney and Lightfoot, *Ind. Eng. Chem. Fundam.* **5:** 25 (1966); Cooney and Strusi, *Ind. Eng. Chem. Fundam.* **11:** 123 (1972); Bradley and Sweed, *AIChE Symp. Ser. No. 152* **71:** 59 (1975)]. The behavior is such that coexisting compositions advance through the bed together at a uniform rate; this is the *coherence* concept of Helfferich and coworkers [see Helfferich (1962) and Helfferich and Klein (1970) in General References].

Nontrace systems have been considered [Sircar and Kumar, *Ind. Eng. Chem. Proc. Des. Dev.* **22:** 271 (1983)].

Constant patterns have been developed for adiabatic adsorption [Pan and Basmadjian, *Chem. Eng. Sci.* **22:** 285 (1967); Ruthven et al., *Chem. Eng. Sci.* **30:** 803 (1975); Kaguei et al., *Chem. Eng. Sci.* **42:** 2964 (1987)].

The constant pattern concept has also been extended to circumstances with nonplug flows, with various degrees of rigor, including flow profiles in tubes [Sartory, *Ind. Eng. Chem. Fundam.* **17:** 97 (1978); Tereck et al., *Ind. Eng. Chem. Res.* **26:** 1222 (1987)], wall effects [Vortmeyer and Michael, *Chem. Eng. Sci.* **40:** 2135 (1985)], channeling [LeVan and Vermeulen in *Fundamentals of Adsorption*, ed. Myers and Belfort, Engineering Foundation, New York, 1984, pp. 305–314; *AIChE Symp. Ser. No. 233* **80:** 34 (1984)], networks [Avilés and LeVan, *Chem. Eng. Sci.* **46:** 1935 (1991)], and general structures of constant cross section [Rudisill and LeVan, *Ind. Eng. Chem. Res.* **29:** 1054 (1991)].

## SQUARE ROOT SPREADING FOR LINEAR ISOTHERMS

The simplest isotherm is $n_i^* = c_i^*$ corresponding to $R = 1$. For this isotherm, the rate equation for external mass transfer, the linear driving force approximation, or reaction kinetics can be combined with Eq. (16-130) to obtain

$$\frac{\partial \bar{n}_i^*}{\partial \tau_1} = -\frac{\partial c_i^*}{\partial \zeta} = N(c_i^* - \bar{n}_i^*) \tag{16-146}$$

The solution to this equation, with initial condition $n_i^* = 0$ at $\tau_1 = 0$ and boundary condition $c_i^* = 1$ at $\zeta = 0$, originally obtained for an analogous heat transfer case [Anzelius, *Z. Angew Math. Mech.* **6:** 291 (1926); Schumann, *J. Franklin Inst.* **208:** 405 (1929)], is

$$c_i^* = J(N\zeta, N\tau_1) \qquad n_i^* = 1 - J(N\tau_1, N\zeta) \tag{16-147}$$

where the $J$ function is [Hiester and Vermeulen, *Chem. Eng. Prog.* **48:** 505 (1952)]

$$J(s,t) = 1 - \int_0^S e^{-t-\xi} I_0(2\sqrt{t\xi})\, d\xi \tag{16-148}$$

where $I_0$ is the modified Bessel function of the first kind of order zero. This linear isotherm result can be generalized to remove the assumption that $\hat{c}_i^* \approx c_i^*$ if the throughput parameter is redefined as

$$\tau_1 = \frac{\tau - \varepsilon\zeta}{(1-\varepsilon)(\rho_p K_i + \varepsilon_p)}$$

A series approximation suitable for practical calculations of the $J$-function is given by Tan, *Chem. Eng.* **84:** 158 (1977). For large argument values, $J$ is approximated by [Vermeulen et al. (1984) in General References]

$$J(s,t) \sim \frac{1}{2}\operatorname{erfc}(\sqrt{s} - \sqrt{t}) \tag{16-149}$$

A derivation for particle-phase diffusion accompanied by fluid-side mass transfer has been carried out by Rosen [*J. Chem. Phys.* **18:** 1587 (1950); *J. Chem. Phys.* **20:** 387 (1952); *Ind. Eng. Chem.* **46:** 1590 (1954)] with the limiting form at $N > 50$:

$$c_i^* = \frac{1}{2}\operatorname{erfc}\left[\frac{\sqrt{N}}{2}(\zeta - \tau_1)\right] \tag{16-150}$$

For axial dispersion in a semi-infinite bed with a linear isotherm, the complete solution has been obtained for a constant flux inlet boundary condition [Lapidus and Amundson, *J. Phys. Chem.* **56:** 984 (1952); Brenner, *Chem. Eng. Sci.* **17:** 229 (1962); Coates and Smith, *Soc. Petrol. Engrs. J.* **4:** 73 (1964)]. For large $N$, the leading term is

$$c_i^* = \frac{1}{2}\operatorname{erfc}\left[\frac{\sqrt{N}}{2\sqrt{\tau_1}}(\zeta - \tau_1)\right] \tag{16-151}$$

All of these solutions are very similar and show, for large $N$, a wave with breadth proportional to the square root of the bed depth through which it has passed.

## ANALYTICAL SOLUTION FOR REACTION KINETICS

In general, full time-dependent analytical solutions to differential equation–based models of the previously described mechanisms have not been obtained for nonlinear isotherms. Only for reaction kinetics with the constant separation factor isotherm has a full solution been found [Thomas, *J. Amer.*

*Chem. Soc.* **66:** 1664 (1944)]. Referred to as the *Thomas solution,* it has been extensively studied [Amundson, *J. Phys. Colloid Chem.* **54:** 812 (1950); Hiester and Vermeulen, *Chem. Eng. Progress* **48:** 505 (1952); Gilliland and Baddour, *Ind. Eng. Chem.* **45:** 330 (1953); Vermeulen, *Adv. in Chem. Eng.* **2:** 147 (1958)]. The solution to Eq. (16-130) for item 4C in Table 16-12 for the same initial and boundary conditions as Eq. (16-146) is

$$c_i^* = \frac{J(RN\zeta, N\tau_1)}{J(RN\zeta, N\tau_1) + e^{-(R-1)N(\zeta-\tau_1)}[1 - J(N\zeta, RN\tau_1)]}$$
$$n_i^* = \frac{1 - J(N\tau_1, RN\zeta)}{J(RN\zeta, N\tau_1) + e^{-(R-1)N(\zeta-\tau_1)}[1 - J(N\zeta, RN\tau_1)]} \qquad (16\text{-}152)$$

The solution gives all of the expected asymptotic behaviors for large $N$—the proportionate pattern spreading of the simple wave if $R > 1$, the constant pattern if $R < 1$, and square root spreading for $R = 1$.

## NUMERICAL METHODS AND CHARACTERIZATION OF WAVE SHAPE

For the solution of sophisticated mathematical models of adsorption cycles incorporating complex multicomponent equilibrium and rate expressions, two numerical methods are popular, including implementations in commercially available software packages. These are finite difference and weighted residual methods. The former vary in the manner in which distance variables are discretized, ranging from simple backward difference stage models (akin to the plate theory of chromatography) to more involved schemes exhibiting little numerical dispersion. The weighted residual method of orthogonal collocation is often thought to be faster computationally, but oscillations in the polynomial trial function can be a problem. The choice of best method is often the preference of the user.

For both the finite difference and weighted residual methods, a set of coupled ordinary differential equations results that are integrated forward in time using the method of lines. Various software packages implementing Gear's method are popular.

The development of mathematical models is described in several of the General References [Guiochon Felinger-Shirazi, and Katti (2006), Rhee, Aris, and Amundson (1986, 1989), Ruthven (1984), Ruthven, Farooq, and Knaebel (1994), Suzuki (1990), Tien (1994), Wankat (1986), and Yang (1987)]. See also Finlayson [*Numerical Methods for Problems with Moving Fronts,* Ravenna Park, Washington, 1992; Holland and Liapis, *Computer Methods for Solving Dynamic Separation Problems,* McGraw-Hill, New York, 1982; Villadsen and Michelsen, *Solution of Differential Equation Models by Polynomial Approximation,* Prentice-Hall, Englewood Cliffs, N.J., 1978].

For the characterization of wave shape and breakthrough curves, three methods are popular. The MTZ method [Michaels, *Ind. Eng. Chem.* **44:** 1922 (1952)] measures the breadth of a wave between two chosen concentrations (e.g., $c_i^* = 0.05$ and 0.95 or $c_i^* = 0.01$ and 0.99). Outside of a laboratory, the measurement of full breakthrough curves is rare, so the breadth of the MTZ is often estimated from an independently determined stoichiometric capacity and a measured small concentration in the "toe" of the breakthrough curve. A second method for characterizing wave shape is by the slope of the breakthrough curve at its midheight (i.e., $c_i^* = 0.5$ [Vermeulen et al. (1984)]). The use of moments of the slope of breakthrough curves is a third means for characterization. They can often be used to extract numerical values for rate coefficients for linear systems [Ruthven (1984) and Suzuki (1990) in General References; Nauman and Buffham, *Mixing in Continuous Flow Systems,* Wiley-Interscience, New York, 1983]. The method of moments is discussed further in the following part of this section.

# CHROMATOGRAPHY

## CLASSIFICATION

Chromatography is a sorptive separation process where a portion of a solute mixture (feed) is introduced at the inlet of a column containing a selective adsorbent (stationary phase) and separated over the length of the column by the action of a carrier fluid (mobile phase) that is continually supplied to the column following introduction of the feed. The mobile phase is generally free of the feed components, but it may contain various other species introduced to modulate the chromatographic separation. The separation occurs as a result of the different partitioning of the feed solutes between the stationary and mobile phases. Chromatography is used both in the analysis of mixtures and in preparative and process-scale applications. It can be used for both trace-level and for bulk separations both in the gas and the liquid phase.

**Modes of Operation** The classical modes of operation of chromatography as enunciated by Tiselius [*Kolloid Z.* **105:** 101 (1943)] are: elution chromatography, frontal analysis, and displacement development. Basic features of these techniques are illustrated in Fig. 16-24. Often, each of the different modes can be implemented with the same equipment and stationary phase. The results are, however, quite different in the three cases.

**Elution Chromatography** The components of the mobile phase supplied to the column after feed introduction have less affinity for the stationary phase than any of the feed solutes. Under trace conditions, the feed solutes travel through the column as bands or zones at different velocities that depend only on the composition of the mobile phase and the operating temperature and that exit from the column at different times.

Two variations of the technique exist: *isocratic elution*, when the mobile phase composition is kept constant, and *gradient elution*, when the mobile phase composition is varied during the separation. Isocratic elution is often the method of choice for analysis and in process applications when the retention characteristics of the solutes to be separated are similar and not dramatically sensitive to very small changes in operating conditions. Isocratic elution is also generally practical for systems where the equilibrium isotherm is linear or nearly linear. In all cases, isocratic elution results in a dilution of the separated products.

In gradient elution, the eluting strength of the mobile phase is gradually increased after supplying the feed to the column. In liquid chromatography, this is accomplished by changing the mobile phase composition. The gradient in the eluting strength of the mobile phase that is established in the column is used to modulate the separation, allowing control of the retention time of weakly and strongly retained components. A similar effect can be obtained in gas chromatography by modulating the column temperature. In either case, the column has to be brought back to the initial conditions before the next cycle is commenced.

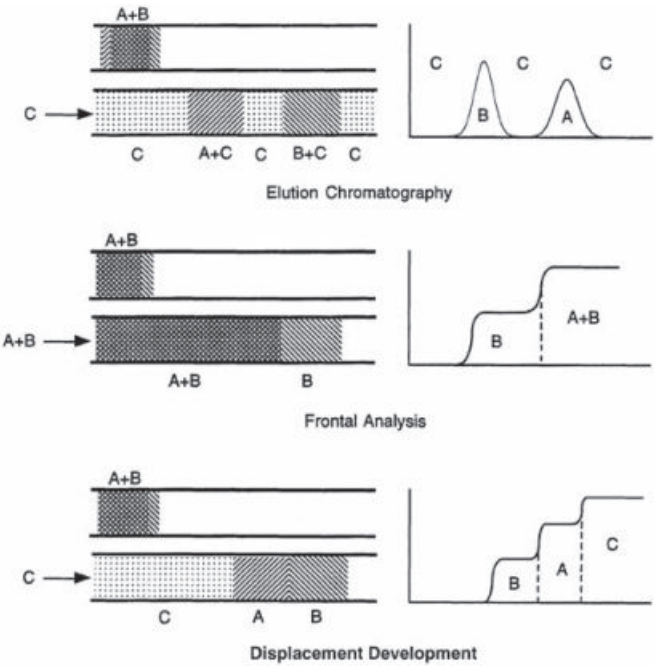

**FIG. 16-24** Modes of operation of chromatography for the separation of a mixture of two components A and B. Figures on the left represent a schematic of the column with sample passing through it. Top diagrams show column at end of feed step. Figures on the right show the corresponding effluent concentrations as might be seen by a nonspecific detector. C is either the eluent or the displacer.

Generally, gradient elution is best suited for the separation of complex mixtures that contain both species that interact weakly with the stationary phase and species that interact strongly. Since the eluting strength of the mobile phase is adjusted continuously, weakly retained components of a mixture are separated in the initial phase when the relative eluting strength of the mobile phase is low, while strongly retained components are separated later in the gradient when the eluting strength is high. In addition, the technique is used to obtain reproducible chromatographic separations when the solute retention characteristics are extremely sensitive to the operating conditions, as in the case of the chromatography of biopolymers, such as proteins. These molecules are often found to transition from being very strongly retained to being completely unretained over an extremely small range of mobile phase compositions, making it difficult to obtain reproducible isocratic separations.

**Frontal Analysis** The feed mixture to be separated is continuously supplied to the column where the mixture components are competitively adsorbed on the stationary phase. These components are then partially separated in a series of fronts, preceded downstream by the least strongly retained species forming a pure component band, and upstream by the feed mixture. The technique is best suited for the removal of strongly adsorbed impurities present in trace amounts from an unretained or weakly adsorbed product of interest. In this case, a large amount of feed can be processed before the impurities begin to break through. When this point is reached, the bed is washed to remove any desired product from the interstitial voids, and the adsorbent is regenerated. The method can only provide a single component in pure form, but avoids product dilution completely. Multicomponent separations require a series of processing steps; either a series of frontal analysis separations, or a combination of elution and displacement separations. Example 16-11 illustrates bed concentration profiles for the frontal analysis separation of two components under local equilibrium conditions.

**Displacement Development** The column is partially loaded with the feed mixture as in frontal analysis, usually for conditions where all solutes of interest are strongly and competitively adsorbed on the stationary phase. The feed supply is then stopped and a mobile phase containing a component that has an affinity for the stationary phase stronger than any of the feed components, termed the *displacer*, is fed to the column. The advancement of the displacer front through the column causes displacement of the feed components from the adsorbent and their competitive readsorption downstream of the displacer front. As in frontal chromatography, the less strongly retained species tends to migrate faster down the column concentrating in a band farthest from the displacer front, while the most strongly adsorbed feed solute tends to move more slowly concentrating in a band adjacent to the displacer front. If the column is sufficiently long, all feed components eventually become distributed into a pattern of adjacent pure component bands where each upstream component acts as a displacer for each downstream species located in the band immediately downstream. When this occurs, all bands in the displacement train move at the same velocity, which is equal to the velocity of the displacer front, and the bed concentration profile is called an *isotachic pattern*.

The various operational steps of a displacement development separation are shown in Fig. 16-25. Ideally, the separated species exit the column as adjacent rectangular bands in order of increasing affinity for the stationary phase as shown in this figure. In practice, dispersion effects result in a partial mixing of adjacent bands requiring recycling of portions of the effluent that do not meet purity requirements. Following separation, the displacer has to be removed from the column with a suitable regenerant and the initial conditions of the column restored before the next cycle. Column regeneration may consume a significant portion of the cycle when removal of the displacer is difficult.

Displacement chromatography is suitable for the separation of multicomponent bulk mixtures. For dilute multicomponent mixtures, it allows a simultaneous separation and concentration. Thus, it permits the separation of compounds with extremely low separation factors without the excessive dilution that would be obtained in elution techniques.

Other modes of operation, including recycle and flow reversal schemes and continuous chromatography, are discussed in Ganetsos and Barker (*Preparative and Production Scale Chromatography,* Marcel Dekker, New York, 1993).

## CHARACTERIZATION OF EXPERIMENTAL CHROMATOGRAMS

**Method of Moments** The first step in the analysis of chromatographic systems is often a characterization of the column response to small pulse injections of a solute under trace conditions in the Henry's law limit of the isotherm. For such conditions, the statistical moments of the response peak are used to characterize the chromatographic behavior. Such an approach is generally preferable to other descriptions of peak properties that are specific to Gaussian behavior, since the statistical moments are directly correlated to equilibrium and dispersion parameters. Useful references are Schneider and Smith [*AIChE J.* **14:** 762 (1968)], Suzuki and Smith [*Chem. Eng. Sci.* **26:** 221 (1971)], Carbonell et al. [*Chem. Eng. Sci.* **9:** 115 (1975); **16:** 221 (1978)], and Carta and Jungbauer [(2010), pp. 237–246 in General References].

The most important moments are:

$$\mu_0 = \int_0^\infty c_i \, dt \tag{16-153}$$

$$\mu_1 = \frac{1}{\mu_0} \int_0^\infty c_i t \, dt \tag{16-154}$$

$$\sigma^2 = \frac{1}{\mu_0} \int_0^\infty c_i (t - \mu_1)^2 \, dt \tag{16-155}$$

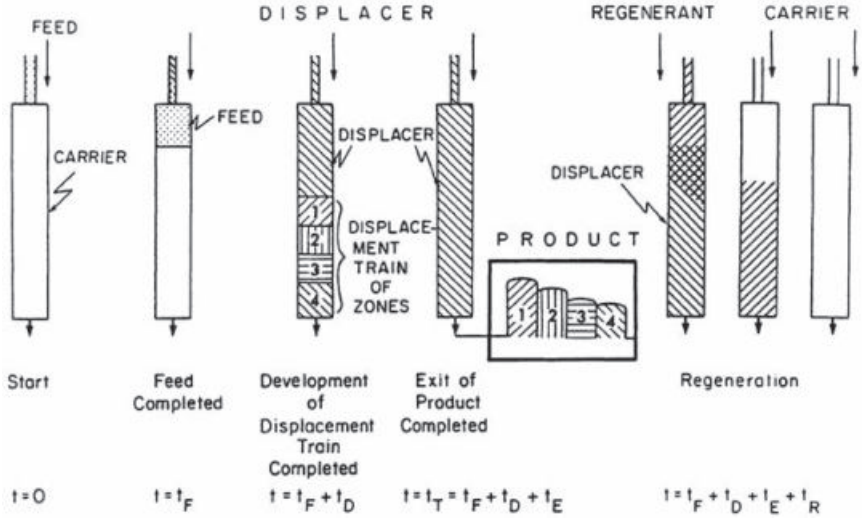

**FIG. 16-25** Operational steps in displacement chromatography. The column, initially equilibrated with a carrier solvent at time 0, is loaded with feed until time $t_F$ and supplied with displacer for a time $t_D + t_E$. Development of the displacement train occurs during the time $t_D$ and elution of the separated products ends at time $t_E$. $t_R$ is the time required to remove the displacer from the column and restore the initial conditions. Components are numbered in order of decreasing affinity for the stationary phase. [Reference: Horvath et al., *J. Chromatogr.* **218:** 365 (1981). Reprinted with permission of *J. Chromatogr.*]

where $c_i$ is the peak profile. $\mu_0$ represents the area, $\mu_1$ the mean residence time, and $\sigma^2$ the variance of the response peak. Moments can be calculated by numerical integration of experimental profiles and time can be replaced by mobile phase volume in these calculations.

The *retention factor* is defined as:

$$k_i' = \frac{\mu_1 - \mu_1^0}{\mu_1^0} \tag{16-156}$$

where $\mu_1^0$ is the first moment obtained for an unadsorbed tracer which is excluded from the stationary phase. $k_i'$ is the equilibrium ratio of the amount of solute in the stationary phase (including any pores) and the amount in the external mobile phase. An alternative commonly used definition of the retention factor uses as a reference the first moment of an inert species that has access to all the pores.

The number of plates, $N_p$, and the height equivalent to a theoretical plate, HETP, are defined as measures of dispersion effects as follows:

$$N_p = \frac{L}{\text{HETP}} = \frac{\mu_1^2}{\sigma^2} \tag{16-157}$$

$$\text{HETP} = \frac{\sigma^2 L}{\mu_1^2} \tag{16-158}$$

A high number of plates and a low HETP indicate a high column efficiency.

Higher moments can also be computed and used to define the skewness of the response peak. However, difficulties often arise in such computations as a result of drifting of the detection system.

In practice, experimental peaks can be affected by extracolumn retention and dispersion factors associated with the injector, connecting tubing, and any detector. For linear chromatography conditions, the apparent response parameters are related to their corresponding true column value by

$$\mu_{1,\text{apparent}} = \mu_1 + \mu_{1,\text{injector}} + \mu_{1,\text{tubing}} + \mu_{1,\text{detector}} \tag{16-159}$$

$$\sigma^2_{\text{apparent}} = \sigma^2 + \sigma^2_{\text{injector}} + \sigma^2_{\text{tubing}} + \sigma^2_{\text{detector}} \tag{16-160}$$

**Approximate Methods** For certain conditions, symmetrical, Gaussian-like peaks are obtained experimentally. Such peaks may be empirically described by:

$$c_i = \frac{Q_i/F_v}{\sigma\sqrt{2\pi}} \exp\left[-\left(\frac{t - t_{Ri}}{\sigma\sqrt{2}}\right)^2\right] = \frac{Q_i/F_v}{t_{Ri}}\sqrt{\frac{N_p}{2\pi}} \exp\left[-\frac{N_p}{2}\left(\frac{t}{t_{Ri}} - 1\right)^2\right] \tag{16-161}$$

where $Q_i$ is the amount of solute injected, $F_v$ is the volumetric flow rate, and $t_{Ri}$ is the peak apex time. The relationships between the moments and other properties of such peaks are shown in Fig. 16-26. For such peaks, approximate calculations of the number of plates can be done with the following equations:

$$N_p = 5.54\left(\frac{t_{Ri}}{\Delta}\right)^2 \tag{16-162}$$

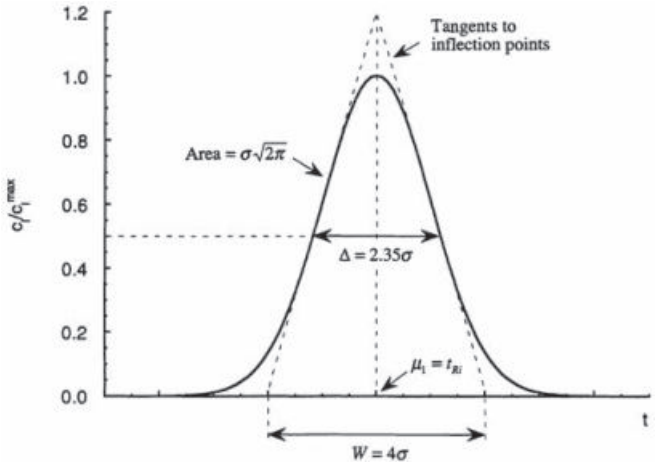

**FIG. 16-26** Properties of a Gaussian peak. $c_i^{\max}$ is the peak height; $t_{Ri}$, the peak apex time; σ, the standard deviation; Δ, the peak width at midheight; and $W$, the distance between the baseline intercepts of the tangents to the peak.

$$N_p = 16\left(\frac{t_{Ri}}{W}\right)^2 \tag{16-163}$$

$$N_p = 2\pi\left(\frac{c_i^{\max} t_{Ri}}{\mu_0}\right)^2 \tag{16-164}$$

where Δ is the peak width at half peak height and $W$ is the distance between the baseline intercepts of the tangents to the inflection points of the peak.

In general, Gaussian behavior can be tested by plotting the cumulative fractional recovery $\int_0^t c_i\,dt/\mu_0$ versus time on probability-linear coordinates; if the plot is linear, Gaussian behavior is confirmed. For nearly Gaussian peaks with asymmetry factor less than about 1.6 (see below), calculations of $N_p$ based on Eqs. (16-162) to (16-164) provide results close to those obtained with a rigorous calculation of moments. When deviations from Gaussian behavior are significant, however, large errors can be obtained using these expressions.

**Tailing Peaks** Tailing peaks can be obtained experimentally when the column efficiency is very low, when there are large extracolumn dispersion effects, when the stationary phase is heterogeneous (in the sense that it contains different adsorption sites), or when the adsorption equilibrium deviates from the Henry's law limit. Asymmetrical tailing peaks can sometimes be described empirically by an exponentially modified Gaussian (EMG) defined as the convolute integral of a Gaussian constituent with mean time $t_G$ and standard deviation $\sigma_G$ and an exponential decay with time constant $\tau_G$ [Grushka, *Anal. Chem.* **44:** 1733 (1972)]:

$$c_i = \frac{Q_i/F_v}{\sigma_G\tau_G\sqrt{2\pi}} \int_0^\infty \exp\left[-\left(\frac{t - t_G - t'}{\sigma_G\sqrt{2}}\right)^2 - \frac{t'}{\tau_G}\right] dt' \tag{16-165}$$

The corresponding moments are calculated directly as $\mu_1 = t_G + \tau_G$ and $\sigma^2 = \sigma_G^2 + \tau_G^2$ and the *peak skew* as:

$$\text{Peak skew} = \frac{1}{\mu_0\sigma^3}\int_0^\infty c_i(t - \mu_1)^3\,dt \sim \frac{2(\tau_G/\sigma_G)^3}{[1 + (\tau_G/\sigma_G)^2]^{3/2}} \tag{16-166}$$

For EMG peaks, peak skew increases with the ratio $\tau_G/\sigma_G$. Figure 16-27 illustrates the characteristics of such a peak calculated for $\tau_G/\sigma_G = 1.5$. In general, with $\tau_G/\sigma_G > 1$ (peak skew > 0.7), a direct calculation of the moments is required to obtain a good approximation of the true value of $N_p$, since other methods give a large error (Yau et al., *Modern Size-Exclusion Liquid Chromatography,* Wiley, New York, 1979). Alternatively, Eq. (16-165) can be fitted to experimental peaks to determine the optimum values of $t_G$, $\sigma_G$, and $\tau_G$.

In practice, the calculation of peak skew for highly tailing peaks is rendered difficult by baseline errors in the calculation of third moments. The *peak asymmetry factor*, $A_s = b/a$, at 10 percent of peak height (see Fig. 16-27) is thus often used. An approximate relationship between peak skew and $A_s$ for tailing peaks, based on data in Yau et al. (*Modern Size-Exclusion Liquid Chromatography,* Wiley, New York, 1979) is: Peak skew ~ $[0.51 + 0.19/(A_s - 1)]^{-1}$. Values of $A_s < 1.25$ (corresponding to peak skew < 0.7) are generally desirable for an efficient chromatographic separation.

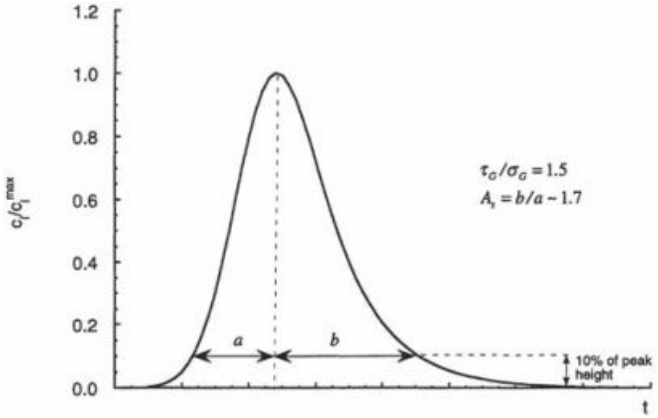

**FIG. 16-27** Exponentially modified Gaussian peak with $\tau_G/\sigma_G = 1.5$. The graph also shows the definition of the peak asymmetry factor $A_s$ at 10 percent of peak height.

**Resolution** The chromatographic separation of two components, A and B, under trace conditions with small feed injections can be characterized in terms of the resolution, $R_s$:

$$R_s = \frac{2(t_{R,A} - t_{R,B})}{W_A + W_B} \sim \frac{\Delta t_R}{4\sigma_{AB}} \tag{16-167}$$

where $\Delta t_R$ is the difference in retention time of the two peaks and $\sigma_{AB} = (\sigma_A + \sigma_B)/2$ is the average of their standard deviations. Time can be replaced with mobile phase volume passed through the column. When Eq. (16-161) is applicable (that is, for nearly Gaussian peaks), the resolution for two closely spaced peaks is approximated by:

$$R_s = \frac{1}{2}\frac{\alpha - 1}{\alpha + 1}\frac{\bar{k}'_i}{1 + \bar{k}'}\sqrt{N_p} \sim \frac{\alpha - 1}{4}\frac{k'_A}{1 + k'_A}\sqrt{N_p} \qquad \text{for } \alpha \sim 1 \tag{16-168}$$

where $\alpha = k'_A/k'_B$ and $\bar{k}' = (k'_A + k'_B)/2$.

Equation (16-168) shows that the resolution is the result of the independent effects of the separation selectivity ($\alpha$), column efficiency ($N_p$), and capacity ($\bar{k}'$). Generally, peaks are essentially completely resolved when $R_s = 1.5$ (>99.5 percent separation). In practice, values of $R_s \sim 1$, corresponding to ~98 percent separation, are often considered adequate.

The preceding equations are accurate to within about 10 percent for feed injections that do not exceed 40 percent of the final peak width. For large, rectangular feed injections, the baseline width of the response peak is approximated by:

$$W \sim 4\sigma + t_F \tag{16-169}$$

where $4\sigma$ is the baseline width obtained with a pulse injection and $t_F$ is the duration of the actual feed injection. In this case, the resolution is defined as [see Ruthven (1984), pp. 324–331]:

$$R_s = \frac{t_{R,A} - t_{R,B} - t_F}{4\sigma_{AB}} \tag{16-170}$$

For strongly retained components ($\bar{k}' >> 1$), the number of plates required to obtain a given resolution with a finite feed injection is approximated by:

$$N_p = 4R_s^2\left(\frac{\alpha + 1}{\alpha - 1}\right)^2\left(1 + \frac{t_F}{4\sigma_{AB}R_s}\right)^2 \tag{16-171}$$

## PREDICTION OF CHROMATOGRAPHIC BEHAVIOR

The conservation equations and the rate models described in the subsection Rate and Dispersion Factors can normally be used for a quantitative description of chromatographic separations. Alternatively, *plate models* can be used for an approximate prediction, lumping together all dispersion contributions into a single parameter, the HETP or the number of plates [Sherwood et al., *Mass Transfer,* McGraw-Hill, New York, 1975, p. 576; Dondi and Guiochon, *Theoretical Advancements in Chromatography and Related Techniques,* NATO-ASI, Series C: Mathematical and Physical Sciences, vol. 383, Kluwer, Dordrecht, 1992, pp. 1–61]. Exact analytic solutions are generally available for linear isocratic elution under trace conditions [see Dondi and Guiochon, cited above, and Ruthven (1984), pp. 324–335; Suzuki (1990), pp. 224–243; and Carta and Jungbauer (2010), pp. 246–258 in General References]. Other cases generally require numerical solution [see Guiochon, Felinger-Shirazi, and Katti (2006) in General References] or approximate treatments with simplified rate models.

**Isocratic Elution** In the simplest case, feed with concentration $c_i^F$ is applied to the column for a time $t_F$ followed by the pure carrier fluid. Under trace conditions, for a linear isotherm with external mass-transfer control, the linear driving force approximation or reaction kinetics (see Table 16-12), solution of Eq. (16-146) gives the following expression for the dimensionless solute concentration at the column outlet:

$$c_i^* = J(N, N\tau_1) - J(N, N\tau'_1) \tag{16-172}$$

where $N$ is the number of transfer units given in Table 16-13 and $\tau_1 = (\varepsilon vt/L - \varepsilon)/[(1 - \varepsilon)(\rho_p K_i + \varepsilon_p)]$ the throughput parameter (see Square Root Spreading for Linear Isotherms in the subsection Fixed-Bed Transitions). $\tau'_1$ represents the value of $\tau_1$ with time measured from the end of the feed step. Thus, the column effluent profile is obtained as the difference between a breakthrough profile for a feed started at $t = 0$ and another for a feed started at $t = t_F$.

The behavior predicted by this equation is illustrated in Fig. 16-28 with $N = 80$. $\tau_F = (\varepsilon vt_F/L)/[(1 - \varepsilon)(\rho_p K_i + \varepsilon_p)]$ is the dimensionless duration of the feed step and is equal to the amount of solute fed to the column divided by the sorption capacity. Thus, at $\tau_F = 1$, the column has been supplied with an amount of solute equal to the stationary phase capacity. The graph shows the transition from a case where complete saturation of the bed occurs before elution ($\tau_F = 1$) to incomplete saturation as $\tau_F$ is progressively reduced. The lower curves with $\tau_F \le 0.4$ are seen to be nearly Gaussian and centered at a dimensionless time $\tau_m \sim (1 - \tau_F/2)$. Thus, as $\tau_F \to 0$, the response curve approaches a Gaussian centered at $\tau_1 = 1$.

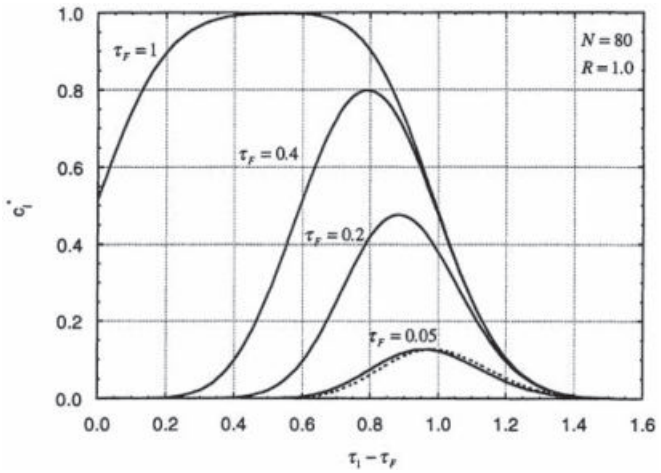

**FIG. 16-28** Elution curves under trace linear equilibrium conditions for different feed loading periods and $N = 80$. Solid lines, Eq. (16-172); dashed line, Eq. (16-174) for $\tau_F = 0.05$.

When $\tau_F$ is small (<<0.4), the solution for a feed pulse represented by a Dirac's delta function at $\zeta = 0$ can be used in lieu of Eq. (16-172). In terms of the dimensionless concentration $c_i^* = c_i/c_i^F$ (Sherwood et al., *Mass Transfer,* McGraw-Hill, New York, 1975, pp. 571–577):

$$c_i^* = \frac{\tau_F N}{\sqrt{\tau_1}} e^{-N} e^{-N\tau_1} I_1(2N\sqrt{\tau_1}) \tag{16-173}$$

where $I_1$ is the Bessel function of the imaginary argument. When $N$ is larger than ~5, this equation is approximated by:

$$c_i^* = \frac{\tau_F}{2\sqrt{\pi}}\sqrt{\frac{N}{\tau_1}}\frac{\exp[-N(\sqrt{\tau_1} - 1)^2]}{(\tau_1)^{1/4}} \tag{16-174}$$

The behavior predicted by Eq. (16-174) is shown in Fig. 16-29 as $c_i^*/(\tau_F\sqrt{N})$ versus $\tau_1$ for different values of $N$. For $N > 50$, the response peak is symmetrical, the peak apex occurs at $\tau_1 = 1$, and the dimensionless peak height is $c_i^{*\max} = \tau_F\sqrt{N/4\pi}$. A comparison of this equation with Eq. (16-172) with $N = 80$ is shown in Fig. 16-28 for $\tau_F = 0.05$.

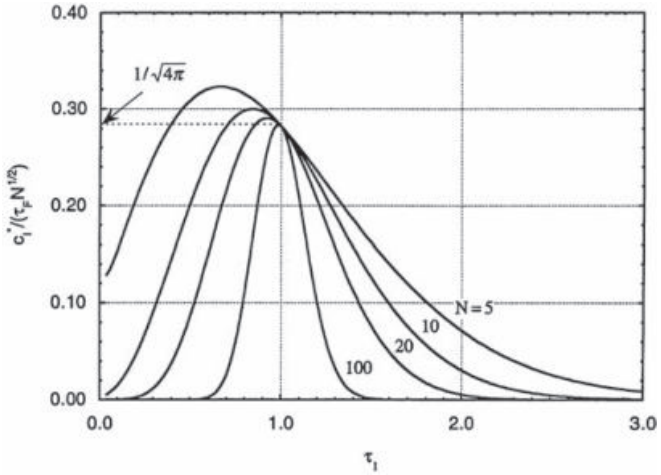

**FIG. 16-29** Elution curves under trace linear equilibrium conditions with a pulse feed from Eq. (16-174).

The moments of the response peak predicted by Eq. (16-173) are

$$\mu_1 = \frac{L}{v}\left[1+\frac{1-\varepsilon}{\varepsilon}(\varepsilon_p+\rho_p K_i)\right] = \frac{L}{v}(1+k_i') \tag{16-175}$$

$$\sigma^2 = \frac{2\mu_1^2}{N}\left(\frac{k_i'}{1+k_i'}\right)^2 \tag{16-176}$$

where $k_i' = (1-\varepsilon)(\varepsilon_p+\rho_p K_i)/\varepsilon$. Correspondingly, the number of plates and the HETP are:

$$N_p = \frac{N}{2}\left(\frac{1+k_i'}{k_i'}\right)^2 \tag{16-177}$$

$$\text{HETP} = \frac{2L}{N}\left(\frac{k_i'}{1+k_i'}\right)^2 \tag{16-178}$$

Since the term $(1+k_i')/k_i'$ approaches unity for large values of $k'$, the number of plates is about equal to one-half the number of transfer units for a strongly retained component. For these conditions, when $N_p \sim N/2$, Eqs. (16-174) and (16-161) produce the same peak retention time, peak spreading, and predict essentially the same peak profile.

In the general case of axially dispersed plug flow with bidispersed particles, the first and second moment of the pulse response are [Haynes and Sarma, *AIChE J.* **19:** 1043 (1973)]:

$$\mu_1 = \frac{L}{v}\left[1+\frac{1-\varepsilon}{\varepsilon}(\varepsilon_p+\rho_p K_i)\right] = \frac{L}{v}(1+k_i') \tag{16-179}$$

$$\sigma^2 = \frac{2LD_L}{v^3}(1+k_i')^2 + 2\frac{L}{v}\frac{\varepsilon k_i'^2}{1-\varepsilon}\left[\frac{r_p}{3k_f}+\frac{r_p^2}{15\varepsilon_p D_{pi}}+\frac{\rho_p K_i}{(\varepsilon_p+\rho_p K_i)^2}\frac{r_s^2}{15D_{si}}\right] \tag{16-180}$$

Correspondingly, the number of plates and the plate height are:

$$N_p = \left\{\frac{2D_L}{vL}+\frac{2\varepsilon}{1-\varepsilon}\frac{v}{L}\left(\frac{k'}{1+k_i'}\right)^2\times\left[\frac{r_p}{3k_f}+\frac{r_p^2}{15\varepsilon_p D_{pi}}+\frac{\rho_p K_i}{(\varepsilon_p+\rho_p K_i)^2}\frac{r_s^2}{15D_{si}}\right]\right\}^{-1} \tag{16-181}$$

$$\text{HETP} = \frac{2D_L}{v}+\frac{2\varepsilon v}{1-\varepsilon}\left(\frac{k_i'}{1+k_i'}\right)^2\times\left[\frac{r_p}{3k_f}+\frac{r_p^2}{15\varepsilon_p D_{pi}}+\frac{\rho_p K_i}{(\varepsilon_p+\rho_p K_i)^2}\frac{r_s^2}{15D_{si}}\right] \tag{16-182}$$

In dimensionless form, a *reduced HETP*, $h = \text{HETP}/d_p$, analogous to the reduced HTU (cf. Fig. 16-13), is obtained as a function of the dimensionless velocity ReSc*:*

$$h = \frac{b}{\text{ReSc}}+a+c\,\text{ReSc} \tag{16-183}$$

where

$$b = 2\varepsilon\gamma_1 \tag{16-184a}$$

$$a = 2\gamma_2 \tag{16-184b}$$

$$c = \frac{1}{30}\frac{1}{1-\varepsilon}\left(\frac{k'}{1+k'}\right)^2\left[\frac{10}{\text{Sh}}+\frac{\tau_p}{\varepsilon_p}+\frac{\rho_p K_i}{(\varepsilon_p+\rho_p K_i)^2}\frac{r_s^2}{D_{si}}\frac{D_{pi}}{r_p^2}\right] \tag{16-184c}$$

Equation (16-183) is qualitatively the same as the **van Deemter equation** [van Deemter and Zuiderweg, *Chem. Eng. Sci.* **5:** 271 (1956)] and is equivalent to other empirical reduced HETP expressions such as the **Knox equation** [Knox, *J. Chromatogr. Sci.* **15:** 352 (1977)].

The Sherwood number, Sh, is estimated from Table 16-9, and the dispersion parameters $\gamma_1$ and $\gamma_2$ from Table 16-10 for well-packed columns. Typical values are $a = 1$–4 and $b = 0.5$–1. Since HETP ~ 2 HTU, Fig. 16-13 can also be used for approximate calculations.

**Concentration Profiles** In the general case but with a linear isotherm, the concentration profile can be found by numerical inversion of the Laplace-domain solution of Haynes and Sarma [see Lenhoff, *J. Chromatogr.* **384:** 285 (1987)] or by direct numerical solution of the conservation and rate equations. For the special case of no axial dispersion, an explicit time-domain solution is also available in the cyclic steady state for repeated injections of arbitrary duration $t_F$ followed by an elution period $t_E$ with cycle time $t_c = t_F + t_E$ [Carta, *Chem. Eng. Sci.* **43:** 2877 (1988)]. For the linear driving force mechanism, the solution is

$$c_i^* = \phi\frac{2}{\pi}\sum_{j=1}^{\infty}\left\{\frac{1}{j}\exp\left(-\frac{j^2N}{j^2+\omega^2}\right)\sin(j\pi\phi)\times\cos\left[\frac{2j\pi}{t_c}\left(t-\frac{t_F}{2}-\frac{L}{v}\right)-\frac{j\omega N}{j^2+\omega^2}\right]\right\} \tag{16-185}$$

where

$$\phi = \frac{t_F}{t_c} \tag{16-185a}$$

$$\omega = \frac{N\varepsilon v t_c/L}{2\pi(1-\varepsilon)(\rho_p K_i+\varepsilon_p)} \tag{16-185b}$$

The average effluent concentration in a product cut between times $t_1$ and $t_2$ can be calculated directly from

$$\bar{c}_i^* = \frac{\int_{t_1}^{t_2} c_i^*\,dt}{t_2-t_1} = \phi+\frac{t_c}{t_2-t_1}\frac{2}{\pi^2}\times\sum_{j=1}^{\infty}\left\{\frac{1}{j^2}\exp\left(-\frac{j^2N}{j^2+\omega^2}\right)\sin(j\pi\phi)\sin\left[j\pi\frac{t_2-t_1}{t_c}\right]\times\cos\left[\frac{2j\pi}{t_c}\left(\frac{t_1+t_2-t_F}{2}-\frac{L}{v}\right)-\frac{j\omega N}{j^2+\omega^2}\right]\right\} \tag{16-186}$$

The same equations can also be used as a good approximation for other rate mechanisms with $N$ calculated according to Table 16-13. When $t_c$ is large, Eq. (16-185) describes a single feed injection and approaches the results of Eqs. (16-173) and (16-148) for small and large values of $\phi$, respectively. For sample calculations, see Carta, *Chem. Eng. Sci.* **43:** 2877 (1988) and Seader and Henley (2006) in General References.

When the adsorption equilibrium is nonlinear, skewed peaks are obtained, even when $N$ is large. For a constant separation-factor isotherm with $R < 1$ ( favorable), the leading edge of the chromatographic peak is steeper than the trailing edge. When $R > 1$ (unfavorable), the opposite is true.

Figure 16-30 portrays numerically calculated chromatographic peaks for a constant separation factor system showing the effect of feed loading on the elution profile with $R = 0.5$ ($\tau_1 - \tau_F = [\varepsilon v(t - t_F)/L - \varepsilon]/\Lambda$). When the dimensionless feed time $\tau_F = 1$, the elution curve comprises a sharp leading profile reaching the feed concentration followed by a gradual decline to zero. As $\tau_F$ is reduced, breakthrough of the leading edge occurs at later times, while the trailing edge, past the peak apex, continues to follow the same profile. As the amount of feed injected approaches zero, mass-transfer resistance reduces the solute concentration to values that fall in the Henry's law limit of the isotherm, and the peak retention time gradually approaches the value predicted in the infinite dilution limit for a linear isotherm.

For high feed loads, the shape of the diffuse trailing profile and the location of the leading front can be predicted from local equilibrium theory (see the subsection Fixed-Bed Transitions). This is illustrated in Fig. 16-30 for $\tau_F = 0.4$. For the diffuse profile (a "simple wave"), Eq. (16-131) gives:

$$c_i^* = \frac{R}{1-R}\left[\left(\frac{1}{R(\tau_1-\tau_F)}\right)^{1/2}-1\right] \tag{16-187}$$

Thus, the effluent concentration becomes zero at $\tau_1 - \tau_F = 1/R$. The position of the leading edge (a "shock front") is determined from Eq. (16-132):

$$\tau_{1s} = \tau_F+\frac{1}{R}\left[1-\sqrt{(1-R)\tau_F}\right]^2 \tag{16-188}$$

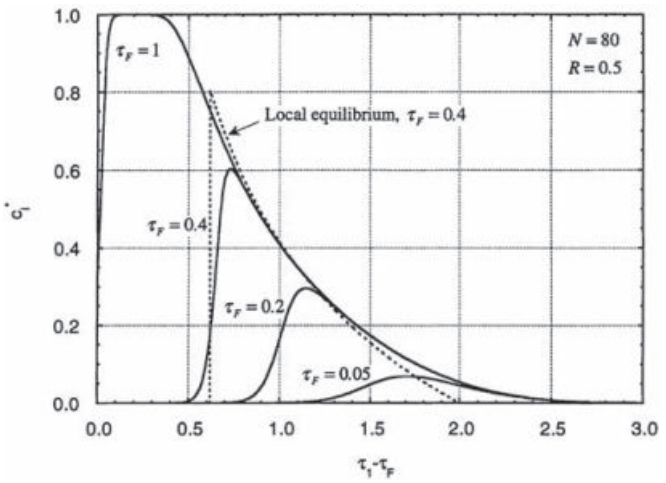

**FIG. 16-30** Elution curves under trace conditions with a constant separation factor isotherm for different feed loadings and $N = 80$. Solid lines, rate model; dashed line, local equilibrium theory for $\tau_F = 0.4$.

and the peak highest concentration by [Golshan-Shirazi and Guiochon, *Anal. Chem.* **60:** 2364 (1988)]:

$$c_i^{*\max} = \frac{R}{1-R}\,\frac{\sqrt{(1-R)\tau_F}}{1-\sqrt{(1-R)\tau_F}} \tag{16-189}$$

The local equilibrium curve is in approximate agreement with the numerically calculated profiles except at very low concentrations when the isotherm becomes linear and near the peak apex. This occurs because band-spreading, in this case, is dominated by adsorption equilibrium, even if the number of transfer units is not very high. A similar treatment based on local equilibrium for a two-component mixture is given by Golshan-Shirazi and Guiochon [*J. Phys. Chem.* **93:** 4143 (1989)].

Prediction of multicomponent nonlinear chromatography accounting for rate factors requires numerical solution [see Guiochon, Felinger-Shirazi, and Katti (2006) and Numerical Methods and Characterization of Wave Shape in the subsection Fixed-Bed Transitions).

**Linear Gradient Elution** Analytical solutions are available for special cases under trace conditions with a linear isotherm. Other situations normally require a numerical solution. General references are Snyder (in Horvath, ed., *High Performance Liquid Chromatography: Advances and Perspectives*, vol. 1, Academic Press, 1980, p. 208), Antia and Horvath [*J. Chromatogr.* **484:** 1 (1989)], Yamamoto et al. (*Ion Exchange Chromatography of Proteins,* Marcel Dekker, 1988), and Guiochon, Felinger-Shirazi, and Katti (2006).

The most commonly used gradients are linear gradients where the starting solvent is gradually mixed with a second gradient-forming solvent at the column entrance to yield a volume fraction φ of the mobile phase modulator that increases linearly with time:

$$\varphi = \varphi_0 + \beta t \tag{16-190}$$

When the mobile phase modulator is a dilute solute in a solvent, as when the modulator is a salt, φ indicates molar concentration. As before, time can be replaced by the volume of mobile phase passed through the column.

Under *trace conditions,* the retention of the modulator in the column is independent of the presence of any solutes. The modulator concentration at the column exit is thus approximated by

$$\varphi = \varphi_0 + \beta\left[t - \frac{L}{v}(1+k'_M)\right] \tag{16-191}$$

where $k'_M$ is the retention factor of the modulator.

For a small feed injection, the modulator concentration $\varphi_R$ at which a feed solute is eluted from the column is obtained from the following integral:

$$G(\varphi_R) = \frac{\beta L}{v} = \int_{\varphi_0}^{\varphi_R} \frac{d\varphi}{k'_i(\varphi) - k'_M} \tag{16-192}$$

where $k'_i(\varphi)$ is the solute retention factor expressed as a function of the mobile phase modulator concentration. Note that the solute retention time in the column is affected by the steepness of the gradient at the column entrance.

$k'_i(\varphi)$ can be obtained experimentally from isocratic elution experiments at different φ values, or from linear gradient elution experiments where the ratio $G = \beta L/v$ is varied. In the latter case, the retention factor is obtained by differentiation of Eq. (16-192) from $k'_i(\varphi_R) = k'_M + (dG/d\varphi_R)^{-1}$.

Table 16-14 gives explicit expressions for chromatographic peak properties in isocratic elution and linear gradient elution for two cases.

In *reversed-phase chromatography* (RPC), the mobile phase modulator is typically a water-miscible organic solvent, and the stationary phase is a hydrophobic adsorbent. In this case, the logarithm of solute retention factor is commonly found to be linearly related to the volume fraction of the organic solvent.

In *ion-exchange chromatography* (IEC), the mobile phase modulator is typically a salt in aqueous solution, and the stationary phase is an ion exchanger. For dilute conditions, the solute retention factor is commonly found to be a power-law function of the salt normality [cf. Eq. (16-27) for ion-exchange equilibrium].

Band broadening is also affected by the gradient steepness. This effect is expressed in Table 16-14 by a *band compression factor C,* which is a function of the gradient steepness and of equilibrium parameters. Since $C < 1$, gradient elution yields peaks that are sharper than those that would be obtained in isocratic elution at $\varphi = \varphi_R$.

Other cases, involving an arbitrary relationship between the solute retention factor and the modulator concentration, can be handled analytically using the approaches of Frey [*Biotechnol. Bioeng.* **35:** 1055 (1990)] and Carta and Stringfield [*J. Chromatogr.* **605:** 151 (1992)].

**Displacement Development** A complete prediction of displacement chromatography accounting for rate factors requires a numerical solution since the adsorption equilibrium is nonlinear and intrinsically competitive. When the column efficiency is high, however, useful predictions can be obtained with the local equilibrium theory (see the subsection Fixed-Bed Transitions). For constant separation factor systems, the h-*transformation* of Helfferich and Klein (1970) or the method of Rhee et al. [*AIChE J.* **28:** 423 (1982)] can be used [see also Helfferich, *Chem. Eng. Sci.* **46:** 3320 (1991)].

**TABLE 16-14 Expressions for Predictions of Chromatographic Peak Properties in Linear Gradient Elution Chromatography Under Trace Conditions with a Small Feed Injection and Inlet Gradient Described by $\varphi = \varphi_o + \beta t$ (Adapted from Refs. A and B)**

| Parameter | Isocratic | Gradient elution—RPC (Ref. A) | Gradient elution—IEC (Ref. B) |
|---|---|---|---|
| Dependence of retention factor on modulator concentration | — | $k' - k'_M = \alpha_s e^{-S\varphi}$ | $k' - k'_M = \alpha_z \varphi^{-z}$ |
| Retention time | $t_R = \frac{L}{v}(1+k'_o)$ | $t_R = \frac{L}{v}(1+k'_M) + \frac{1}{S\beta}\ln\left[\frac{S\beta L}{v}(k'_o - k'_M) + 1\right]$ | $t_R = \frac{L}{v}(1+k'_M) + \frac{1}{\beta}\left[\frac{\alpha_Z \beta L}{v}(Z+1) + \varphi_o^{Z+1}\right]^{1/(Z+1)} - \frac{\varphi_o}{\beta}$ |
| Mobile phase composition at column exit | $\varphi_R = \varphi_o$ | $\varphi_R = \varphi_o + \beta\left[t_R - \frac{L}{v}(1+k'_M)\right]$ | $\varphi_R = \varphi_o + \beta\left[t_R - \frac{L}{v}(1+k'_M)\right]$ |
| Retention factor at peak elution | $k'_R = k'_o$ | $k'_R = \frac{k'_o + (k'_o - k'_M)\,S\beta L/v}{1 + (k'_o - k'_M)\,S\beta L/v}$ | $k'_R = \alpha_Z\left[\frac{\alpha_Z \beta L}{v}(Z+1) + \varphi_o^{Z+1}\right]^{-Z/(Z+1)} + k'_M$ |
| Peak standard deviation | $\sigma = \frac{L/v}{\sqrt{N_p}}(1+k'_o)$ | $\sigma = C\frac{L/v}{\sqrt{N_{pR}}}(1+k'_R)$ | $\sigma = C\frac{L/v}{\sqrt{N_{pR}}}(1+k'_R)$ |
| Band compression factor | — | $C = \frac{(1+p+p^2/3)^{1/2}}{1+p}$<br>$p = \frac{(k'_o - k'_M)(1+k'_M)\,S\beta L/v}{1+k'_o}$ | $C = \begin{cases} \sqrt{M'} & \text{for } M' < 0.25 \\ \frac{3.22M'}{1+3.13M'} & \text{for } 0.25 < M' < 0.25 \\ 1 & \text{for } M' > 120.25 \end{cases}$<br>$M' = \frac{1}{2}\,\frac{1+k'_R}{1+k'_M}\,\frac{Z+1}{Z}$ |

Analyses of displacement chromatography by the method of characteristics with non-Langmuirian systems is discussed by Antia and Horvath [*J. Chromatogr.* **556:** 199 (1991)] and Carta and Dinerman [*AIChE J.* **40:** 1618 (1994)]. Optimization studies and analyses by computer simulations are discussed by Jen and Pinto [*J. Chromatogr.* **590:** 47 (1992)], Katti and Guiochon [*J. Chromatogr.* **449:** 24 (1988)], and Phillips et al. [*J. Chromatogr.* **54:** 1 (1988)]. A detailed example of displacement chromatography based on the *h*-transformation and the preceding equations is given elsewhere [LeVan and Carta (2008)].

## DESIGN FOR TRACE SOLUTE SEPARATIONS

The design objectives of the analyst and the production line engineer are generally quite different. For analysis the primary concern is typically resolution. Hence operating conditions near the minimum value of the HETP or the HTU are desirable (see Fig. 16-13).

In preparative chromatography, however, it is generally desirable to reduce capital costs by maximizing the *productivity*, or the amount of feed processed per unit column volume, subject to specified purity requirements. This reduction, however, must be balanced against operating costs that are determined mainly by the mobile phase flow rate and the pressure drop. In practice, preparative chromatography is often carried out under *overload conditions*, that is, in the nonlinear region of the adsorption isotherm. Optimization under these conditions is discussed in Guiochon, Felinger-Shirazi, and Katti (2006). General guidelines for trace-level, isocratic binary separations, in the Henry's law limit of the isotherm are:

1. The stationary phase is selected to provide the maximum selectivity. Where possible, the retention factor is adjusted (by varying the mobile phase composition, temperature, or pressure) to an optimum value that generally falls between 2 and 10. Resolution is adversely affected when $k' \ll 2$, while product dilution and separation time increase greatly when $k' \gg 10$. When this is not possible for all feed components and large differences exist among the $k'$-values of the different solutes, gradient elution should be considered.
2. The average feed mixture charging rate, molar or volumetric, is fixed by the raw material supply or the demand for finished product.
3. The value of $N_p$ required to achieve a desired resolution is determined by Eq. (16-168) or (16-171). Since $N = L/\text{HTU} \sim 2N_p = 2L/\text{HETP}$, Fig. 16-13 or Eq. (16-183) can be used to determine the range of the dimensionless velocity ReSc that maximizes $N_p$ for a given particle diameter and column length.
4. The allowable pressure drop influences the choice of the particle size and helps determine the column length. Equations for estimating the pressure drop in packed beds are given in Sec. 6.
5. For a binary separation, the component bands may occupy only a small portion of the total column volume at any given instant. In such cases, the productivity is improved by cyclic feed injections, timed so that the most strongly retained component from an injection elutes just before the least strongly retained component from the following injection [see Fig. 10.5 in Carta and Jungbauer (2010)]. For the linear isotherm case with $\bar{k}' > 1$, when the same resolution is maintained between bands of the same injections and bands of successive injections, the cycle time $t_c$ and the plate number requirement are:

$$t_c = 2(t_{R,A} - t_{R,B}) = \frac{2L}{v}(k'_A - k'_B) \tag{16-193}$$

$$N_p = 4R_s^2\left(\frac{\alpha+1}{\alpha-1}\right)^2 (1-2\phi)^{-2} \tag{16-194}$$

where $\phi = t_F/t_c$ is the fraction of the cycle time during which feed is supplied to the column. The productivity, $P$ = volume of feed/(time × bed volume), is:

$$\begin{aligned} P &= \frac{1}{4R_s^2}\left(\frac{\alpha-1}{\alpha+1}\right)^2 \frac{\varepsilon v}{\text{HETP}}\phi(1-2\phi)^2 \\ &= \frac{1}{4R_s^2}\left(\frac{\alpha-1}{\alpha+1}\right)^2 \frac{D_i}{d_p^2}\left(\frac{\text{ReSc}}{b/\text{ReSc} + a + c\text{ReSc}}\right)\phi(1-2\phi)^2 \end{aligned} \tag{16-195}$$

For a given resolution, $P$ is maximized when $\phi = 1/6$ (i.e., feed is supplied for one-sixth of the cycle time), and by the use of small particle sizes. The function $\text{ReSc}/(b/\text{ReSc} + a + c\text{ReSc})$ generally increases with ReSc, so that productivity generally increases with the mobile phase velocity. For typical columns, however, this function is within about 10 percent of its maximum value ($\sim 1/c$) when ReSc is in the range 30–100. Thus, increasing the velocity above this range must be balanced against the costs associated with the higher pressure drop. Similar results are predicted with Eq. (16-185).

When using highly selective adsorbents for chromatographic separations, the process is often operated in a so-called load-wash-elute mode. The product of interest is selectively adsorbed in the load step, unbound impurities are removed in the wash step, and the product is recovered in the elution step. Optimization of productivity for this mode of operation is discussed in Carta and Jungbauer (2010), pp. 311–321. In general, when intraparticle mass transfer is controlling, an optimum residence time exists for the load step that maximizes productivity.

# PROCESS CYCLES

## GENERAL CONCEPTS

The mode of operation of an adsorption process may consist of just one step with the adsorbent removed at the end for reactivation or disposal. Such a process may be carried out in a fixed bed or agitated vessel. These are discussed in Batch Adsorption. Although there are many practical applications for which the sorbent is discarded after one use, most applications involve the removal of adsorbates from the adsorbent (i.e., regeneration). This allows the adsorbent to be reused and the adsorbates to be recovered, and the adsorption process is carried out in a cyclic fashion.

A cyclic adsorption process generally consists of repeated adsorption and desorption (regeneration) cycles carried out *in situ*. Some such applications may involve a single bed as in simple water softening, but most applications involve multiple beds running in a sequence. While one or more beds are in an adsorption mode, one or more beds are in a desorption mode, and after a certain time the roles of beds switch and the cycle continues. Cyclic adsorption processes are commonly carried out today in fixed and simulated moving beds. Regeneration is accomplished by changing a thermodynamic variable such as temperature, total pressure, partial pressure, or adsorptive selectivity. These cyclic adsorption processes are respectively called temperature-swing adsorption (TSA), pressure-swing adsorption (PSA), inert purge, and displacement purge. Ideal equilibrium cycles for each of these processes are shown in Fig. 16-31. Alternative to equilibrium-based separations are separations based on different mass transfer rates of the adsorbates in the adsorbent (i.e., kinetic separations) or size exclusion. Examples of the separation modes are given in Table 16-1.

## BATCH ADSORPTION

Some applications of adsorption and ion exchange are achieved by sorbent–fluid contact in batch equipment. Batch methods are well adapted to laboratory use and have also been applied on a larger scale. In a batch run for either adsorption or ion exchange, a sorbent is added to a fluid, mixed, and separated. Batch treatment is adopted when the capacity and equilibrium of the sorbent are large enough to give nearly complete sorption in a single step, as in purifying and decoloration of laboratory preparations with carbons and clays. Batch runs are useful in the measurement of equilibrium isotherms and adsorptive diffusion rates.

Some commercial applications use the adsorbent on a throwaway basis. Reasons for using sorption nonregeneratively are usually: (1) low cost of the sorbent, (2) high value of the product, (3) very low dosage (sorbent-to-fluid ratio), and (4) difficulty in desorbing the sorbates. Magnesium perchlorate and barium oxide are used for drying, iron sponge (hydrated iron oxide on wood chips) is used to remove hydrogen sulfide, and sodium or potassium hydroxide is applied to remove sulfur compounds or carbon dioxide. In wastewater treatment, powdered activated carbon (PAC) is added to enhance biological treatment but is not regenerated; instead, it remains with the sludge. Silica gel is used as a desiccant in packaging, especially with electronics and medicines. Activated carbon is used in packaging and storage to adsorb other chemicals for preventing the tarnishing of silver, retarding the ripening or spoiling of fruits, "gettering" (scavenging) out-gassed solvents from electronic components, and removing odors. Synthetic zeolites, or blends of zeolites with silica gel, are used in dual-pane windows

to adsorb water during initial dry-down and any in-leakage and to adsorb organic solvents emitted from the sealants during their cure; this prevents fogging between the sealed panes that could result from the condensation of water or the solvents [Ausikaitis, *Glass Digest* **61:** 69 (1982)]. Activated carbon is used to treat recirculated air in office buildings, apartments, and manufacturing plants using thin filter-like frames to treat the large volumes of air with low pressure drop. On a smaller scale, activated carbon filters are in kitchen hoods, air conditioners, electronic air purifiers, and faucets and refrigerators for water purification. On the smallest scale, gas masks containing carbon or carbon impregnated with promoters are used to protect individual wearers from industrial odors, toxic chemicals, and gas-warfare chemicals. Activated carbon fibers have been formed into fabrics for clothing to protect against vesicant and percutaneous chemical vapors [Macnair and Arons, in Cheremisinoff and Ellerbusch (1978) in General References] and to prevent the scent of humans from being detected by animals being hunted.

Ion exchangers are sometimes used on a throwaway basis also, with detergency being an extensive application. In the laboratory, ion exchangers are used to deionize water, purify reagents, and prepare inorganic sols. In medicine, they are used as antacids, for sodium reduction, for sustained release of drugs, in skin-care preparations, and in toxin removal.

## ADSORPTION CYCLES

The maximum efficiency that a cyclic adsorption process can approach for any given set of operating conditions is given by the adsorptive loading in equilibrium with the feed. This is true whether the separation is based on equilibrium, kinetics, or molecular sieving, because it is anticipated that a faster diffusing or nonexcluded component in a fluid approaches its equilibrium loading. There are several factors that reduce the practical (or "operating") adsorption performance: mass-transfer resistance (see above), deactivation, and incomplete regeneration. The severity of regeneration influences how closely the dynamic capacity of an adsorbent resembles that of fresh, virgin material. Regeneration requires a reduction in the driving force for adsorption. This is accomplished by increasing the equilibrium driving force for the adsorbed species to desorb from the solid to the surrounding fluid.

## TEMPERATURE-SWING ADSORPTION

A temperature-swing or thermal-swing adsorption (TSA) process cycle is one in which desorption takes place at a temperature much higher than adsorption. The elevation of temperature is used to shift the adsorption equilibrium and effect regeneration of the adsorbent. Figure 16-31*a* illustrates the principle of the TSA cycle. The feed fluid containing an adsorbate at a partial pressure of $p_1$ is passed through an adsorbent at temperature $T_1$. This adsorption step continues until the equilibrium loading $n_1$ is achieved with $p_1$. Next, the adsorbent temperature is raised to $T_2$ (heating step) so that the partial pressure in equilibrium with $n_1$ is increased to $p_2$, creating a partial pressure driving force for desorption into fluid containing less than $p_2$ of the adsorbate. By passing a purge fluid across the adsorbent, the adsorbate is swept away, and the equilibrium proceeds down the isotherm to some point such as $p_1$, $n_2$. (As a practical matter, in some applications, roll-up of the adsorbed-phase concentration occurs during heating such that in some regions of the bed $p_2$ reaches the condensation pressure of the component, causing a condensed liquid phase to form temporarily in particles [Friday and LeVan, *AIChE J.* **31:** 1322 (1985)]. Also, a heel of adsorbate is often left in the bed for an optimal process, especially for very favorable isotherms, for which it is difficult to remove trace quantities of adsorbate.) During a cooling step, the adsorbent temperature is returned to $T_1$. The new equilibrium $p_3$, $n_2$ represents the best-quality product that can be produced from the adsorbent at a regenerated loading of $n_2$ in the simplest cycle. The adsorption step is now repeated. The differential loading, $n_1 - n_2$, is the maximum loading that can be achieved for a TSA cycle operating between a feed containing $p_1$ at temperature $T_1$, regeneration at $T_2$, and a product containing a partial pressure $p_3$ of the adsorbate. The regeneration fluid will contain an average partial pressure between $p_2$ and $p_1$ and will therefore have

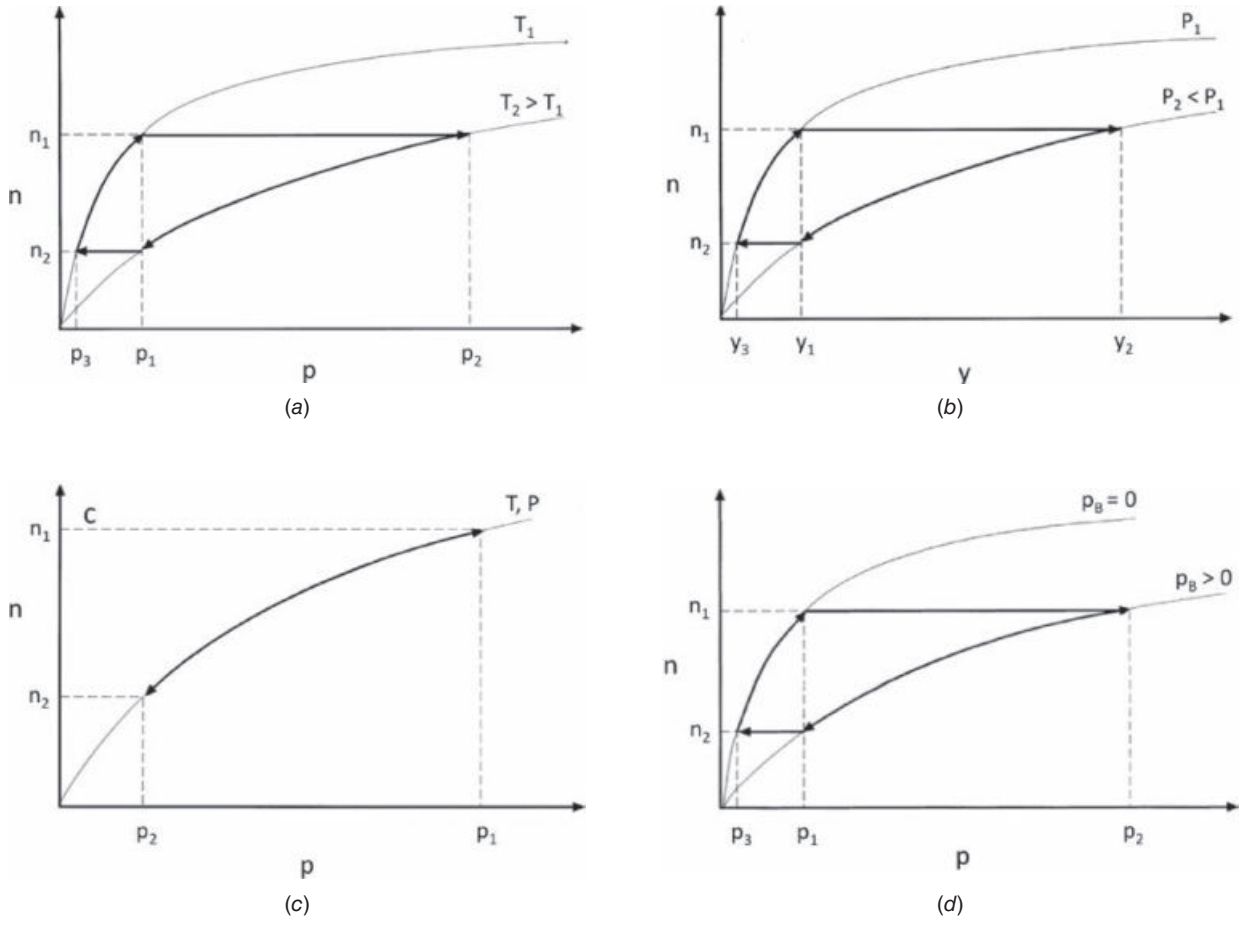

**FIG. 16-31** Idealized adsorption cycles: (*a*) temperature swing, (*b*) pressure swing, (*c*) inert-purge swing, and (*d*) displacement-purge swing. (*Reprinted with permission of UOP.*)

accomplished a concentration of the adsorbate in the regenerant fluid. For liquid-phase adsorption, the partial pressure can be replaced by the fugacity of the adsorbate. Then, the entire preceding discussion is applicable whether the regeneration is by a fluid in the gas or liquid phase.

In a TSA cycle, the heating step must provide the thermal energy necessary to raise the adsorbate, adsorbent, and adsorber temperatures, to desorb the adsorbate, and to make up for heat losses. Heating is accomplished by either direct contact of the adsorbent with the heating medium (external heat exchange to a purge gas) or by indirect means (heating elements, coils, or panels inside the adsorber). Direct heating is the most commonly used, especially for stripping-limited heating. Indirect heating can be considered for stripping-limited heating, but the complexity of indirect heating limits its practicality to heating-limited regeneration where purge gas is in short supply. Microwave fields [Benchanaa et al., *Thermochim. Acta* **152:** 43 (1989)] and dielectric fields [Burkholder et al., *Ind. Eng. Chem. Fundam.* **25:** 414 (1986)] are also used to supply indirect heating.

**Other Cycle Steps** Besides the necessary adsorption and heating steps, TSA cycles may employ additional steps. A purge or sweep gas removes the thermally desorbed components from the adsorbent, and cooling returns it to adsorption temperature. Although the cooling is normally accomplished as a separate step after the heating, sometimes adsorption is started on a hot bed. If certain criteria are met [Basmadjian, *Can. J. Chem. Eng.* **53:** 234 (1975)], the dynamic adsorption efficiency is not significantly affected by the lack of a cooling step.

For liquid-phase adsorption cycles when the unit is to treat a product of significant value, there must be a step to remove the liquid from the adsorbent and one to displace any liquid regenerant thoroughly before filling with the valuable fluid. Because adsorbents and ion exchangers are porous, some retention of the product is unavoidable, but it needs to be minimized to maximize recovery. When regeneration is by a gas, removal and recovery are accomplished by a drain (or pressure-assisted drain) step using the gas to help displace liquid from the sorbent before heating. When the regenerant is another liquid, the feed or product can be displaced out of the adsorbent. When heating and cooling are complete, liquid feed must be introduced again to the adsorbent with a corresponding displacement of the gas or liquid regenerant. In ion exchange, these steps for draining and filling are commonly referred to as "sweetening off" and "sweetening on," respectively.

**Applications** Drying is the most common gas-phase application of TSA. The natural gas, chemical, and cryogenics industries all use adsorbents to dry streams. Zeolites, activated alumina, and silica gel are used for drying pipeline natural gas. Alumina and silica gel are used because they have higher equilibrium capacity and are more easily regenerated with waste-level heat [Crittenden, *Chem. Engr.* **452:** 21 (1988); Goodboy and Fleming, *Chem. Eng. Progr.* **80:** 63 (1984); Ruthven, *Chem. Eng. Progr.* **84:** 42 (1988)]. The low dewpoint that can be achieved with zeolites is especially important when drying cryogenic-process feed streams to prevent freeze-up. Zeolites dry natural gas before liquefaction to liquefied natural gas (LNG) and before ethane recovery using the cryogenic turboexpander process [Anderson in Katzer, ed., *Molecular Sieves—II, Am. Chem. Soc. Symp. Ser.* **40:** 637 (1977); Brooking and Walton, *The Chem. Engr.* **257:** 13 (1972)]. Zeolites, silica gel, and activated alumina are used to dry synthesis gas, inert gas, hydrocracker gas, rare gases, and reformer recycle $H_2$. Because 3A and pore-closed 4A zeolites size-selectively adsorb water but exclude hydrocarbons, they are used extensively to dry reactive streams such as cracked gas in order to prevent coke formation on the adsorbent. This molecular sieving increases the recovery of hydrocarbons by reducing the coadsorption that would otherwise cause them to be desorbed and lost with the water.

Another area of application for TSA processes is in sweetening. $H_2S$, mercaptans, organic sulfides and disulfides, and carbonyl sulfide all must be removed from natural gas, $H_2$, biogas, and refinery streams in order to prevent corrosion and catalyst poisoning. Natural gas feed to steam methane reforming is sweetened in order to protect the sulfur-sensitive, low-temperature shift catalyst. Wellhead natural gas is treated by TSA to prevent pipeline corrosion using 4A zeolites to remove sulfur compounds without the coadsorption of $CO_2$ that would cause shrinkage. Sweetening and drying of refinery hydrogen streams are needed to prevent poisoning of reformer catalysts. Adsorption can be used to dry and sweeten these in the same unit.

TSA processes are applied to the removal of many inorganic pollutants. $CO_2$ is removed from base-load and peak-shaving natural-gas liquefaction facilities using 4A zeolite in a TSA cycle. The Sulfacid and Hitachi fixed-bed processes, the Sumitomo and BF moving-bed processes, and the Westvaco fluidized-bed process all use activated carbon adsorbents to remove $SO_2$ from flue gases and sulfuric acid plant tail gases [Juentgen, *Carbon* **15:** 273 (1977)]. Activated carbon with a catalyst is used by the Unitaka process to remove $NO_x$ by reacting with ammonia, and activated carbon has been used to convert NO to $NO_2$, which is removed by scrubbing. Mercury vapor from air and other gas streams is removed and recovered by activated carbon impregnated with elemental sulfur; the Hg is then recovered by thermal oxidation in a retort [Lovett and Cunniff, *Chem. Eng. Progr.* **70:** 43 (1974)]. Applications for HCl removal from $Cl_2$, chlorinated hydrocarbons, and reformer catalyst gas streams use TSA with mordenite and clinoptilolite zeolites [Dyer (1988), pp. 102–105 in General References]. Activated aluminas are also used for HCl adsorption as well as fluorine and boron-fluorine compounds from alkylation processes [Crittenden, *Chem. Engr.* **452:** 21 (1988)].

Another important application of TSA is for the purification of air before it enters cryogenic air separation units. These TSA prepurification units (PPUs) remove carbon dioxide, water vapor, and trace organic compounds, among many other compounds, to avoid plugging, prevent explosions, and minimize corrosion in the cryogenic units [Kumar et al., *Adsorption* **9:** 243 (2003)]. The TSA vessels usually contain consecutive layers of activated alumina and molecular sieve zeolite (e.g., NaX). Additional layers of other adsorbents may also be used depending on the feed components [Kumar et al., *Adsorption* **9:** 243 (2003)]. Regeneration is carried out at high temperature using a purge gas at ambient pressure, usually nitrogen in an amount equivalent to about 10 percent of the feed gas.

## PRESSURE-SWING ADSORPTION

A pressure-swing adsorption (PSA) process cycle is one in which desorption takes place at a pressure much lower than adsorption. Reduction of pressure is used to shift the adsorption equilibrium and affect regeneration of the adsorbent. Figure 16-31*b* depicts a simplified PSA cycle. Feed containing adsorbate at a mole fraction of $y_1 = p_1/P_1$ is passed through an adsorbent bed at conditions $T_1$, $P_1$, and the adsorption step continues until the equilibrium loading $n_1$ is achieved with $y_1$. Next, the total pressure is reduced to $P_2$ during the depressurization (or blowdown) step. Now, although the partial pressure in equilibrium with $n_1$ is still $p_1$, there is a concentration driving force of $y_2 = p_1/P_2 > y_1$ for desorption into fluid containing less than $y_2$. By passing a fluid across the adsorbent in a purge step, adsorbate is swept away, and the equilibrium proceeds down the isotherm to some point such as $y_1$, $n_2$. (The choice of $y_1$ is arbitrary and need not coincide with the feed composition.) The adsorbent is then repressurized to $P_1$. The new equilibrium $y_3$, $n_2$ represents the best-quality (light) product that can be produced from the adsorbent at a regenerated loading of $n_2$. The adsorption step is now repeated. The differential loading, $n_1 - n_2$, is the maximum loading that can be achieved for a PSA cycle operating between a feed containing $y_1$ and a light product containing $y_3$ of the adsorbate. The regeneration fluid will contain an average concentration between $y_2$ and $y_1$ and will therefore have accomplished a concentration of the adsorbate in the regenerant gas, that is, in the heavy product. There is no analog for a liquid-phase PSA process cycle.

Thus, in a PSA process cycle, regeneration is achieved by a depressurization that must reduce the partial pressure of the adsorbates to allow desorption. These cycles operate at constant temperature, requiring no heating or cooling steps. Rather, they use the exothermic heat of adsorption remaining in the adsorbent to supply the energy needed for desorption. Pressure-swing cycles are classified as: (1) PSA, which, although used broadly, usually swings between a high superatmospheric and a low superatmospheric pressure; (2) VSA (vacuum-swing adsorption), which swings from a slightly superatmospheric pressure to a low subatmospheric pressure; (3) PVSA, which swings from a high superatmospheric pressure to a low subatmospheric pressure; and (4) rapid (R) PSA or rapid cycle (RC) PSA, characterized by very fast cycle times (seconds) and high bed velocities, with minimal bed pressure drop afforded in some cases by using structured adsorbents. Two other classes also exist that affect separation by forcing a significant pressure gradient along the adsorbent bed by using small adsorbent particles and very fast cycle times (seconds). These are (5) PSPP (pressure-swing parametric pumping) and (6) an older version of RPSA, better termed pressure drop (PD) PSA so as not to confuse it with its modern analog (these are discussed in the subsection Parametric Pumping). For all six classes of PSA, the broad principles nevertheless remain the same, with their performance judged by the purity and recovery of any of the desirable species in the light or heavy product and either the feed throughput—that is, the amount of feed processed per unit time per unit mass of adsorbent—or the productivity—that is, the amount of product produced per unit time per unit mass of adsorbent.

Low pressure is not as effective in totally reversing adsorption as is temperature elevation unless very high feed-to-purge-pressure ratios are applied (e.g., deep vacuum). Therefore, most PSA cycles are characterized by high residual loadings and thus low operating loadings. These low capacities at high concentrations require that cycle times be short for reasonably sized beds (usually minutes). These short cycle times are attainable because adsorbent particles respond quickly to changes in pressure.

**Cycle Steps** A PSA cycle may have several other steps in addition to the basic adsorption (or feed), depressurization (countercurrent), and

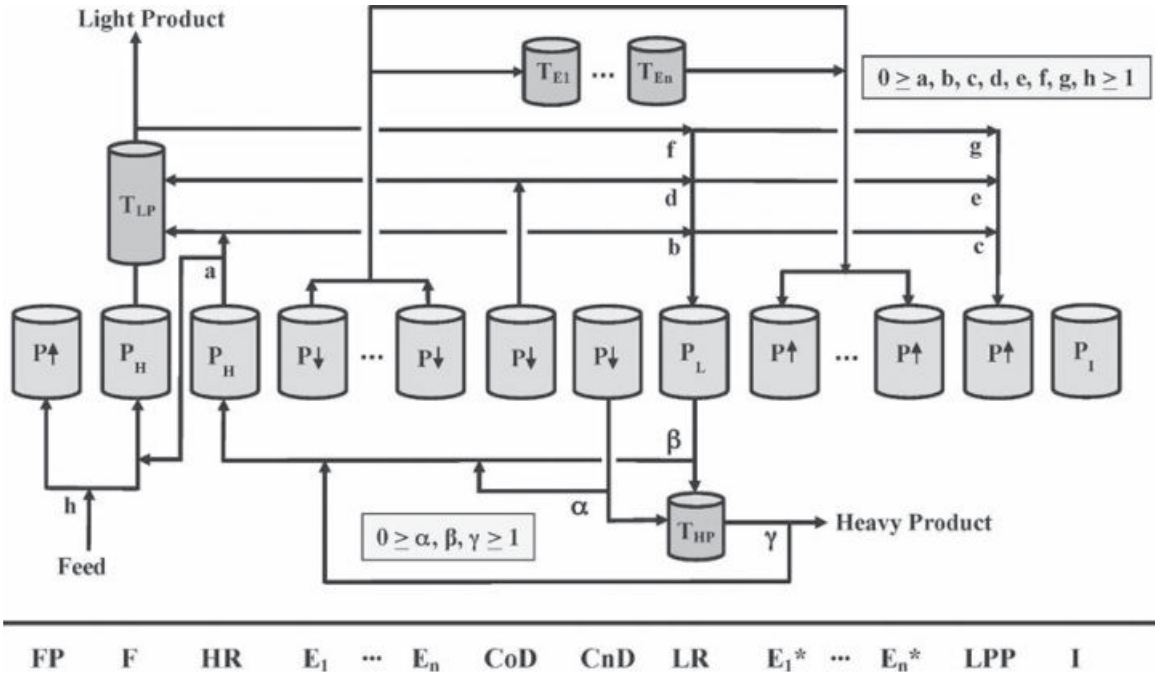

**FIG. 16-32** Possible steps in a PSA cycle: feed (F), cocurrent depressurization (CoD), countercurrent depressurization (CnD), purge or light reflux (LR), rinse or heavy reflux (HR), bed-to-bed pressure equalization (E), light product or feed pressurization (LPP, FP), bed-to-tank-to-bed pressure equalization (with T), and idle (I).

repressurization steps introduced with reference to Fig. 16-31*b*. Cocurrent depressurization, purge (or light reflux), bed-to-bed pressure equalization, and rinse (or heavy reflux) steps can be added to increase separation efficiency and improve recovery of the light and/or heavy products. Thus, there are just these seven possible fundamental steps in any PSA process. Each of these steps and how they communicate with other beds undergoing other cycle steps by providing or receiving gas are shown in Fig. 16-32. Two additional but less common steps are also shown in this figure. They are a bed-to-tank-to-bed equalization step and an idle step. The former uses a tank that does not contain any adsorbent to equalize with a bed in two successive steps. The latter occurs when a bed sits idle for a certain time during the cycle, and although it performs no separative work while doing so and thus should be avoided, idle steps are required in some cases to schedule the sequence of cycle steps in each bed so they all align properly in time.

The sequence of steps from left to right in Fig. 16-32 is just one way they may be carried out in time in a PSA process. Another example would be to have the cocurrent depressurization step between two pressure equalization steps. All of these steps may be used in a PSA process, or just some of them, or just the three basic steps, depending on the application.

A PSA cycle schedule is defined by the cycle step sequence and the number of beds, with each bed running the exact same sequence but out of phase with each other. A PSA process usually contains two or more beds interconnected in some fashion, but a process with only one bed can also be used with the proper use of tanks (uncommon). When just considering the use of some or all of these seven to nine steps and the fact that modern PSA processes routinely operate with 2 to 20 interconnected beds, literally thousands of different designs or permutations exist in the development of a PSA cycle schedule [see Mehrotra et al., *Adsorption* **16:** 113 (2010)]. To further complicate the design of a PSA process, there are many choices to be made on the gas flow interconnects or couplings between the beds, as shown in Fig. 16-32. The role of each cycle step and the options that exist with it are discussed next.

The feed (F) step or adsorption step is carried out at the highest pressure ($P_H$) in the cycle and is usually the main light product production step. Some of the feed may be used to finish pressurizing the bed to $P_H$ (as denoted by h). By the end of the F step, the more weakly adsorbed species are recovered as light product, but there is still a significant amount of light product held up in the bed in the interparticle and intraparticle void spaces.

A heavy refux (HR) step, bed-to-bed or bed-to-tank-to-bed pressure equalization steps, and/or a cocurrent depressurization (CoD) step can be added after the feed step and before the countercurrent depressurization (CnD) step to flush the weakly adsorbed species out of the bed cocurrently, thereby also filling the bed with the more strongly adsorbed species. These steps either recycle this gas containing some more weakly adsorbed species back to another bed or it may be taken as additional light product (as denoted by a, b, ... g, h).

The main role of the HR step is to produce a high-purity heavy product (just like in distillation) by taking heavy product gas selected from a variety of sources (as denoted by α, β, and γ), compressing it to $P_H$, and recycling it back to a bed just after the feed step to further concentrate it. The HR step should be thought of as a more concentrated feed step. Instead of at $P_H$, the HR step may also be carried out at some intermediate pressure after an E or CoD step.

Notice that "n" equalization steps are indicated in Fig. 16-32, either bed-to-bed or bed-to-tank-to-bed. Typically, for every additional equalization step, another adsorbent bed is required, possibly with the use of idle steps, unless a tank is used instead [Ebner et al., *Adsorption* **21:** 229 (2015)]. For example, Xu et al. [U.S. Patent 6,454,838 (2002)] discloses two PSA cycle schedules with four equalization steps and just six beds, in one case using idle steps and in another case without using any idle steps because an equalization tank is used.

Even without any equalization steps, the CoD step can be an important step to include. For example, in some applications, the purity of the more strongly adsorbed components has also been shown to be heavily dependent on the CoD step [Cen and Yang, *Ind. Eng. Chem. Fundam.* **25:** 758 (1986)]. CoD is optional because there is always a countercurrent one, that is, the CnD step. Skarstrom developed criteria to determine when the use of the CoD step is justified [Skarstrom, in Li, *Recent Developments in Separation Science,* vol. II, CRC Press, Boca Raton, 1975].

The next step, the CnD step, is one of the three basic cycle steps, as it constitutes the beginning of heavy product production and is thus required in all PSA processes. Once the CnD step commences, unless there is an HR step, all the weakly adsorbed species exiting the bed during this step end up in the heavy product. This reduces the light component recovery and the heavy product purity. The roles of the HR, E, and CoD steps in preventing some of the weakly adsorbed species from ending up in the heavy product via recycle are now clear, with the most efficient cycle being one that most closely matches available pressures and adsorbate concentrations to the appropriate portion of the bed at the proper point in the cycle.

The CnD step may optionally be followed by a purge or light reflux (LR) step. This step is carried out at the lowest pressure ($P_L$) in the PSA cycle and strips additional adsorbates from the adsorbent by decreasing their partial pressures, and it also flushes them from the voids. The main role of the LR step is to produce a high-purity light product (again, just like in distillation).

This is also a heavy product production step unless there is a HR step with certain values of α, β, and γ selected. The LR step can begin toward the end of CnD or immediately afterward. The source of the LR gas may be from the F, HR, or CoD step (as denoted by f, d, and b), with F and CoD being most common.

After the LR step, a bed begins repressurization, either via one or more equalization steps followed by light product pressurization (LPP) or feed pressurization (FP), with LPP being preferred when a high-purity light product is sought. It is worth noting that the equalization steps not only conserve gas via recycle, but they also conserve compression energy. The source of LPP can be from the F, HR, or CoD step (as denoted by g, e, and c). The source of FP is obvious (as denoted by h). FP should be followed by LPP if both are used to keep the heavier adsorbate species more toward the feed end of the bed. Once the bed is back to the feed pressure, the cycle repeats with the feed step. The example provided next serves to illustrate the foundation of a PSA cycle schedule, the associated bed interconnects or coupled steps, and how every bed undergoes the same sequence of cycle steps just out of phase with each other.

The six-bed, 16-step PSA cycle schedule with four equalization steps and three idle steps is shown in Fig. 16-33 [adapted from Xu et al., U.S. Patent 6,454,838 (2002)]. Although it looks complicated, there is much symmetry to a PSA cycle schedule. Bed 1 carries out the cycle step sequence in order by progressing step by step in time. A careful examination shows that this is the case for every bed; they are just out of phase with each other. There are also the six indicated boxes (unit blocks) within this cycle schedule, necessarily one for each bed. Within each unit block, every cycle step must be occurring somewhere in one of the beds. For example, in the leftmost unit block, the cycle step sequence is also written in order by progressing step by step in going from bed 1 to bed 2 and so on to bed 6. Notice that three idle steps are required in this PSA cycle schedule to align properly and thus accommodate all the equalization steps. This is also a continuous feed PSA cycle, with bed 1 being fed first in time, then bed 6, and so on. The feed step is the longest step in the cycle and occupies four unit time steps in each unit block. Some steps occupy only one unit time step, while others occupy two unit time steps, and one occupies three unit time steps. The number of unit time steps in a unit block is a PSA cycle schedule design choice, with a minimum number always advantageous [Mehrotra et al., *Adsorption* **17:** 337 (2011)]. This unequal step time PSA cycle schedule is common because it minimizes the number of beds for a long cycle step sequence and thus maximizes the throughput or productivity. Consider that if each cycle step were the same duration, then 16 beds would be required to run this same 16-step cycle step sequence [Reynolds et al., *Ind. Eng. Chem. Res.* **45:** 4278 (2006)]. More details on PSA cycle schedules and their creation are provided in the works of Ritter and coworkers [*Adsorption* **15:** 406 (2009); **16:** 113 (2010); **17:** 337 (2011); **21:** 229 (2015)].

**Applications** Major uses for PSA processes include the purification of lighter adsorbate species with a feed containing <10 vol% contaminants, as well as applications where heavy adsorbate species are present at high concentrations (>10 vol%), that is, for bulk separations. From 1960 to 1980, the major applications were air drying, hydrogen purification, large-scale oxygen production from air, nitrogen production from air using carbon molecular sieve, and small-scale medical oxygen production (even using a single-bed PSA unit). From 1980 to 1990, additional applications include helium recovery and purification, carbon dioxide recovery, natural gas purification, small-scale nitrogen production from air, linear from branched hydrocarbons (isosiv), solvent vapor recovery, and trace contaminant removal (military). From 2000 onward, new applications include hydrocarbon recovery from nitrogen, helium upgrading from dilute helium streams, ethanol dehydration at an elevated temperature, portable medical oxygen production from air using RCPSA, hydrogen upgrading using RCPSA, and biogas purification (landfill gas) using a titanium silicate molecular sieve (ETS-4). Newer applications still under development include olefin/paraffin separations, carbon dioxide capture from flue gas and from spacecraft cabin air for NASA, bulk purification of ammonia from nitrogen and hydrogen, xenon concentration from air, and even carbon monoxide isotope separation and enrichment [see Bhadra et al., *Adsorption* **19:** 11 (2013)]. Some of the more important or unique commercial and developmental applications are discussed next.

One of the earliest applications of PSA was the original Skarstrom two-bed, four-step cycle [adsorption (F), countercurrent depressurization (CnD), countercurrent purge (LR), and cocurrent repressurization (FP)] that was designed to dry an ambient air stream to less than 1 ppm $H_2O$ [Skarstrom, in Li, *Recent Developments in Separation Science,* vol. II, CRC Press, Boca Raton, 1975]. Instrument-air dryers still use a PSA cycle similar to Skarstrom's with activated alumina or silica gel [Armond, in Townsend, *The Properties and Applications of Zeolites*, The Chemical Society, London, 1980]. With hydrocarbons being excluded by small-pore zeolites, PSA air dryers designed to work with air-brake compressors could achieve a 10 to 30 K dewpoint depression, even at high discharge air temperatures in the presence of compressor oil [Ausikaitis, in Katzer, *Molecular Sieves—II, Am. Chem. Soc. Symp. Ser.* **40:** 681 (1977)]. PSA air dryers are still ubiquitous today.

The next major application for PSA technology was hydrogen purification from a feed stream containing 60 to 70 vol% $H_2$. The high-purity hydrogen employed in processes such as hydrogenation, hydrocracking, and ammonia and methanol production is produced by PSA cycles with layered adsorbent beds typically containing three layers of alumina, activated carbon, and zeolites [Baksh and Terbot, U.S. Patent 6,503,299 (2003)]. Layered beds of activated carbon, zeolite, and carbon molecular sieve have also been used [Martin et al., *Adv. Cryog. Eng.* **31:** 1071 (1986); Ruthven, Farooq, and Knaebel (1994), p. 242 in General References]. The impurities to be removed include water vapor, ammonia, carbon oxides, nitrogen, oxygen, methane, and heavier hydrocarbons. This important application of PSA technology began with four-bed PSA systems routinely achieving hydrogen purities as high as 99.999 vol%. To improve recovery and productivity and also purity to 99.9999 vol%, five- to 16-bed PSA systems with complex PSA cycle schedules (e.g., see Fig. 16-33), such as the UOP Polybed™ PSA systems [Elseviers et al., *50 Years of PSA Technology for $H_2$ Purification*, UOP LLC (2015)], have been commercialized over the past 50 years. A change of the adsorbent inventory moved the focus from $H_2$ purification to the recovery of $CO_2$ from a very large-scale 20-bed PSA process, which began operation at an iron-making facility in Korea in 2013 [Elseviers et al., *50 Years of PSA Technology for $H_2$ Purification*, UOP LLC (2015)]. A unique RCPSA process for upgrading hydrogen in various refinery streams was jointly developed by Xebec Adsorption Inc. and ExxonMobil and commercialized in 2007. It uses a complex PSA

**Time**

**FIG. 16-33** Cycle step sequence and schedule for a six-bed, 16-step PSA process with equalization idle steps (*Adapted from Xe et al., U.S. patent number 6,454,838, 2002*).

cycle schedule operating with cycle times of a few seconds or less in a rotary, five-bed system [Connor et al., U.S. Patent 6,406,523 (2002)] containing a structured adsorbent [Keefer et al., U.S. Patent 6,692,626 (2004)].

Ambient air separation was perhaps the next major type of bulk separation commercialized using PSA. PSA process cycles are used to produce oxygen, nitrogen, or both from air. Synthetic zeolites, clinoptilolite, mordenite, and carbon molecular sieves are all used in various PSA, VSA, VPSA, and RCPSA cycles. Since the mid-1980s, a LiLSX zeolite has been the preferred adsorbent for oxygen production for most large- or small-scale applications [Yang (2003) in General References]. The 85 to 95 percent purity oxygen produced is employed for electric furnace steel, waste water treating, solid waste combustion, and kilns [Martin et al., *Adv. Cryog. Eng.* **31:** 1071 (1986)]. Small medical oxygen PSA units have been used for some time for patients requiring inhalation therapy in the hospital and at home [Cassidy and Holmes, *AIChE Symp. Ser.* **80:** 68 (1984)] and for pilots on board aircraft [Tedor, Horch, and Dangieri, *SAFE J.* **12:** 4 (1982)]. Today, portable medical oxygen PSA technology based on RCPSA technology has flourished because it has made patients more ambulatory. These RCPSA units, provided by many different vendors, use cycle times less than 10 seconds, which makes them very small, lightweight, low power, and battery operated [Rao et al., *AIChE J.* **60:** 3330 (2014)]. Lower-purity oxygen (25 to 55 percent) can be produced to enhance combustion, chemical reactions, and ozone production [Sircar, in Rodrigues, LeVan, and Tondeur (1989), pp. 285–321 in General References]. The $O_2$ depleted product in the tail gas (heavy product) from an $O_2$ PSA unit, which can be tuned to range from about 10 to 15 vol%, has also been used for hypoxic training [Kotliar, U.S. Patent 5,799,652 (1998)], with variants also being proposed for hypoxic fire prevention and suspension systems [Kotliar, U.S. Patent 6,314,754 (2001)]. High-purity nitrogen (up to 99.99 percent) for inert blanketing is produced in PSA and VSA processes using zeolites and carbon molecular sieves [Kawai and Kaneko, *Gas Sep. & Purif.* **3:** 2 (1989); Ruthven et al. 1994].

Another very successful bulk separation done by PSA is the UOP IsoSiv℠ process. The PSA process exploits the pore-size selectivity of zeolite 5A to adsorb straight-chain molecules while excluding branched and cyclic species. This PSA process separates $C_5$ to $C_9$ range hydrocarbons into a normal-hydrocarbon fraction of better than 95 percent purity, and a higher-octane isomer fraction with less than 2 percent normals [Cassidy and Holmes, *AIChE Symp. Ser.* **80:** 68 (1984)].

Methane is upgraded to natural gas pipeline quality by another PSA process. The methane is recovered from fermentation gases of landfills and wastewater purification plants and from poor-quality natural gas wells and tertiary oil recovery. Carbon dioxide is the major bulk contaminant, but the gases contain water and other undesired components such as sulfur and halogen compounds, alkanes, and aromatics [Kumar and VanSloun, *Chem. Eng. Progr.* **85:** 34–40 (1989)]. These impurities are removed by TSA using activated carbon or carbon molecular sieves, and then the $CO_2$ is adsorbed using a PSA cycle. The cycle can use zeolites or silica gel in an equilibrium-selective separation [Knaebel, *Adsorption* **9:** 87 (2003)] or a carbon molecular sieve in a rate-selective separation [Kapoor and Yang, *Chem. Eng. Sci.* **44:** 1723 (1989); Richter et al., *Petrochem.* **40:** 432 (1987)]. The newest commercial PSA systems that treat natural gas or landfill gas use a titanium silicate (ETS-4) adsorbent to kinetically separate $CH_4$ from $N_2$ and/or $CO_2$ [Butwell et al., U.S. Patent 6,197,092 (2001)]. An interesting series of PSA-TSA-PSA, PSA-PSA-PSA, or PSA-PSA processes has also been developed for this purpose [Knaebel, U.S. Patent 8,211,211 (2012)].

Another important application of PSA is for the purification of air before it enters cryogenic air separation units. PSA competes with TSA for this application, depending on many factors [Kumar et al., *Adsorption* **9:** 243 (2003)]. These PSA prepurification units (PPUs), like the TSA PPUs, remove carbon dioxide, water vapor, and trace organic compounds, among many other compounds, to avoid plugging, prevent explosions, and minimize corrosion in the cryogenic units [Kumar et al., *Adsorption* **9:** 243 (2003)]. The PSA PPU usually contains activated alumina and operates a four-step Skarstrom-like cycle using two beds or even three or more beds to produce more purified air. Regeneration is carried out at ambient pressure ($P_L$) using a purge gas (LR), usually nitrogen in an amount equivalent to about 40 percent of the feed gas.

In the late 1980s and throughout the 1990s, PSA technology emerged as an efficient way to concentrate and recover trace chemicals [White, *AIChE Symp. Ser.* **84:** 129 (1988); Ritter and Yang, *Ind. Eng. Chem. Res.* **30:** 1023 (1991)], solvent vapors [Robbins et al., U.S. Patent 4,857,084; Hall and Larrinaga, *Proceedings from the 16th National Industrial Energy Technology Conference*, Houston 1994] and gasoline vapors [Pezolt et al., *Environ. Prog.* **16:** 16 (1997); Liu et al., *AIChE J.* **46:** 540 (2000); Liu et al., *Sep. Purif. Technol.* **20:** 111 (2000)] from air. In each case, the focus was to produce clean air as a light product and a concentrated vapor as a heavy product using a two-bed, four-step Skarstrom-like PSA cycle.

A dual reflux PSA cycle with both stripping and enriching PSA sections and a feed location along the axial length of the column (just like a distillation column), first proposed by Wilson [U.S. Patent 4,359,328 (1982)], has been used to obtain high enrichment and recovery of both products. With the feed being delivered to a two-bed system at the low pressure of the PSA cycle, the separation is much better than that obtainable by normal PSA and suggests that it is possible to obtain two nearly pure products from a dilute feed stream [see McIntire et al., *Ind. Eng. Chem. Res.* **41:** 3499 (2002)]. When using just the enriching section in the same way, that is, with the feed at $P_L$, trace levels of Xe were concentrated up to 80 times with 90 percent recovery using 13X zeolite in a two-bed system with a pressure ratio of only 12.5 [Yoshida et al., *Ind. Eng. Chem. Res.* **42:** 1795 (2003)]. This Xe enrichment PSA technology was commercialized in Japan. A similar enriching PSA cycle was able to separate $N_2$ from air using 13X zeolite in a two-bed, four-step system [Reynolds et al., *Ind. Eng. Chem. Res.* **45:** 3256 (2006)]. The heavy product contained only 0.8 vol% $O_2$ with an $N_2$ recovery of 23.7 percent. Enriching and dual reflux PSA cycles were also used to concentrate organic vapors to the point where they condensed into a liquid without the need of any other unit operation [R. Wakasugi et al., *J. Chem. Eng. Japan* **37:** 374 (2004); *Adsorption* **11:** 561 (2005)].

One of the newest applications for PSA is $CO_2$ capture and concentration from a variety of feed streams where the $CO_2$ is the intended product. These include chemical process flue gas, where it has been commercialized by Mitsubishi Heavy Industry using a layered PSA bed containing X and A type zeolites and activated carbon [Izumi, 8th International Conference on Fundamentals of Adsorption, Sedona, AR, May 2004]; food grade $CO_2$ from $H_2$ production processes commercialized by Linde AG [Voss, *Adsorption* **11:** 527 (2005)]; as previously mentioned, recovery of $CO_2$ from a very large-scale 20-bed PSA process, which began operation at an iron-making facility in Korea in 2013 [Elseviers et al., *50 Years of PSA Technology for $H_2$ Purification*, UOP LLC (2015)]; and for coal-fired power plant flue gas, where it is still under development [Reynolds et al., *Ind. Eng. Chem. Res.* **45:** 4278 (2006)]. It has also been shown experimentally that it is possible to concentrate $CO_2$ in spacecraft cabins from about 4000 ppm to over 90 vol% at 82 percent recovery using a three-bed, eight-step heavy reflux PSA cycle using 13X zeolite (Erden et al., "New PSA Cycle for $CO_2$ Removal During Closed-Loop Human Space Exploration Missions," AIChE Annual Meeting, Salt Lake City, UT, November 2015).

## PURGE/CONCENTRATION SWING ADSORPTION

A purge-swing adsorption cycle is usually considered to be one in which desorption takes place at the same temperature and total pressure as adsorption. Desorption is accomplished either by partial-pressure reduction using an inert gas purge or by adsorbate displacement with another adsorbable component. Purge cycles operate adiabatically at nearly constant inlet temperature and require no heating or cooling steps. As with PSA, they can utilize the heat of adsorption remaining in the adsorbent (if any) to supply the heat of desorption. Purge processes are classified as (1) inert or (2) displacement.

**Inert Purge** In inert-purge desorption cycles, *inert* refers to the fact that the purge gas is not adsorbed significantly at the cycle conditions. Inert purging desorbs the adsorbate solely by partial pressure reduction. Figure 16-31*c* depicts a simplified inert-purge swing cycle using a nonadsorbing purge fluid. The feed stream containing an adsorbate at a partial pressure of $p_1$ is passed through an adsorbent at temperature $T$ and total pressure $P$, and the adsorption step continues until the equilibrium loading $n_1$ is achieved. Next, the nonadsorbing fluid is introduced to reduce the partial pressure below $p_1$. Therefore, there is a partial pressure driving force for desorption into the purge fluid, and the equilibrium proceeds down the isotherm to the point $p_2$, $n_2$, where $p_2$ represents the best-quality product that can be produced from the adsorbent at a regenerated loading of $n_2$. The adsorption step is now repeated, and the differential loading is $n_1 - n_2$. The regeneration fluid will contain an average partial pressure between $p_2$ and $p_1$, and the cycle will have transferred the adsorbate to a fluid from which it may be more easily separated, if desired, by means such as distillation.

Like PSA cycles, inert-purge processes are characterized by high residual loadings, low operating loadings, and short cycle times (minutes). Bulk separations of contaminants not easily separable at high concentration and of weakly adsorbed components are especially suited to inert-purge-swing adsorption. Another version of UOP's IsoSiv process employs $H_2$ in an inert-purge cycle for separating $C_5$ to $C_9$ naphtha by adsorbing straight-chain molecules and excluding branched and cyclic species on size selective 5A zeolite [Cassidy and Holmes, *AIChE Symp. Ser.* **80:** 68 (1984)]. Automobiles made in the United States have canisters of activated carbon to adsorb gasoline vapors lost from the fuel intake system or the gas tank; the vapors are desorbed by an inert purge of air that is drawn into the intake manifold as fuel when the engine is running [Clarke et al., *S.A.E. Trans.* **76:** 824 (1968); Johnson et al., in *Carbon Materials for Advanced Technologies*, ed. T. D. Burchell, Pergamon, New York, 1999]. UOP's Adsorptive Heat Recovery

drying system has been commercialized for drying azeotropic ethanol to be blended with gasoline into gasohol; the process uses a closed loop of $N_2$ as the inert purge to desorb the water [Garg and Yon, *Chem. Eng. Progr.* **82:** 54 (1986)].

**Displacement Purge** Isothermal, isobaric regeneration of the adsorbent can also be accomplished by using a purge fluid that can adsorb. In displacement-purge stripping, *displacement* refers to the displacing action of the purge fluid caused by its ability to adsorb at the cycle conditions. Figure 16-31*d* depicts a simplified displacement-purge swing cycle using an adsorbable purge. Again, the feed stream containing an adsorbate at a partial pressure of $p_1$ is passed through an adsorbent bed at temperature $T_1$, and the adsorption step continues until the equilibrium loading $n_1$ is achieved. Next the displacement fluid, B, is introduced. The presence of another adsorbable species reduces the adsorptivity of the key adsorbate, A. Therefore, there exists a partial pressure driving force for desorption into the purge fluid, and the equilibrium proceeds down the isotherm to some point such as $p_1$, $n_2$ (again, arbitrary.) Next, the adsorbent is recharged with a fluid that contains no component B, shifting the effective isotherm to where the equilibrium of component A is $p_3$. The new equilibrium $p_3$, $n_2$ represents the best-quality product that can be produced from the adsorbent at a regenerated loading of $n_2$. The adsorption step is now repeated. The differential loading $(n_1 - n_2)$ is the maximum loading that can be achieved for a pressure-swing cycle operating between a feed containing $y_1$ and a product containing a partial pressure $p_3$ of the adsorbate. The regeneration fluid will contain an average partial pressure between $p_2$ and $p_1$ and will therefore have accomplished a concentration of the adsorbate in the regenerant gas.

Displacement-purge cycles are not as dependent on energy from the heat of adsorption remaining on the adsorbent, because the adsorption of purge releases most or all of the energy needed to desorb the adsorbate. It is best if the adsorbate is more selectively adsorbed than the displacement purge, so that the adsorbates can easily desorb the purge fluid during adsorption. The displacement purge must be carefully selected because it contaminates both the product stream and the recovered adsorbate and requires separation for recovery (e.g., by distillation).

Displacement-purge processes are more efficient for less selective adsorbate/adsorbent systems, while systems with high equilibrium loading of adsorbate will require more purging [Sircar and Kumar, *Ind. Eng. Chem. Proc. Des. Dev.* **24:** 358 (1985)]. Several displacement-purge-swing processes have been commercialized for the separation of branched and cyclic $C_{10}$–$C_{18}$ from straight-chain molecules using the molecular-size selectivity of 5A zeolite: Exxon's Ensorb, UOP's IsoSiv, Texaco Selective Finishing (TSF), Leuna Werke's Parex, and the Shell Process [Ruthven (1984)]. All use a purge of normal paraffin or light naphtha with a carbon number of two to four less than the feed stream except for Ensorb, which uses ammonia [Yang (1987) in General References]. UOP has also developed a similar process, OlefinSiv, which separates isobutylene from normal butenes with displacement purge and a size-selective zeolite [Adler and Johnson, *Chem. Eng. Progr.* **75:** 77 (1979)]. Solvent extraction to regenerate activated carbon is another example of a displacement-purge cycle; the adsorbent is then usually steamed to remove the purge fluid [Martin and Ng, *Water Res.* **18:** 59 (1984)]. The best use of solvent regeneration is for water phase adsorption where the separation of water from carbon would use too much steam and where purge and water are easily separated, and for vapor-phase where the adsorbate is highly nonvolatile but soluble. Air Products has developed a process for separating ethanol and water on activated carbon using acetone as a displacement agent and adding a water rinse to improve the recovery of two products [Sircar, U.S. Patent 5,026,482 (1991)].

Displacement-purge forms the basis for most simulated continuous countercurrent systems (see hereafter) such as the UOP Sorbex$^{SM}$ processes. UOP has licensed about one hundred Sorbex units for its family of processes: Parex$^{SM}$ to separate *p*-xylene from $C_8$ aromatics, Molex$^{SM}$ for *n*-paraffin from branched and cyclic hydrocarbons, Olex$^{SM}$ for olefins from paraffin, Sarex$^{SM}$ for fructose from dextrose plus polysaccharides, Cymex$^{SM}$ for *p*- or *m*-cymene from cymene isomers, and Cresex$^{SM}$ for *p*- or *m*-cresol from cresol isomers. Toray Industries' Aromax$^{SM}$ process is another for the production of *p*-xylene [Otani, *Chem. Eng.* **80**(9): 106 (1973)]. Illinois Water Treatment [*Making Waves in Liquid Processing,* Illinois Water Treatment Company, IWT Adsep System, Rockford, IL, **6**(1): 1984] and Mitsubishi [Ishikawa, Tanabe, and Usui, U.S. Patent 4,182,633 (1980)] have also commercialized displacement-purge processes for the separation of fructose from dextrose.

## ION EXCHANGE

Except in very small-scale applications, ion exchangers are used in cyclic operations involving sorption and desorption steps. A typical ion-exchange cycle used in water-treatment applications involves (*a*) *backwash*—used to remove accumulated solids obtained by an upflow of water to expand (50–80 percent expansion is typical) and fluidize the exchanger bed; (*b*) *regeneration*—a regenerant is passed slowly through the spent bed to restore the original ionic form of the exchanger; (*c*) *rinse*—water is passed through the bed to remove regenerant from the void volume and, in the case of porous exchangers, from the resin pores; (*d*) *loading*—the fresh solution to be treated is passed through the bed until leakage begins to occur. Water softening is practiced in this way with a cation exchange column in sodium form. At the low ionic strength used in the loading step, calcium and magnesium are strongly preferred over sodium, allowing nearly complete removal. Since the selectivity for divalent cations decreases sharply with ionic concentration, regeneration with a concentrated sodium chloride solution is also very efficient. Removal of sulfates from boiler feed water is done by similar means with anion exchangers in chloride form.

Many ion-exchange columns operate with downflow and are regenerated in the same direction (Fig. 16-34*a*). However, a better regeneration and lower leakage during loading can be achieved by passing the regenerant countercurrently to the loading flow. Specialized equipment is available to perform countercurrent regeneration (see Equipment in this subsection). One approach (Fig. 16-34*b*) is to apply a vacuum to remove the regenerant at the top of the bed.

Complete deionization with ion-exchange columns is the classical method of producing ultrapure water for boiler feed, in electronics manufacture, and for other general uses in the chemical and allied industries. Deionization requires use of two exchangers with opposite functionality to remove both cations and anions. These can be in separate columns, packed in adjacent layers in the same column, or, more frequently, in a mixed bed. In the latter case, the two exchangers are intimately mixed during the loading step. For regeneration, backwashing separates the usually lighter anion exchanger from the usually denser cation exchanger. The column typically has a screened distributor at the interface between the two exchangers, so that they may be separately regenerated without removing them from the column. The most common cycle (Fig. 16-35) permits sequential regeneration of the two exchangers, first with alkali flowing downward through the anion exchanger to the interface distributor and then acid flowing downward from the interface distributor through the cation exchanger. After regeneration and rinsing, the exchangers are remixed by compressed air. To alleviate the problem of intermixing of the two different exchangers and chemical penetration through the wrong one, an inert material of intermediate density can be used to provide a buffer zone between layers of cation and anion exchangers.

When recovery of the sorbed solute is of interest, the cycle is modified to include a displacement step. In the manufacture of pharmaceuticals, ion exchangers are used extensively in recovery and separation. Many of these compounds are amphoteric and are positively or negatively charged, depending on the solution pH. Thus, for example, using a cation exchanger, loading can be carried out at a low pH and displacement at a high pH. Differences in selectivity for different species can be used to carry out separations during the displacement [Carta et al., *AIChE Symp. Ser.* **84:** 54 (1988)]. Multibed cycles are also used to facilitate integration with other chemical process operations. Figure 16-36 shows a two-bed ion-exchange system using both cation and anion exchangers to treat and recover chromate from rinse water in plating operations. The cation exchanger removes trivalent chromium, while the anion exchanger removes hexavalent chromium as an anion. Regeneration of the cation exchanger with sulfuric acid produces a concentrated solution of trivalent chromium as the sulfate salt. The hexavalent chromium is eluted from the anion exchanger with sodium

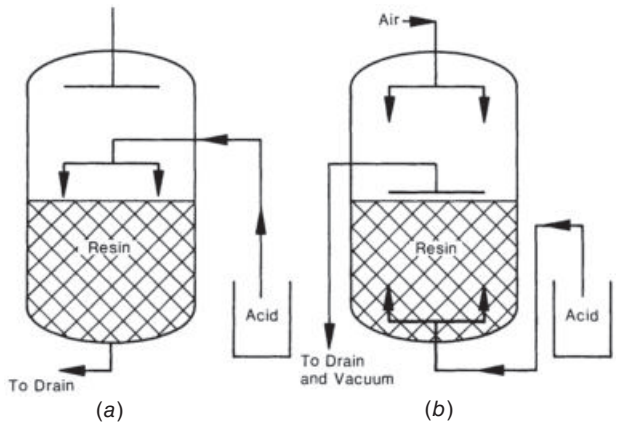

**FIG. 16-34** Ion-exchanger regeneration. (*a*) Conventional. Acid is passed downflow through the cation-exchange resin bed. (*b*) Counterflow. Regenerant solution is introduced upflow with the resin bed held in place by a dry layer of resin.

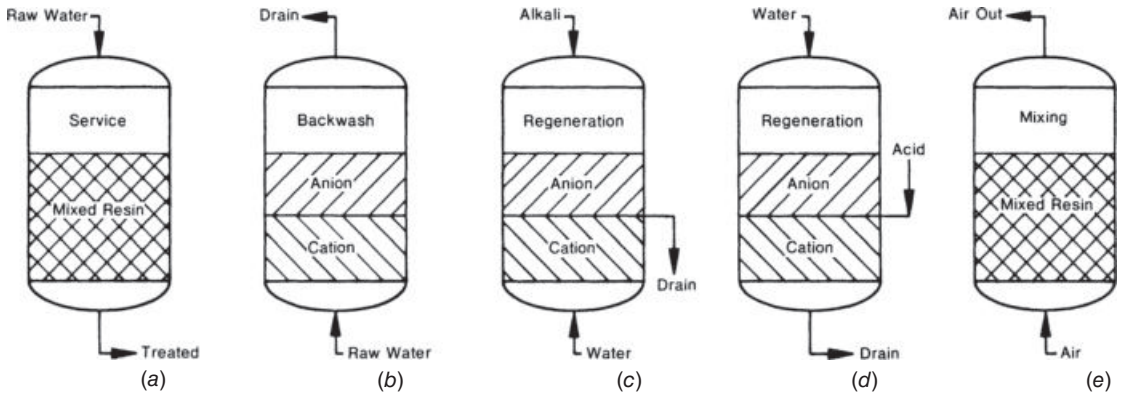

**FIG. 16-35** Principles of mixed-bed ion exchange. (*a*) Service period (loading). (*b*) Backwash period. (*c*) Caustic regeneration. (*d*) Acid regeneration. (*e*) Resin mixing.

hydroxide in a concentrated solution. This solution is recycled to the plating tank by passing it through a second cation exchange column in hydrogen form to convert the sodium chromate to a dilute chromic acid solution that is concentrated by evaporation.

## PARAMETRIC PUMPING

The term *parametric pumping* was coined by Wilhelm et al. [Wilhelm, Rice, and Bendelius, *Ind. Eng. Chem. Fundam.* **5:** 141 (1966)] to describe a liquid-phase adsorption process in which separation is achieved by periodically reversing not only flow but also an intensive thermodynamic property such as temperature, which influences adsorption equilibrium. Moreover, they considered the concurrent cycling of pressure, pH, and electrical and magnetic fields. A lot of research and development has been conducted on thermal, pressure, and pH-driven cycles, but to date only gas-phase pressure-swing parametric pumping has found extensive commercial acceptance.

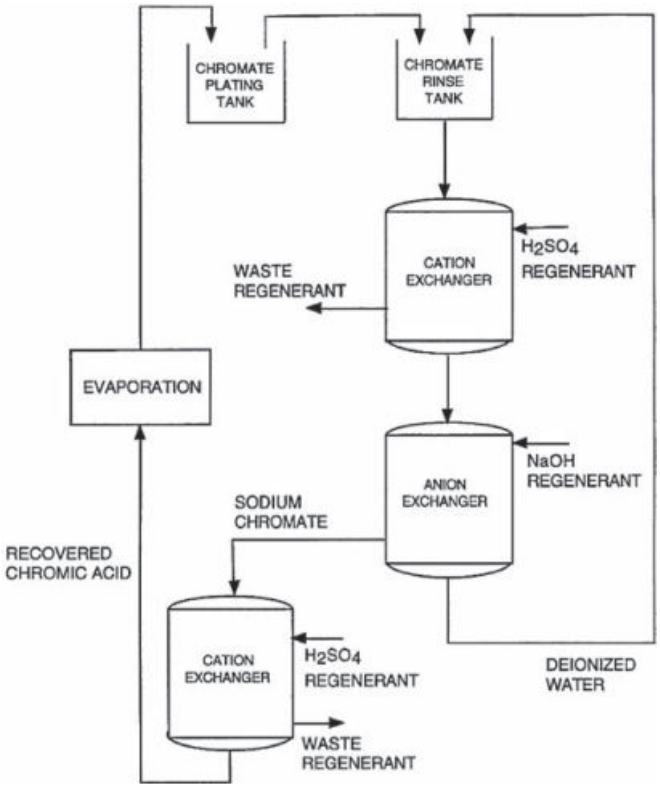

**FIG. 16-36** Multicomponent ion-exchange process for chromate recovery from plating rinse water. (*Adapted from "Ion Exchange Resins for Metal Plating and Surface Finishing," Rhom and Haas Company, Philadelphia, PA, USA, December 1999.*)

**Temperature** Two modes of temperature parametric-pumping cycles have been defined—direct and recuperative. In direct mode, an adsorbent column is heated and cooled while the fluid feed is pumped forward and backward through the bed from reservoirs at each end. When the feed is a binary fluid, one component will concentrate in one reservoir and one in the other. In recuperative mode, the heating and cooling takes place outside the adsorbent column. Parametric pumping, thermal and pH modes, have been widely studied for separation of liquid mixtures. However, the primary success for separating gas mixtures in thermal mode has been the separation of propane/ethane on activated carbon [Jencziewski and Myers, *Ind. Eng. Chem. Fundam.* **9:** 216 (1970)] and of air/$SO_2$ on silica gel [Patrick et al., *Sep. Sci.* **7:** 331 (1972)]. The difficulty with applying the thermal mode to gas separation is that in a fixed volume, gas pressure increases during the hot step, which defeats the desorption purpose of this step. No thermal parametric-pumping cycle has yet been practiced commercially.

**Pressure** Another approach to parametric pumping is accomplished by pressure cycling of an adsorbent. An adsorbent bed is alternately pressurized with forward flow and depressurized with backward flow through the column from reservoirs at each end. Like TSA parametric pumping, one component concentrates in one reservoir and one in the other. The pressure mode of parametric pumping has been called pressure-swing parametric pumping (PSPP) and rapid pressure-swing adsorption (RPSA) or pressure drop (PD) PSA to avoid confusing it with its modern RC PSA (or RPSA) analog discussed in the PSA section. It was developed to minimize process complexity and investment at the expense of product recovery. RPSA (or PDPSA) is practiced in single-bed [Keller and Jones, in Flank, *Adsorption and Ion Exchange with Synthetic Zeolites* **135:** 275–286 (1980)] and multiple-bed (Earls and Long, U.S. Patent number 4,194,892, 1980) implementations. Adsorbers are short (about 0.3 to 1.3 m), and particle sizes are very small (about 150 to 400 mm). The total cycle time, including adsorption (F), dead (idle) time, countercurrent depressurization (CnD), and sometimes a second dead (idle) time, ranges from a few to about 30 seconds. The feature of RPSA (or PD PSA) that differentiates it from traditional PSA is the existence of axial pressure profiles throughout the cycle, much as temperature gradients are present in TSA parametric pumping. Whereas PSA processes have essentially constant pressure through the bed at any given time, the flow resistance of the very small adsorbent particles produces substantial pressure drop in the bed. These pressure dynamics are important to the attainment of separation performance. The light product end of the bed stays essentially at $P_H$ over the entire cycle, while the feed/heavy product end of the bed cycles between $P_H$ and $P_L$, thereby forcing adsorption and desorption of the heavier adsorbate species. Effectively, the light species is parametrically pumped up a pressure gradient to the light product end of the bed, while the heavier species are removed from the other end when the cycle is changing from $P_H$ to $P_L$. RPSA (or PD PSA) has been commercialized for the production of oxygen and for the recovery of ethylene and chlorocarbons (the selectively adsorbed species) in an ethylene-chlorination process while purging nitrogen (the less selectively adsorbed species).

## SIMULATED MOVING BED SYSTEMS

The concept of a simulated moving-bed (SMB) system was originally used in a process developed and licensed under the name UOP Sorbex process [Broughton et al., *Pet. Int. (Milan)* **23**(3): 91 (1976); **23**(5): 26 (1976)]. The basic process, used for separating a binary mixture, is illustrated in Fig. 16-37. As shown, the process employs a stack of packed beds connected to a

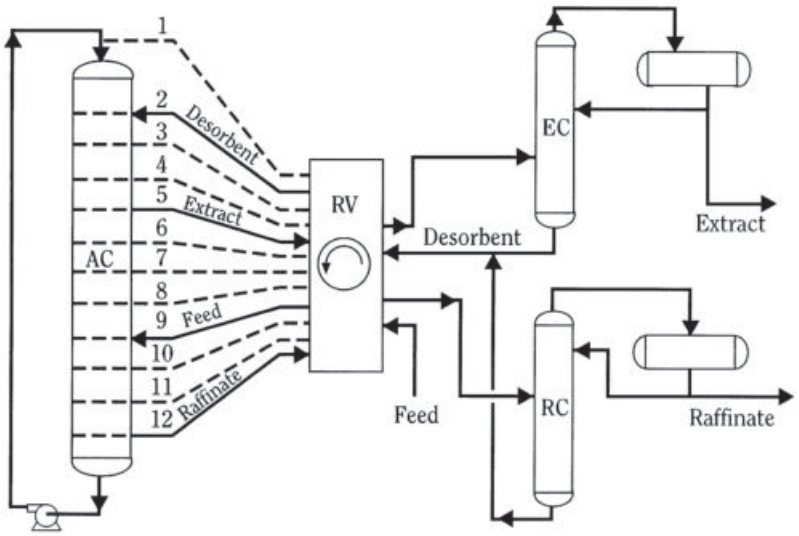

**FIG. 16-37** UOP Sorbex process. (*Reprinted with permission of John Wiley & Sons, Inc. Reference: Gembicki, Oroskar, and Johnson, "Adsorption, Liquid Separation," in* Kirk-Othmer Encyclopedia of Chemical Technology, *4th ed., John Wiley & Sons, Inc., New York, 1991.*)

rotary valve (RV) that allows the introduction of feed and desorbent and the collection of extract and raffinate streams at different junctions. Feed and withdrawal points are switched periodically as shown, resulting in a periodic counterflow of adsorbent. Even with a small number of packed beds, the periodic countercurrent action closely simulates the behavior of a true countercurrent system without the complexities associated with particle flows. Distillation columns are shown in Fig. 16-37 integrated with the adsorption system to recover and recycle the desorbent. Although the Sorbex process was originally applied to hydrocarbon separations, extensive industrial applications have been developed for sugars, amino acids, and fine chemicals, especially chiral separations. Practical operation is not restricted to rotary valves. Using multiple individual valves to control the distribution of flows is often more practical, especially on a smaller scale.

The basic principle of operation is illustrated in Fig. 16-38 by reference to an equivalent true countercurrent moving-bed (TMB) system comprising four idealized moving-bed columns or "zones." The feed containing components *A* and *B* is supplied between zones II and III. The least strongly adsorbed species, *A*, is recovered between zones III and IV, while the more strongly adsorbed species, *B*, is recovered between zones I and II. The adsorbent is recirculated from the bottom of zone I to the top of zone IV. A desorbent or eluent makeup stream is added to the fluid recycled from zone IV, and the combined stream is fed to the bottom of zone I. The main purpose of each zone is as follows: Zone III adsorbs *B* while letting *A* pass through. Zone II desorbs *A* while adsorbing *B*. Zone I desorbs *B*, allowing recycle of the adsorbent. Zone IV adsorbs *A*. Proper selection of operating conditions is needed to obtain the desired separation. The ensuing analysis is based on local equilibrium and plug flow conditions and assumes linear isotherms with a nonadsorbable desorbent. In the following $u^j$ [$m^3/(m^2 \cdot s)$] represents the fluid-phase velocity in zone $j$ and $u_s$ [$kg/(m^2 \cdot s)$] the adsorbent velocity, with both velocities defined based on the column cross-sectional area. Net upward transport of each component is determined by the component velocity

$$u_i^j = u^j - u_s\left(\frac{\varepsilon_p}{\rho_p} + \frac{n_i}{c_i}\right) \tag{16-196}$$

The following inequalities must be met to obtain the desired separation:

$$u_B^{\mathrm{I}} > 0 \tag{16-197a}$$

$$u_A^{\mathrm{II}} > 0, \quad u_B^{\mathrm{II}} < 0 \tag{16-197b}$$

$$u_A^{\mathrm{III}} > 0, \quad u_B^{\mathrm{III}} < 0 \tag{16-197c}$$

$$u_A^{\mathrm{IV}} < 0 \tag{16-197d}$$

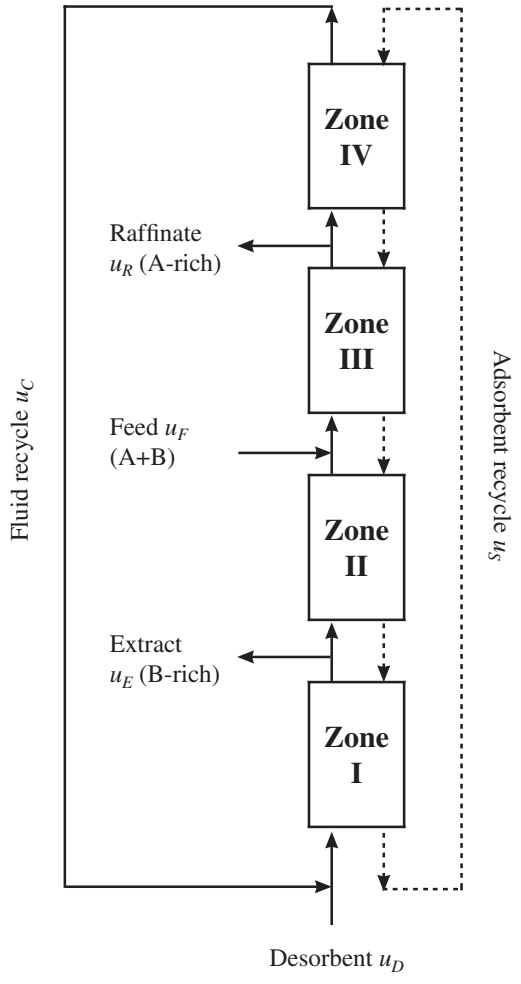

**FIG. 16-38** General scheme of a true moving-bed (TMB) adsorption system for binary separations. *A* is less strongly retained than *B*.

Accordingly, $A$ moves downward in zone IV and upward in zone III and is recovered between these two zones. Similarly, $B$ moves upward in zone I and downward in zone II and is recovered between these two zones. Combining Eqs. (16-196) and (16-197) yields the following constraints:

$$m^{\mathrm{I}} > K_B \tag{16-198a}$$

$$K_B > m^{\mathrm{II}} > K_A \tag{16-198b}$$

$$K_B > m^{\mathrm{III}} > K_A \tag{16-198c}$$

$$m^{\mathrm{IV}} < K_A \tag{16-198d}$$

where $K_i$ is the linear isotherm slope [cf. Eq. (16-12)] and

$$m^j = \frac{u^j - u_s \varepsilon_p / \rho_p}{u_s} \tag{16-199}$$

is a flow ratio ($m^3$/kg). Inequalities (16-197$b$) and (16-197$c$) determine whether separation will occur and can be represented on the $m^{\mathrm{III}} - m^{\mathrm{II}}$ plane in Fig. 16-39. Since $m^{\mathrm{III}} > m^{\mathrm{II}}$, only the region above the 45° line is valid. Values of $m^{\mathrm{II}}$ and $m^{\mathrm{III}}$ below $K_A$ or above $K_B$ result in incomplete separation. Thus, complete separation requires operation within the shaded triangular region. The vertex of this triangle represents the point of maximum productivity under ideal conditions. In practice, mass-transfer resistances and deviations from plug flow will result in imperfect separation even within the shaded region. As a result, operating away from the vertex and closer to the 45° line is usually needed at the expense of lower productivity. By introducing a safety margin $\beta \geq 1$ [Seader and Henley (2006) in General References], Eqs. (16-198) are transformed to

$$m^{\mathrm{I}} = K_B \beta \tag{16-200a}$$

$$m^{\mathrm{II}} = K_A \beta \tag{16-200b}$$

$$m^{\mathrm{III}} = K_B / \beta \tag{16-200c}$$

$$m^{\mathrm{IV}} = K_A / \beta \tag{16-200d}$$

$\beta = 1$ yields maximum productivity under ideal conditions, while larger values provide a more robust design up to the maximum $\beta = \sqrt{K_B / K_A}$. For a given $\beta$, external and internal flow velocities are calculated from

$$u_S = u_F / (K_B / \beta - K_A \beta) \tag{16-201a}$$

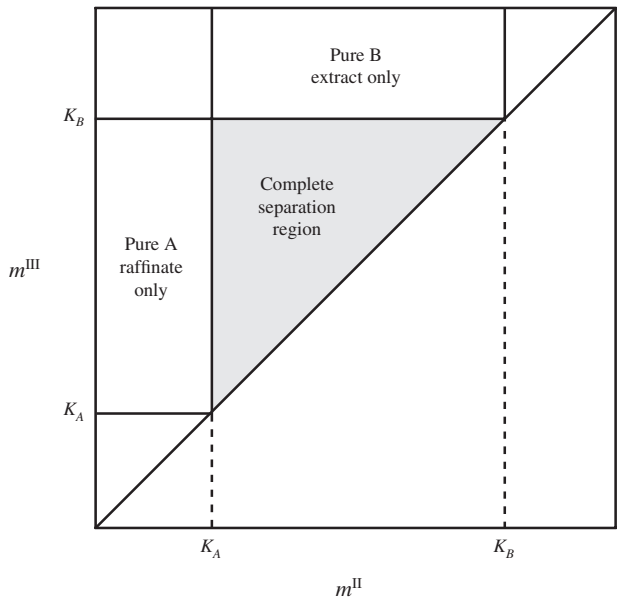

**FIG. 16-39** $m^{\mathrm{III}}$-$m^{\mathrm{II}}$ plane showing regions of complete and incomplete separation. Area below the 45° line is invalid.

$$u_E = u_S (K_B - K_A) \beta \tag{16-201b}$$

$$u_R = u_S (K_B - K_A) / \beta \tag{16-201c}$$

$$u_D = u_E + u_R - u_F \tag{16-201d}$$

$$u^{\mathrm{I}} = u_S (K_B \beta + \varepsilon_p / \rho_p) \tag{16-201e}$$

$$u^{\mathrm{II}} = u^{\mathrm{I}} - u_E \tag{16-201f}$$

$$u^{\mathrm{III}} = u^{\mathrm{II}} + u_F \tag{16-201g}$$

$$u^{\mathrm{IV}} = u^{\mathrm{III}} - u_R \tag{16-201h}$$

$$u_C = u^{\mathrm{I}} - u_D \tag{16-201i}$$

Analogous relationships are derived for SMB systems where each zone comprises a number of fixed beds operated in a merry-go-round sequence, as shown in Fig. 16-40. External flow velocities are calculated from Eqs. (16-201$a$) to (16-201$d$), replacing $u_S$ with

$$u_{S,\mathrm{SMB}} = \frac{\rho_b L}{p} \tag{16-202}$$

where $L$ is the length of a single bed and $p$ is the switching period. Internal flow velocities equivalent to the TMB operation are increased from the values calculated from Eqs. (16-201$e$) to (16-201$i$) to compensate for the extra-particle fluid carried along in each bed at each switch according to

$$u^j_{\mathrm{SMB}} = u^j + \frac{\varepsilon L}{p} \tag{16-203}$$

In practice, a small number of beds in series in each zone provide a close approach to the performance of ideal, true countercurrent system. Industrial SMB systems normally use one to three beds per zone.

**Complete Design and Extensions** Complete design of SMB systems requires a full description of equilibrium and rate factors. For an existing SMB unit, initial stream flow rates and switching period can be selected based on Eqs. (16-201) to (16-203) so that the operating point lies within the desired separation region. Column length design requires a dynamic adsorption model including a description of mass-transfer rates, adsorption kinetics, and axial dispersion. An analytical solution for the linear isotherm with an LDF model is available in Carta and Jungbauer [(2010), pp. 327–338]

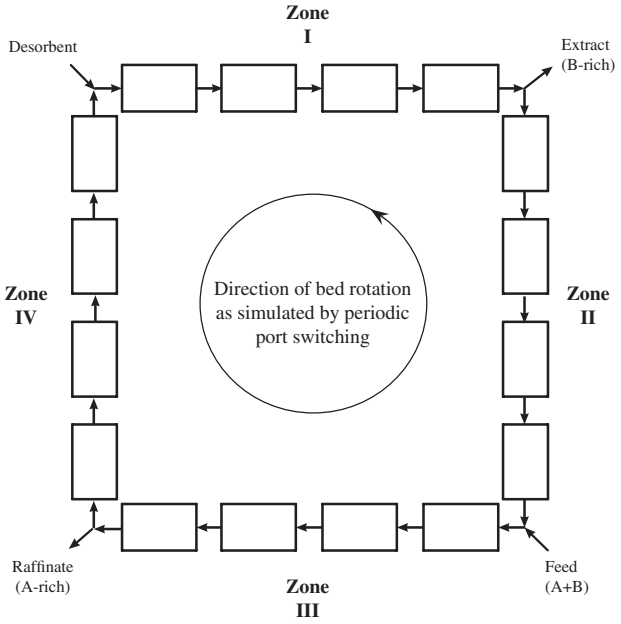

**FIG. 16-40** General scheme of a simulated moving-bed (SMB) adsorption system. Bed rotation is simulated by periodic switching of ports in the direction of fluid flow. $A$ is less strongly retained than $B$.

and Dunnebier et al., *Ind. Eng. Chem. Res.* **39:** 2290 (2000). Operation with a nonlinear isotherm is analyzed in a similar manner. In this case, the right triangle defining the complete separation region in Fig. 16-39 is distorted, acquiring one or more curved sides and further restricting the range of conditions leading to complete separation. Operating conditions can be selected on this basis, but a complete design typically requires a numerical solution. As is evident from the analysis above, only binary separations are achievable with a four-zone system. Multicomponent separations require multiple SMB units or integrated units comprising more than four zones. Useful references covering SMB design for linear and nonlinear isotherms are by Ruthven and Ching, *Chem. Eng. Sci.* **44:** 1011 (1989); Storti et al., *Chem. Eng. Sci.* **44:** 1329 (1989); Zhong and Guiochon, *Chem. Eng. Sci.* **51:** 4307 (1996); Mazzotti et al., *J. Chromatogr. A* **769:** 3 (1997); Mazzotti et al., *AIChE J.* **40:** 1825 (1994); and Minceva and Rodrigues, *Ind. Eng. Chem. Res.* **41:** 3454 (2002).

## OTHER ADSORPTION CYCLES

**Hybrid Recycle Systems** Liquid chromatography has been used commercially to separate glucose from fructose and other sugar isomers, for recovery of nucleic acids, and for other uses. Sanmatsu Kogyo Co., Ltd. [Yoritomi, Kezuka, and Moriya, U.S. Patent number 4,267,054, (1981)] developed an improved chromatographic process that is simpler to build and operate than simulated moving-bed processes. Figure 16-41 [see Keller, Anderson, and Yon (1987) in General References] diagrams its use for a binary separation. It is a displacement-purge cycle where pure component cuts are recovered, while cuts that contain both components are recycled to the feed end of the column.

The UOP Cyclesorb℠ is another adsorptive separation process with semicontinuous recycle. It uses a series of chromatographic columns to separate fructose from glucose. A series of internal recycle streams of impure and dilute portions of the chromatograph are used to improve the efficiency [Gerhold, U.S. Patent numbers 4,402,832 (1983) and 4,478,721 (1984)]. A schematic diagram of a six-vessel UOP Cyclesorb process is shown in Fig. 16-42 [Gembicki, Oroskar, and Johnson (1991), p. 595 in General References]. The process has four external streams and four internal recycles: dilute raffinate and impure extract are like displacement steps; and impure raffinate and dilute extract are recycled from the bottom of an adsorber to its top. Feed and desorbent are fed to the top of each column in a predetermined sequence. The switching of the feed and desorbent are accomplished by the same rotary valve used for Sorbex switching (see hereafter). A chromatographic profile is established in each column that is moving from top to bottom, and all portions of an adsorber are performing a useful function at any time.

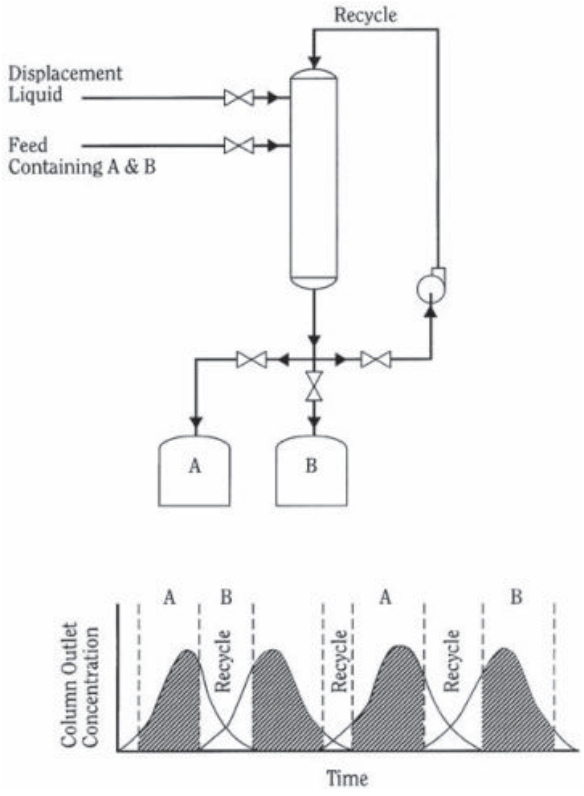

**FIG. 16-41** Sanmatsu Kogyo chromatographic process. (*Reprinted with permission of Wiley. Reference: Keller, Anderson, and Yon, Chap. 12 in Rousseau*, Handbook of Separation Process Technology, *John Wiley & Sons, Inc., New York, 1987.*)

**Steam Regeneration** When steam is used for regeneration of activated carbon, it is desorbing by a combination of thermal swing and displacement purge (described earlier in this section). The exothermic heat released when the steam is adsorbed (condensed in pores) supplies the thermal energy much

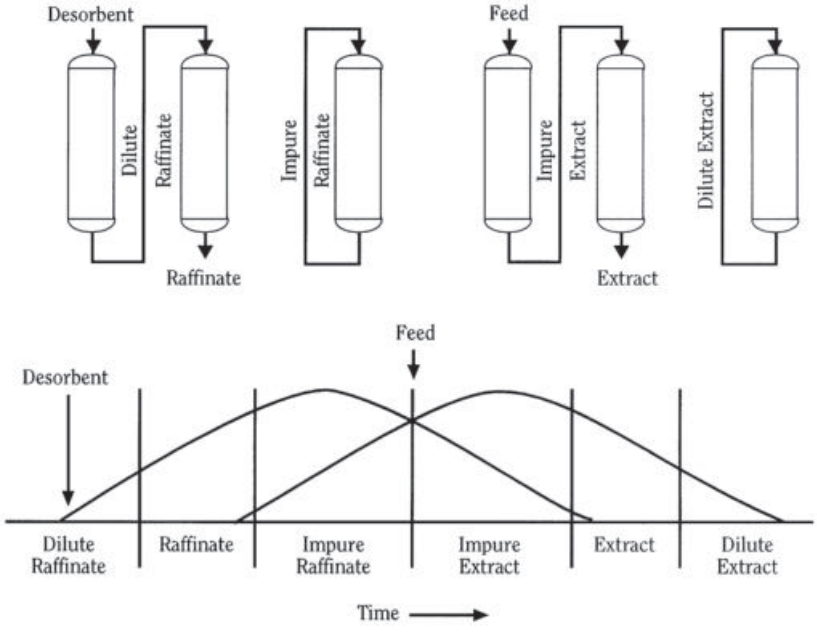

**FIG. 16-42** UOP Cyclesorb process. (*Reprinted with permission of John Wiley & Sons, Inc. Reference: Gembicki, Oroskar, and Johnson, "Adsorption, Liquid Separation," in* Kirk-Othmer Encyclopedia of Chemical Technology, *4th ed., Wiley, New York, 1991.*)

more efficiently than is possible with heated purge gas. Slightly superheated steam at about 130°C is introduced into the bed countercurrent to adsorption; for adsorbates with high boiling points, the steam temperature must be higher. Adsorbates are desorbed and purged out of the bed with the steam. Steam and desorbates then go to a condenser for subsequent separation. The water phase can be further cleaned by air stripping, and the sorbate-laden air from that stripper can be recycled with the feed to the adsorption bed.

Steam regeneration is most commonly applied to activated carbon that has been used in the removal and/or recovery of solvents from gases. At volatile organic compound (VOC) concentration levels from 500 to 15,000 ppm, recovery of the VOC from the stream used for regeneration is economically justified. Below about 500 ppm, recovery is not economically justifiable, but environmental concerns often dictate adsorption followed by destruction. While activated carbon is also used to remove similar chemicals from water and wastewater, regeneration by steam is not usual (because the water-treatment carbon contains 1 to 5 kg of water per kg of adsorbent that must be removed by drying before regeneration or an excessive amount of superheated steam will be needed). In water treatment, there can also be significant amounts of nonvolatile compounds that do not desorb during steam regeneration and that residual will reduce the adsorption working capacity. There is a growing use of reticulated styrene-type polymeric resins for VOC removal from air [Beckett et al., *Environ. Technol.* **13:** 1129 (1992); Heinegaard, *Chem.-Ing.-Tech.* **60:** 907 (1988)]. LeVan and Schweiger [in Mersmann and Scholl, eds., *Fundamentals of Adsorption,* United Engineering Trustees, New York, 1991, pp. 487–496] tabulate reported steam utilizations (kg steam/kg adsorbate recovered) for a number of processes.

**Energy Applications** Desiccant cooling is a means for more efficiently providing air conditioning for enclosures such as supermarkets, ice rinks, hotels, and hospitals. Adsorbers are integrated with evaporative and electric vapor compression cooling equipment into an overall air handling system. Air conditioning is comprised of two cooling loads, latent heat for water removal and sensible heat for temperature reduction. The energy savings derive from shifting the latent heat load from expensive compression cooling (chilling) to cooling tower load. Early desiccant cooling used adsorption wheels (see hereafter) impregnated with the hygroscopic salt, LiCl. More recently, these wheels are being fabricated with zeolite and/or silica gel. They are then incorporated into a system such as the example shown in Fig. 16-43 [Collier et al., in Harrimam, *Desiccant Cooling and Dehumidification,* ASHRAE, Atlanta (1992)]. Process air stream 6, to be conditioned, passes through the adsorbent wheel, where it is dried. This is a nonisothermal process due to the release of the heat of adsorption and transfer of heat from a wheel that may be above ambient temperature. The dry but heated air (7) is cooled in a heat exchanger that can be a thermal wheel. This stream (8) is further cooled, and the humidity adjusted back up to a comfort range by direct contact evaporative cooling to provide supply air. Regeneration air stream 1, which can be ambient air or exhausted air, is evaporatively cooled to provide a heat sink for the hot, dry air. This warmed air (3) is heated to the desired temperature for regeneration of the adsorbent wheel and exhausted to the atmosphere. Many other combinations of drying and cooling are used to accomplish desiccant cooling [Belding, in *Proceedings of AFEAS Refrigeration and Air Conditioning Workshop,* Breckenridge, CO (June 23–25, 1993)].

Adsorption refrigeration technology (ART), often referred to as adsorptive heat pumps, is another developing application of adsorbents with some limited commercial success [Wang et al., *Adsorption Refrigeration Technology: Theory and Application*, Wiley, Singapore (2014)]. The single adsorbate–adsorbent working pair is central to their operation. Common pairs include methanol–activated carbon, ammonia–activated carbon, water–zeolite (e.g., NaX and high-silica NaY), water–silica gel, hydrogen–metal hydrides, ammonia–calcium chloride, and ammonia–strontium chloride. All of these adsorbate–adsorbent working pairs provide a means of transferring heat from a low temperature to a higher, more valuable level. Data have demonstrated that hydrothermally stable Na-mordenite and dealuminated NaY can be used with water in chemical heat pumps to upgrade 100°C heat sources by 50°C to 80°C using a 20°C heat sink [Fujiwara et al., *J. Chem. Eng. Japan* **23:** 738 (1990)]. Other work has shown that integration of two adsorber beds can achieve heating coefficients of performance of 1.56 for the system NaX/water, upgrading 150°C heat to 200°C with a 50°C sink [Douss et al., *Ind. Eng. Chem. Res.* **27:** 310 (1988)].

Gas storage for onboard vehicular fuel is important to providing alternatives to gasoline and diesel fuel. Natural gas is cleaner burning, and hydrogen would burn essentially pollution-free. Onboard storage of natural gas is typically as a high-pressure compressed gas. Adsorbed natural gas systems are a desirable solution because they could operate at lower pressures while maintaining the same capacities. The major problem currently impeding commercialization is the development of adsorbent materials with desirable isotherm capacities and shapes. Also, the exothermic nature of physical adsorption has a negative impact on charge and discharge in a gas storage cycle. Heat released during adsorption will increase the temperature of the adsorbent, thereby lowering the total amount of gas that can be stored. The vessel will cool during the discharge step, decreasing the amount of gas that can be delivered. Technological solutions are being developed and should appear in coming years [Chang and Talu, *Appl. Therm. Eng.* **16:** 359 (1996); Mota, *AIChE J.* **45:** 986 (1999)].

**Energy Conservation Techniques** The major use of energy in an adsorption cycle is associated with the regeneration step, whether it is thermal energy for TSA or compression energy for PSA. Since the regeneration energy per pound of adsorbent tends to be about constant, the first step in minimizing consumption is to maximize the operating loading. When the mass-transfer zone (MTZ) is a large portion of the adsorber relative to the

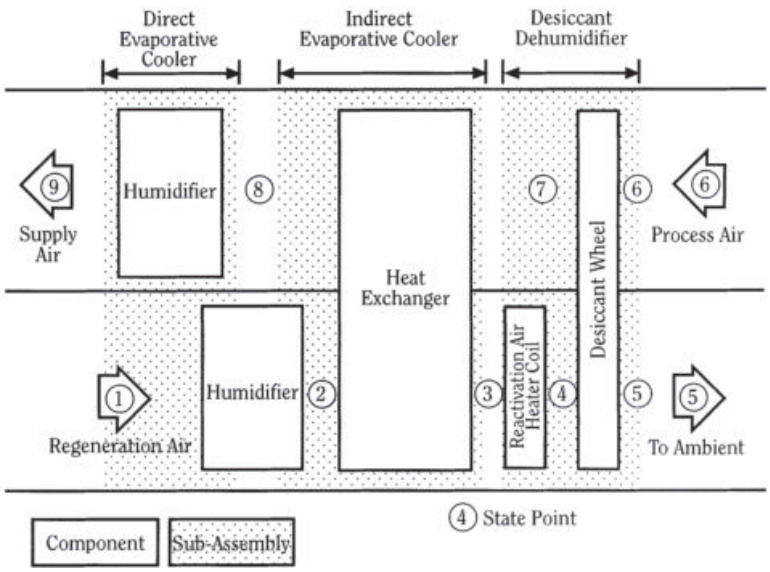

**FIG. 16-43** Flow diagram of desiccant cooling cycle. [*Reprinted with permission of American Society of Heating, Refrigeration and Air Conditioning Engineers, Inc. (ASHRAE). Reference: Collier, Cohen, and Slosberg in Harrimam,* Desiccant Cooling and Dehumidification, ASHRAE, *Atlanta, 1992.*]

equilibrium section, the fraction of the bed being fully utilized is small. Most fixed-bed adsorption systems have two adsorbers so that one is on stream while the other is being regenerated. One means of improving adsorbent use is to use a lead/trim (or cascade, or merry-go-round) cycle. Two (or more) adsorbent beds in series treat the feed. The feed enters the lead bed first and then the trim bed. The trim bed is the one that has most recently been regenerated. The MTZ is allowed to proceed through the lead beds but not to break through the trim bed. In this way the lead bed can be almost totally used before being regenerated. When a lead bed is taken out of service, the trim bed is placed in the lead position, and a regenerated bed is placed in the trim position.

A thermal pulse cycle is a means of conserving thermal energy in heating-limited desorption. A process cycle that is heat-limited needs only a very small time (dwell) at temperature to achieve satisfactory desorption. If the entire bed is heated before the cooling is begun, every part of the bed will dwell at temperature for the entire time it takes the cooling front to traverse the bed. Thus, much of the heat in the bed at the start of cooling would be swept from the bed. Instead, cooling is begun before any heat front has exited the bed creating a thermal pulse that moves through the bed. The pulse expends its thermal energy for desorption so that only a small temperature peak remains at the end of regeneration and no excess heat has been wasted. If the heating step is stripping-limited, a thermal pulse is not applicable.

A series cool/heat cycle is another way in which the heat that is purged from the bed during cooling can be conserved. Sometimes the outlet fluid is passed to a heat sink where energy is stored to be reused to preheat heating fluid, or cross exchanged against the purge fluid to recover energy. However, there is also a process cycle that accomplishes the same effect. Three adsorbers are used, with one on adsorption, one on heating, and one on cooling. The regeneration fluid flows in series, first to cool the bed just heated and then to heat the bed to be desorbed. Thus, all of the energy swept from the adsorber during heating can be reused to reduce the heating requirement. Unlike thermal pulse, this cycle is applicable to both heat- and stripping-limited heating.

**TABLE 16-15 Process Descriptors**

| Number | Statement |
|---|---|
| 1 | Feed is a vaporized liquid or a gas. |
| 2 | Feed is a liquid that can be fully vaporized at less than about 200°C. |
| 3 | Feed is a liquid that cannot be fully vaporized at 200°C. |
| 4 | Adsorbate concentration in the feed is less than about 3 wt%. |
| 5 | Adsorbate concentration in the feed is between about 3 and 10 wt%. |
| 6 | Adsorbate concentration in the feed is greater than about 10 wt%. |
| 7 | Adsorbate must be recovered in high purity (> than 90–99% rejection of nonadsorbed material). |
| 8 | Adsorbate can be desorbed by thermal regeneration. |
| 9 | Practical purge or displacement agents cannot be easily separated from the adsorbate. |

Keller, Anderson, and Yon in Rousseau (ed.), *Handbook of Separation Process Technology,* John Wiley & Sons, Inc., New York, 1987; reprinted with permission.

**Process Selection** The preceding sections present many process cycles and their variations. It is important to have some guidelines for design engineers to narrow their choice of cycles to the most economical for a particular separation. Keller and coworkers [see Keller, Anderson, and Yon (1987) in General References] have presented a method for choosing appropriate adsorption processes. Their procedure considers the economics of capital, energy, labor, and other costs. Although these costs can vary from site to site, the procedure is robust enough to include most scenarios. In Table 16-15, nine statements are made about the character of the separation being considered. The numbers of the statements that are true (i.e., applicable) are used in the matrix in Table 16-16. A "no" for any true statement under a given process should remove that process from further consideration. Any process having all "yes" answers for true statements deserves strong consideration. Entries other than "yes" or "no" provide a means of prioritizing processes when more than one cycle is satisfactory.

# EQUIPMENT

## ADSORPTION

**General Design** Adsorbents can be used in adsorbers with fixed inventory, with intermittent solids flow, or with continuous-moving solids flow. The most common are fixed beds operating as batch units or as beds of adsorbent through which the feed fluid passes, with periodic interruption for regeneration. Total systems consist of pressure vessels or open tanks along with the associated piping, valves, controls, and auxiliary equipment needed to accomplish regeneration of the adsorbent. Gas treating equipment includes blowers or compressors with a multiplicity of paths to prevent dead-heading. Liquid treating equipment includes pumps with surge vessels as needed to assure continuous flow.

**Adsorber Vessel** The most frequently used method of fluid–solid contact for adsorption operations is in cylindrical, vertical vessels, with the adsorbent particles in a fixed and closely but randomly packed arrangement. The adsorber must be designed with consideration for pressure drop and must contain a means of supporting the adsorbent and a means of assuring that the incoming fluid is evenly distributed to the face of the bed. There are additional design considerations for adsorbers when the streams are liquid and for high-performance separation applications using very small particles (<0.05 mm) such as in HPLC.

For most large-scale processes, adsorbent particle size varies from 0.06 to 6 mm (0.0025 to 0.25 in), but the adsorbent packed in a fixed bed will have a fairly narrow particle size range. Pressure drop in adsorbers can be changed by changing the diameter to bed depth ratio and by changing the particle size (see Sec. 5). Adsorbent size also determines separation performance of adsorbent columns, increasing efficiency with decreasing particle size. In liquid-phase processing, the total cost of the adsorption step can sometimes be reduced by designing for overall pressure drops as large as 300 to 600 kPa (45 to 90 psi) because pumping is not the major utility cost.

**TABLE 16-16 Process Selection Matrix**

*Includes powdered, fixed-bed, and moving-bed processes.
†Very high ratio of feed to desorption pressure (>10:1) will be required. Vacuum desorption will probably be necessary.
‡If adsorbate concentration in the feed is very low, it may be practical to discard the loaded adsorbent or reprocess off-site.
§If it is not necessary to recover the adsorbate, these processes are satisfactory.
Keller, Anderson, and Yon in Rousseau (ed.), *Handbook of Separation Process Technology,* John Wiley & Sons, Inc., New York, 1987; reprinted with permission.

In special, high-resolution applications (HPLC), pressure drops as high as 5000–25,000 kPa (800–4000 psi) are sometimes used, requiring special pumping and column hardware [Colin, in Ganetsos and Barker, *Preparative and Production Scale Chromatography,* Marcel Dekker, New York, 1993, pp. 11–45]. However, the cost of compressing gases is significant. Since blowers are limited to about 5 kPa (20 in wc) of lift, atmospheric gas applications are typically designed with adsorbent pressure drops of 1 to 4 kPa (4 to 16 in wc). To keep the compression ratio low, compressed gas adsorption pressure drops are 5 to 100 kPa (0.7 to 15 psi), depending on the pressure level.

Besides influencing how much pressure drop is allowable, the operating pressure determines other design features. When adsorption and/or regeneration is to be performed at pressures above atmospheric, the adsorber vessels are designed like process pressure vessels (see Fig. 16-44) [EPA (1973) in General References]. Their flow distributors can consume more gas momentum at higher pressure. On the other hand, for applications near atmospheric pressure, any pressure drop can be costly, and most design choices are made in the direction of minimizing head loss. Beds have large face areas and shallow depth. Many times, the choice is to fabricate a horizontal (horizontal axis) vessel where flows are radial rather than axial as in conventional vertical beds. Figure 16-45 [Leatherdale in Cheremisinoff and Ellerbusch (1978) in General References] depicts how a rectangular, shallow adsorber bed is oriented in a horizontal vessel. Flow distributors, especially for large units, are often elaborate in order to evenly divide the flow.

There are two types of support systems used for fixed beds of adsorbent. The first is a progressive series of grid and screen layers. In this system, each higher-layer screen has successively smaller openings, with the last small enough to prevent particles from passing through. Each lower layer has greater strength. A series of I-beams can be used to support a layer of subway grating that, in turn, supports several layers of screening. In other cases, special support grills such as Johnson™ screens may rest on the I-beams or on clips at the vessel wall and thus directly support the adsorbent. The topmost screen must retain the original-size particles and some reasonable size of broken particles. The second type of support is a graded system of particles such as ceramic balls or gravel that rests directly on the bottom of the adsorber. A typical system might consist of 100 mm (4 in) or 50 mm (2 in) diameter material, covered by succeeding layers of 25, 12, and 6 mm (1, ½, and ¼ in) of support material for a 3 mm (⅛ in) adsorbent. This type of multi-segmented flow distributor for PSA systems has been described in detail by Baksh et al., US 2005/0155492 A1 (2005). In water treatment, the support may actually start with filter blocks and have an upper layer of sand (see Fig. 16-46) [EPA (1973)].

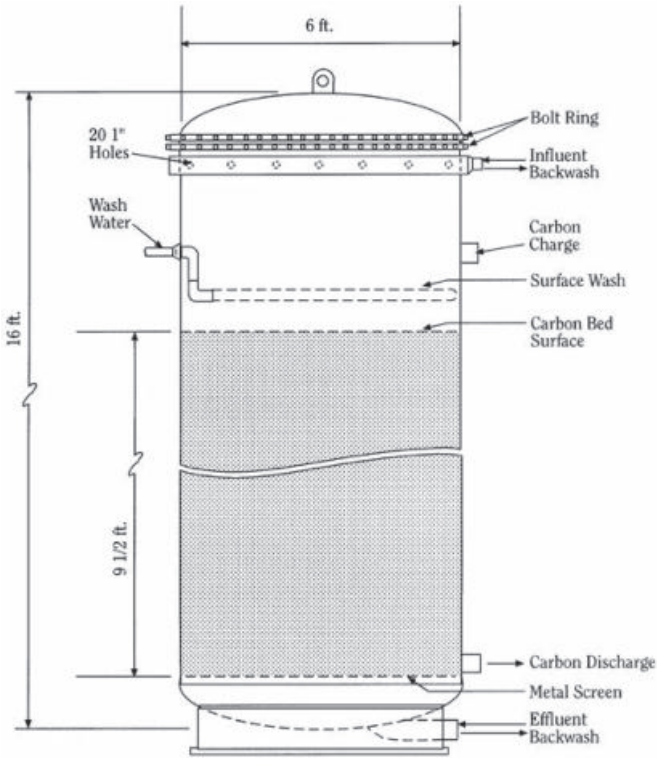

**FIG. 16-44** Pressurized adsorber vessel. (*Reprinted with permission of EPA. Reference: EPA,* Process Design Manual for Carbon Adsorption, *U.S. Envir. Protect. Agency, Cincinnati, 1973*)

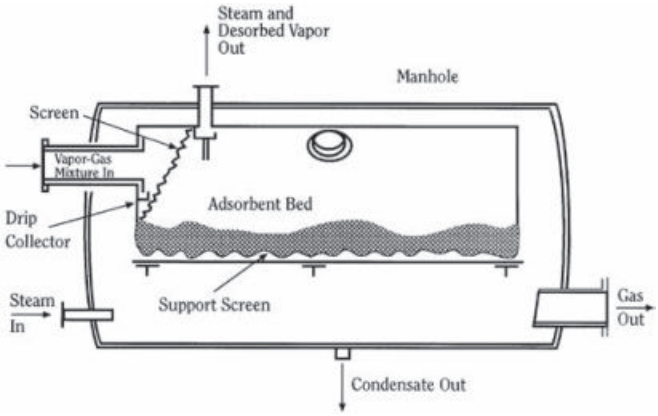

**FIG. 16-45** Ambient pressure adsorber vessel. (*Reprinted with permission of Ann Arbor Science. Reference: Leatherdale in Cheremisinoff and Ellerbusch,* Carbon Adsorption Handbook, *Ann Arbor Science, Ann Arbor, 1978.*)

If flow is not evenly distributed throughout the bed of adsorbent, there will be less than maximum utilization of the adsorbent during adsorption and of the desorption fluid during regeneration. Incoming fluids from the nozzles are at a much higher velocity than the average through the bed and may have asymmetric momentum components due to the piping manifold. The simplest means of allowing flow to redistribute across the face of the bed is to employ ample plenum space above and below the fixed bed. In many situations this excess dead volume in the bed may be detrimental to the separation performance [Baksh et al., US 2005/0155492 A1 (2005)]. A much more cost-effective method is to install simple baffle plates with symmetrically placed inlet and outlet nozzles. The solid, or perforated, baffles are designed to break the momentum of the incoming fluid and redistribute it to prevent direct impingement on the adsorbent. When graded bed support is installed at the bottom, the baffles should be covered by screening to restrain the particles. An alternative to screened baffles is slotted metal or Johnson™ screen distributors. Shallow horizontal beds often have such a large flow area that multiple inlet and outlet nozzles are required. These nozzle headers must be carefully designed to assure balanced flow to each nozzle. In liquid systems, a single inlet may enter the vessel and branch into several pipes that are often perforated along their length (Fig. 16-44). Such "spiders" and "Christmas trees" often have holes that are not uniformly spaced and sized but are distributed to provide equal flow per bed area.

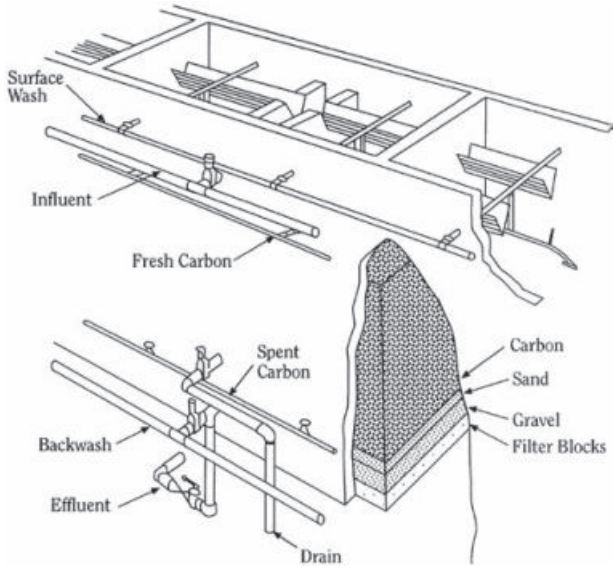

**FIG. 16-46** Adsorber vessel with graded support system. (*Reprinted with permission of EPA. Reference: EPA,* Process Design Manual for Carbon Adsorption, *U.S. Envir. Protect. Agency, Cincinnati, 1973.*)

The gas flows through PSA vessels must be given special consideration. The feed flow is usually up through a PSA bed, so the bed support systems just described are all effective and used in practice. However, flow reversal is essential to any PSA process and happens every few seconds to minutes, and the gas necessarily expands significantly as the pressure in a PSA bed decreases during any of the pressure changing steps. As a result, the velocities leaving and/or entering a vessel from the top header are usually much greater than that associated with the feed step, making flow distruibution and bed retention at the top of a PSA vessel critical to prevent the adsorbent particles from moving. In fact, for upflow through a PSA vessel, the velocity should be less than 70 to 80 percent of the particle fluidization velocity, and for downflow it should be less than 180 percent of it [Ruthven (1984)]. This is significant because the ratio of the downflow to upflow velocity in a PSA bed can easily exceed 2.0. So, when baffle plates with Johnson™ screens are used to distribute the flow entering the top of the bed to go radially outward toward the vessel walls before going down into the bed, a bed retention system is usually installed on top of the bed to prevent movement of the adsorbent particles. A typical bed retention system in this case would consist of a four- to six-inch layer of ceramic stone or other dense media. Alternatively, a multisegmented flow distributor system similar to that described by Baksh et al. [US 2005/0155492 A1 (2005)] circumvents the use of baffle plates and screens, thereby minimizing the plenum space and also serving as the bed retention system.

Although allowable pressure loss with liquids is not a restricting factor, there are also special considerations for liquid treating systems. Activated carbon adsorbers used in water and wastewater treatment are designed and constructed using the same considerations used for turbidity removal by sand or multilayer filters. A typical carbon bed is shown in Fig. 16-46. Such contactors for liquids at ambient pressure are often nothing more than open tanks or concrete basins, with flow distribution simply an overflow weir. In liquid treating, the adsorbers must be designed with a means for liquid draining and filling occasionally or during every cycle when a gas is used for regeneration. Draining is by gravity, sometimes assisted by a 70–140 kPa (10–20 psig) pressure pad. Even with time to drain, there will be significant liquid holdup to recover. As much as 40 cc of liquid per 100 g of adsorbent is retained in the micro- and macropores and bridged between particles. When drain is cocurrent to adsorption, the drained liquid can be recovered as treated product. When drain is countercurrent, drained fluid must be returned to feed surge. Minimizing other holdup in dead volume is especially important for liquid separation processes such as chromatography because it adversely affects product recovery and regeneration efficiency. In filling an adsorber, there must be sufficient time for any gas trapped in the pores to escape. The fill step is preferably upflow to sweep the vapor out and to prevent gas pockets that could cause product contamination, bed lifting, or flow maldistribution. In liquid upflow, the buoyancy force of the liquid plus the pressure drop must not exceed the gravitational forces if bed lifting is to be prevented. Because there is very little increase in pressure drop beyond the lifting (or fluidization) velocity, some liquid systems are designed with bed expansion to limit pressure drop. Upflow-adsorption expanded beds are also preferred when the liquid contains suspended solids, so that the bed does not act as a filter and become plugged. Since increased expansion causes the adsorbent to become increasingly well mixed, with accompanying drop in removal efficiency, expansion is usually limited to about 10 percent. Higher velocities also tend to cause too much particle turbulence, abrasion, attrition, and erosion.

**Regeneration Equipment** Sometimes it is economically justified to remove the adsorbent from the adsorber when it is exhausted and have an outside contractor regenerate it rather than install on-site regeneration equipment. This is feasible only if the adsorbent can treat feed for weeks or months rather than only hours or days. In other cases, the process conditions during regeneration are so much more severe than those for adsorption that a single regenerator with materials of construction capable of handling the conditions is more cost-effective than to make all adsorbers of the expensive material. This is true for most water and wastewater treatment with thermally reactivated carbon. Otherwise, desorption is conducted in situ with any additional equipment connected to the adsorbers.

Figure 16-47 [*Engineering Data Book*, 10th ed., Gas Processors Suppliers Association, Tulsa, 1988, Sec. 20, p. 22] depicts the flow scheme for a typical two-bed TSA dryer system showing the auxiliary equipment associated with regeneration. Some of the dry product gas is externally heated and used countercurrently to heat and desorb water from the adsorber not currently drying feed. The wet, spent regeneration gas is cooled; the water is condensed out; and the gas is recycled to feed for recovery.

The thermal reactivation of spent activated carbon may require the same high temperatures and reaction conditions used for its manufacture. Although the exact conditions to be used for reactivation depend on the type of carbon and the adsorbates to be removed, the objective is to remove the adsorbed material without altering the carbon structure. This occurs in four stages: (*a*) drying, (*b*) desorption, (*c*) pyrolysis and carbonization, and (*d*) burnoff. Each of these steps is associated with a particular temperature range [see LeVan and Carta (2008)].

**Cycle Control** Valves are the heart of cycle control for cyclic adsorption systems. These on/off valves switch flows among beds so that external to the system it appears as if operation is continuous. In general, one valve is needed for each bed at each end for each step that is performed (e.g., for a two-bed system with an adsorption step plus heating and cooling step [carried out in the same direction and during the same step], only $2 \times 2 \times 2 = 8$ valves would be needed [see Fig. 16-47]). In some cycles such as pressure-swing systems, it may be possible to use valves for more than one function (e.g., repressurization with feed gas using the same manifold as adsorption feed). Without multiple use, the cycle in Fig. 16-48 would need $9 \times 2 \times 5 = 90$ valves instead of 55 to accommodate the five steps of feed (adsorption), cocurrent depressurization, countercurrent depressurization, light reflux, and light product repressurization (even without the equalization steps). For some applications, three- and four-way valves can replace two and four valves, respectively. The ultimate integration of switching valves is the UOP rotary valve discussed below. For long step times (eight hours or more), it is possible for the valves to be manually switched by operators. For most systems, it is advantageous that the opening and closing of the valves be controlled by automatic timers. The same logic controller can be responsible for maintaining flows and pressure, proceeding only on completion of events, and safety bypass or shutdown. Automatic control can provide for

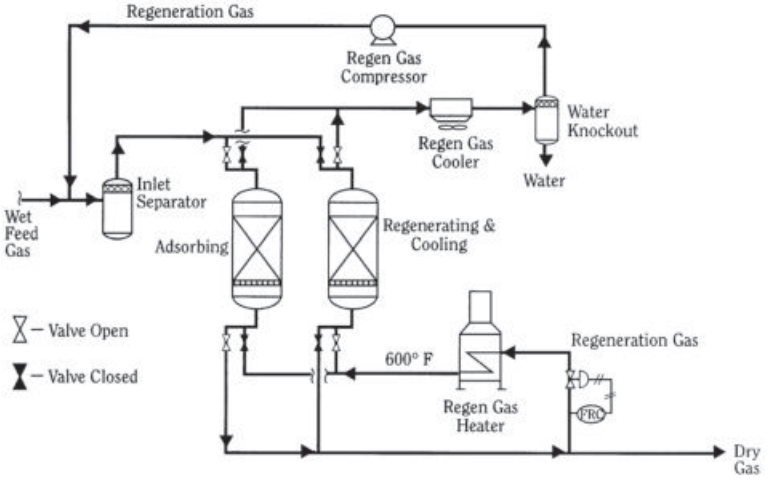

**FIG. 16-47** Two-bed TSA system with regeneration equipment. (*Reprinted with permission of GPSA. Reference:* Engineering Data Book, *10th ed., Gas Processors Suppliers Association, Tulsa, 1988, Sec. 20, p. 22.*)

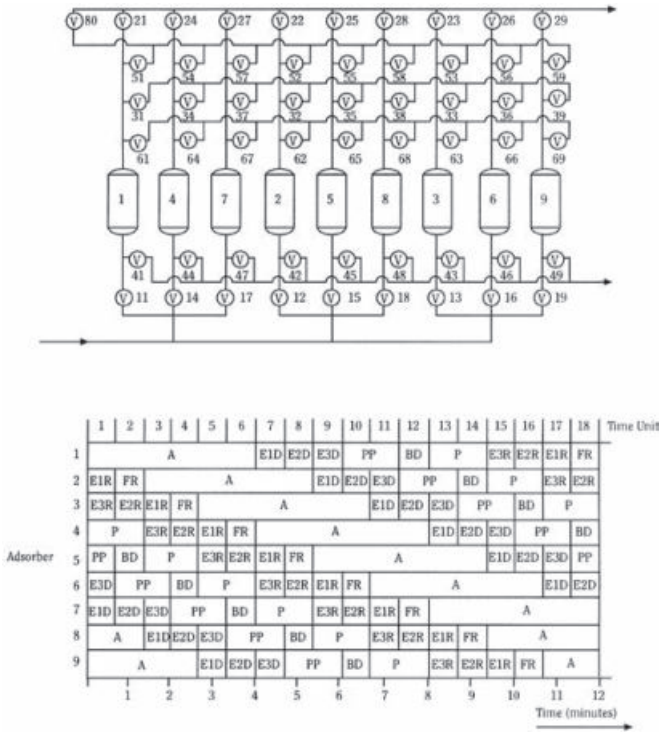

**FIG. 16-48** Column and valving flow scheme for the UOP nine-bed polybed PSA $H_2$ unit. (*Reference: Fuderer and Rudelstorfer, U.S. patent number 3,986,849, 1976.*)

a period of parallel flow paths to assure transitions. In some applications, process analyzers can interface with the controller to initiate bed switching when adsorbate is detected breaking through into the effluent.

**Continuous Countercurrent Systems** Most adsorption systems use fixed-bed adsorbers. However, if the fluid to be separated and that used for desorption can be countercurrently contacted by a moving bed of the adsorbent, there are significant efficiencies to be realized. Because the adsorbent leaves the adsorption section essentially in equilibrium with the feed composition, the inefficiency of the mass-transfer zone is eliminated. The adsorption section only needs to contain an MTZ length of adsorbent compared to an MTZ plus an equilibrium section in a fixed bed. Likewise, countercurrent regeneration is more efficient. Since the adsorbent is moved from an adsorption chamber to another chamber for regeneration, only the regeneration section is designed for the often more severe conditions. Countercurrent adsorption can take advantage of an exceptionally favorable equilibrium in water softening, and the regeneration step can be made favorable by the use of relatively concentrated elutent. Continuous units generally require more headroom but much less footprint. The foremost problems to be overcome in the design and operation of continuous countercurrent sorption operations are the mechanical complexity of equipment and the attrition of the sorbent.

**Cross-Flow Systems** There are at least three implementations of moving-bed adsorption that are cross-flow rather than fixed beds or countercurrent flow: (1) panel beds, (2) adsorbent wheels, and (3) rotating annular beds. *Cross-flow* means that the adsorbent is moving in a direction perpendicular to the fluid flow. All of these employ moving adsorbent—the first, a downflowing solid; and the others, a constrained solid. Panel beds of activated carbon have been applied to odor control [Lovett and Cunniff, *Chem. Eng. Progr.* **70**(5): 43 (1974)] and to the desulfurization of waste gas [Richter et al., *Verfahrenstechnik (Mainz)* **14:** 338 (1980)]. The spent solid falls from the bottom panel into a load-out bin, and fresh regenerated carbon is added to the top; gas flows across the panel.

The heart of an adsorbent wheel system is a rotating cylinder containing the adsorbent. Figure 16-49 illustrates two types: horizontal and vertical. In some adsorbent wheels, the adsorbent particles are placed in basket segments (a multitude of fixed beds) to form a horizontal wheel that rotates around a vertical axis. In other instances, the adsorbent is integral to the monolithic wheel or coated onto a metal, paper, or ceramic honeycomb substrate. These monolithic or honeycomb structures rotate around either a vertical or a horizontal axis. The gas to be treated usually flows through the wheel parallel to the axis of rotation, although some implementations use radial flow configurations. Most of the wheel is removing adsorbates. The remaining (smaller) portion of the wheel is undergoing thermal regeneration—usually countercurrently. The wheel constantly rotates to provide a continuous treated stream and a steady concentrated stream. Adsorbent wheels are most often used to treat ambient air because they have very low pressure drop. One application of wheels is the removal of VOC where the regeneration stream is usually sent to an incinerator for destruction of VOC. Another use is in desiccant cooling (see previously). They do suffer from low efficiency due to the short contact time, mechanical leakage at seals, and the tendency to allow the wheel to exceed breakthrough in order to get better adsorbent utilization. Some adsorbent wheels are operated in an intermittent manner such that the wheel periodically indexes to a new position; this is particularly true of radial flow wheels.

The rotating annular bed system for liquid chromatographic separation (two-dimensional chromatography) is analogous to the horizontal adsorbent wheel for gases [see LeVan and Carta (2008)]. Feed to be separated flows to a portion of the top face of an annular bed of sorbent. A displacement purge in the form of a solvent or carrier gas flows to the rest of the annulus. The less strongly adsorbed components travel downward through the sorbent at a higher rate. Thus, they will exit at the bottom of the annulus at a smaller angular distance from the feed sector. The more strongly adsorbed species will exit at a greater angle. Several potential applications are reviewed by Carta and Byers (*Chromatographic and Membrane Processes in Biotechnology,* NATO ASI Proceeding, Kluwer, 1991).

## ION EXCHANGE

A typical fixed-bed ion exchanger consists of a vertical cylindrical vessel of lined steel or stainless steel. Linings are usually of natural or synthetic rubber. Spargers are provided at the top and bottom, and often a separate distributor is used for the regenerant solution. The resin bed, consisting of a meter or more of ion-exchange particles, is supported by the screen of the bottom distributor. Externally, the unit is provided with a valve manifold to permit downflow loading, upflow backwash, regeneration, and rinsing. For deionization, a two-exchanger assembly comprising a cation and an anion exchanger is a common configuration (Fig. 16-50).

Column hardware designed to allow countercurrent, upflow regeneration of ion-exchange resins is available. An example is given in Fig. 16-51. During upflow of the regenerant, bed expansion is prevented by withdrawing the effluent by applying vacuum. A layer of drained particles is formed at the top of the bed, while the rest of the column functions in the usual way.

Typical design data for fixed-bed ion-exchange columns are given in Table 16-17. These should be used for preliminary evaluation purposes only. Characteristic design calculations are presented and illustrated by Applebaum (*Demineralization by Ion Exchange,* Academic, New York, 1968). Large amounts of data are available in published literature and in bulletins of manufacturers of ion exchangers. In general, however, laboratory testing and pilot-plant work are advisable to determine usable exchanger capacities, regenerant quantities, exchanger life, and quality of product for any application not already thoroughly proven in other plants for similar conditions. Firms that manufacture ion exchangers and ion-exchange equipment will often cooperate in such tests.

**TABLE 16-19 Design Data for Fixed-Bed Ion Exchanger***

| Type of resin | Maximum and minimum flow, m/h [gal/(min · ft²)] | Minimum bed depth, m (in) | Maximum operating temperatures, °C (°F) | Usable capacity, g-equivalent/L† | Regenerant, g/L resin‡ |
|---|---|---|---|---|---|
| Weak acid cation | 20 max. (8)<br>3 min. (1) | 0.6 (24) | 120 (248) | 0.5–2.0 | 110% theoretical (HCl or $H_2SO_4$) |
| Strong acid cation | 30 max. (12)<br>3 min. (1) | 0.6 (24) | 120 (248) | 0.8–1.5<br>0.5–1.0<br>0.7–1.4 | 80–250 NaCl<br>35–200 66° Bé. $H_2SO_4$<br>80–500 20° Bé. HCl |
| Weak and intermediate base anions | 17 max. (7)<br>3 min. (1) | 0.75 (30) | 40 (104) | 0.8–1.4 | 35–70 NaOH |
| Strong-base anions | 17 max. (7)<br>3 min. (1) | 0.75 (30) | 50 (122) | 0.35–0.7 | 70–140 NaOH |
| Mixed cation and strong-base anion (chemical-equivalent mixture) | 40 max. (16) | 1.2 (47) | 50 (122) | 0.2–0.35 (based on mixture) | Same as cation and anion individually |

*These figures represent the usual ranges of design for water-treatment applications. For chemical-process applications, allowable flow rates are generally somewhat lower than the maximums shown, and bed depths are usually somewhat greater.

†To convert to capacity in terms of kilograins of $CaCO_3$ per cubic foot of resin, multiply by 21.8.

‡To convert to pounds of regenerant per cubic foot of resin, multiply by 0.0625.

Consider a bed of particles in a column that is supported by a distributor plate with small holes in it. If gas is passed through the plate so that the gas is evenly distributed across the column, the drag force on the particles produced by the gas flowing through the particles increases as the gas flow through the bed is increased. When the gas flow through the bed causes the drag forces on the particles to equal the weight of the particles in the bed, the particles are fully supported, and the bed is said to be fluidized. Further increases in gas flow through the bed cause bubbles to form in the bed, much as in a fluid, and early researchers noted that this resembled a fluid and called this a fluidized state.

When fluidized, the particles are suspended in the gas, and the fluidized mass (called a fluidized *bed*) has many properties of a liquid. Like a liquid, the fluidized particles seek their own level and assume the shape of the containing vessel. Large, heavy objects sink when added to the bed, and light particles float. If the bed is tilted, the surface of the bed will remain parallel to the surface of the earth.

Fluidized beds are used successfully in many processes, both catalytic and noncatalytic. Among the catalytic processes are fluid catalytic cracking and reforming, oxidation of naphthalene to phthalic anhydride, the production of polyethylene, and ammoxidation of propylene to acrylonitrile. Some of the noncatalytic uses of fluidized beds are in the roasting of sulfide ores, coking of petroleum residues, calcination of ores, combustion of coal, incineration of sewage sludge, and drying and classification.

Although it is possible to fluidize particles as small as about 1 μm and as large as 4 cm, the range of the average size of solid particles which are more commonly fluidized is about 30 μm to over 2 cm. Particle size affects the operation of a fluidized bed more than particle density or particle shape. Particles with an average particle size of about 40 to 125 μm fluidize smoothly because bubble sizes are relatively small in this size range. Larger particles (125 μm and larger) produce larger bubbles when fluidized. The larger bubbles result in a less homogeneous fluidized bed, which can manifest itself in large pressure fluctuations. If the bubble size in a bed approaches approximately one-half to two-thirds the diameter of the bed, the bed will slug. A slugging bed is characterized by large pressure fluctuations that can result in instability and severe vibrations in the system. Small particles (smaller than about 30 μm in diameter) have large interparticle forces (generally van der Waals, electrostatic, or capillary forces) that cause the particles to stick together, as flour particles do. These types of solids fluidize poorly because of the agglomerations caused by the cohesive forces. At velocities that would normally fluidize larger particles, channels, or spouts (commonly called "ratholes"), form in the bed of these small particles, resulting in severe gas bypassing. To fluidize these small particles, it is generally necessary to operate at very high gas velocities so that the shear forces are larger than the cohesive forces of the particles. Using a high-shear gas distributor that contains many high-velocity horizontal jets can also prevent cohesive agglomeration from occurring for some materials. Adding finer-sized particles to a coarse bed, or coarser-sized particles to a bed of cohesive material (i.e., increasing the particle size range of a material), usually results in better (smoother) fluidization.

Gas velocities in fluidized beds generally range from 0.1 to 3 m/s (0.33 to 9.9 ft/s). The gas velocities referred to in fluidized beds are superficial gas velocities—the volumetric flow through the bed divided by the bed area. More detailed discussions of fluidized beds can be found in Kunii and Levenspiel, *Fluidization Engineering,* 2d ed., Butterworth Heinemann, Boston, 1991; Pell, *Gas Fluidization,* Elsevier, New York, 1990; Geldart, ed., *Gas Fluidization Technology,* Wiley, New York, 1986; Yang, ed., *Handbook of Fluidization and Fluid Particle Systems,* Marcel Dekker, New York, 2003; and papers published in periodicals, transcripts of symposia, and the American Institute of Chemical Engineers symposium series.

## GAS–SOLID SYSTEMS

Researchers in the fluidization field have long recognized that particles of different size behave differently in fluidized beds, and several have tried to define these differences. Some of these characterizations are described below.

**Types of Solids** Perhaps the most widely used categorization of particles is that of Geldart [*Powder Technol.* **7:** 285–292 (1973)]. Geldart categorized solids into four different groups (Geldart Groups A, B, C, and D) that exhibited different properties when fluidized with a gas. He classified the four groups in his famous plot, shown in Fig. 17-1. This plot defines the four groups as a function of average particle size $d_{sv}$, μm, and density difference $\rho_p - \rho_g$, kg/m$^3$, where $\rho_p$ = particle density, kg/m$^3$; $\rho_g$ = gas density, lb/ft$^3$; and $d_{sv}$ = surface volume diameter (also called the Sauter mean diameter) of the particles, μm. Generally, $d_{sv}$ is the preferred average particle size for fluid-bed applications because it is based on the surface area of the particle. The drag force used to generate the pressure drop used to fluidize the bed is proportional to the surface area of the particles. Another widely used average particle size is the median particle size, $d_{p,50}$.

When the gas velocity through a bed of Geldart Group A, B, C, or D particles increases, the pressure drop through the bed also increases. The pressure drop increases until it equals the weight of the bed ($W$) divided by the cross-sectional area of the column ($A$). The gas velocity at which this occurs is called the minimum fluidizing velocity, $U_{mf}$. After the minimum fluidization velocity is achieved, increases in gas velocity for a bed of Geldart Group A particles (generally in the particle size range between 30 and 120 μm) will result in a uniform expansion of the particles without bubbling until at some higher gas velocity (called the minimum bubbling velocity, $U_{mb}$) gas bubbles start to form. For Geldart Group B particles (between 120 and about 1000 μm) and Geldart Group D particles (about 1000 μm and larger), bubbles start to form immediately after $U_{mf}$ is achieved, so that $U_{mf}$ and $U_{mb}$ are essentially equal for these two Geldart groups. Geldart Group C particles (generally smaller than 30 μm) are termed cohesive particles and clump together in particle agglomerates because of interparticle forces (generally van der Waals, electrostatic, or capillary forces). When gas is passed through beds of cohesive solids, the gas tends to channel or "rathole" through the bed. Instead of fluidizing the particles, the gas opens channels that extend from the gas distributor to the surface of the bed. At higher gas velocities where the shear forces are great enough to overcome the interparticle forces, or with mechanical agitation or vibration, cohesive particles will fluidize, but generally with larger clumps or clusters of particles formed in the bed.

**Two-Phase Theory of Fluidization** The two-phase theory of fluidization assumes that all gas in excess of the minimum bubbling velocity passes through the bed as bubbles [Toomey and Johnstone, *Chem. Eng. Prog.* **48:** 220 (1952)]. In this view of the fluidized bed, the gas flowing through the emulsion phase in the bed is at the minimum bubbling velocity, while the gas flow above $U_{mb}$ is in the bubble phase. This view of the bed is an approximation, but it is a helpful way of understanding what happens as the gas velocity is increased through a fluidized bed. As the gas velocity is increased above $U_{mb}$, more and larger bubbles are formed in the bed. As more bubbles are produced in the bed, the bed expands, and the bed density decreases.

For Geldart groups (A, B, C, and D) that are satisfactorily fluidized, as the gas velocity is increased, the fluidized-bed density is decreased and the turbulence, or agitation, of the bed is increased. In smaller-diameter beds, but especially with Geldart Group B and D powders, slugging will occur as the bubbles increase in size to a diameter greater than one-half to two-thirds of the bed diameter. Slugging does not occur in large, commercial beds because the bubbles will not grow to a size that is one-half to two-thirds the diameter of the commercial unit. Bubbles grow by vertical and lateral merging (called coalescence), and they increase in size as the gas velocity is increased (Whitehead, in *Fluidization,* ed. Davidson and Harrison, Academic, London and New York, 1971). As the gas velocity is increased further, the stable bubbles break down into smaller, unstable voids, which only exist for a few seconds before breaking up and reforming.

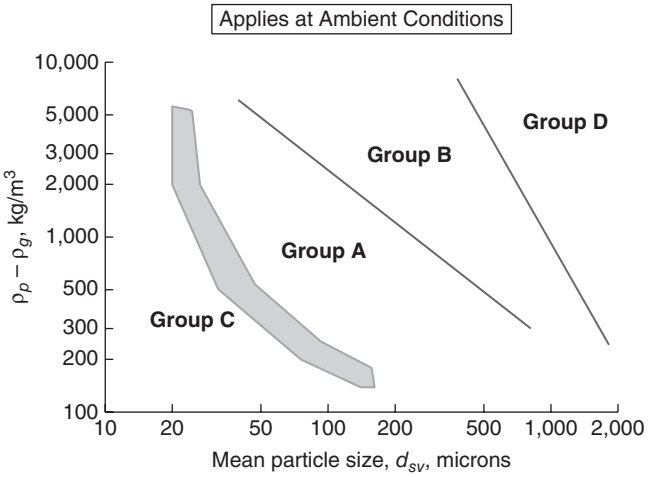

**FIG. 17-1** Power-classification diagram for fluidization by air (ambient conditions). (*Courtesy of PSRI, Chicago Ill.*)

When the unstable voids characterize the gas phase in fluidized beds, the bed is not in the bubbling regime anymore, but is said to be in the turbulent regime. The turbulent regime is a much more vigorous regime than the bubbling regime. Because of the high rates of void breakup and recoalescence, the turbulent regime is characterized by higher heat- and mass-transfer rates than bubbling fluidized beds, and the pressure fluctuations in the bed are reduced relative to bubbling beds as the voids are smaller. As the gas velocity is increased above the turbulent fluidized regime, the turbulent bed gradually changes into the pneumatic conveying regime.

**Phase Diagram (Upward Gas Flow)** A phase diagram for upward gas flow in gas/particle systems is shown in Fig. 17-2. The diagram indicates how the pressure drop per unit length ($P_2 - P_1$) across a length ($L$) of vertical line varies as a function of gas velocity with solids mass flux ($G$) as a parameter. Line OD in Fig. 17-2 is the pressure drop versus gas velocity curve for a packed bed, and line DE is the curve for a fluidized bed with no net solids flow through it. Line OK is the pressure drop versus velocity curve for a vertical line with no solids flow through it. Line ABC is the curve for the dilute-phase, pneumatic conveying region at a constant mass flux of $G_1$. Zenz (Zenz and Othmer, *Fluidization and Fluid Particle Systems*, Reinhold, New York, 1960) indicated that there was an instability between points C and E because with no solids flow, all the particles will be entrained from the bed. However, if solids are added to replace those entrained, curve ABC prevails.

**Phase Diagram (Grace)** Grace [*Can. J. Chem. Eng.* **64:** 353–363 (1986)] has correlated the various types of gas–solid systems in which the gas is flowing vertically upward in a status graph using the parameters of the Archimedes number, Ar, for the particle size and a nondimensional velocity, $U^*$, for the gas effects. This plot is shown in Fig. 17-3. By means of this plot, the fluidization regime for various operating systems can be roughly approximated. This plot is a good guide to estimate the fluidization regime for various particle sizes and operating conditions. However, it should not be substituted for more exact methods of determining the actual fluidization operating regime.

**Regime Diagram (Grace)** Grace [*Can. J. Chem. Eng.* **64:** 353–363 (1986)] approximated the appearance of the different regimes of fluidization as shown in the schematic drawing of Fig. 17-4. This drawing shows the fluidization regimes that occur as superficial gas velocity is increased from the low-velocity, packed-bed regime to the high-velocity, pneumatic conveying transport regime. As the gas velocity is increased, the bed transitions from the packed-bed regime (also called the fixed bed regime) into the fluidization regime. At the fluidization regime, the velocity reaches a value $U_{mf}$ (the minimum fluidization velocity), where the drag forces on the particles equal the weight of the bed particles, and the particles become suspended in the gas stream. At this point, the particles are said to be fluidized. If the particles are Geldart Group A particles, then a "bubbleless" particulate fluidization regime is first formed called the particulate regime. As the gas velocity is further increased, bubbles start to form in the bed. The velocity at which bubbles start to form is called the minimum bubbling velocity, $U_{mb}$. For Geldart Group B and D particles, the particulate fluidization regime does not form. Instead, the bed passes directly from the packed-bed regime to the bubbling fluidized-bed regime. As the gas velocity is increased above $U_{mb}$, the bubbles in the bed grow in size. In small laboratory beds, if the bubble size grows to a value equal to approximately one-half to two-thirds the diameter of the fluidization column, the bed will slug. The slugging fluidized bed is characterized by severe pressure fluctuations and limited solids mixing. It only occurs with small-diameter fluidization columns. Commercial fluidized beds are too large for bubbles to grow to the size where slugging will occur.

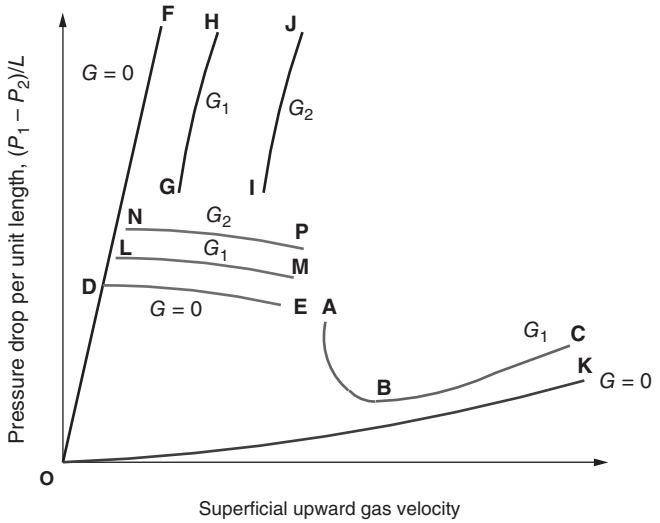

**FIG. 17-2** Schematic phase diagram in the region of upward gas–solid flow. $G$ = solids mass flux, lb/(s-ft$^2$); $L$ = length, ft; $P_1$ and $P_2$ = pressure, lb/ft$^2$. (*Courtesy of PSRI, Chicago, Ill.*)

Key:

| | |
|---|---|
| OD = packed bed | DF = constrained packed bed (no solids flow) |
| DE = fluidized bed | GH, IJ = constrained packed bed (with solids flow) |
| OK = gas flow only | LM, NP = dense, fluidized solids flow |
| ABC = dilute-phase pneumatic conveying | |

At high gas velocities in the bed, the stable bubbles break down into unstable voids that continuously disintegrate and reform. This type of bed is said to be operating in the turbulent fluidized-bed regime, and it is characterized by higher heat- and mass-transfer rates than in the bubbling bed. As the gas velocity is increased further, the bed transitions from the turbulent bed into the dilute-phase pneumatic transport regime. The dilute-phase, pneumatic transport regime is composed of two basic regions: the lower-velocity, fast fluidized-bed regime, and the higher-velocity pneumatic conveying regime. The pneumatic transport regime is a very important regime and is defined by the curve ABC for the constant solids mass flux, $G_1$, in Fig. 17-2. A more detailed drawing of the pneumatic transport regime is shown in Fig. 17-5. In this figure, it can be seen that as the gas velocity is decreased from point C, the pressure drop per unit length begins to decrease. This occurs because the total pressure drop in the transport regime is composed of two types of terms—a term composed of frictional pressure drops (gas/wall friction, solid/wall friction, and gas/solids friction) and a term required to support the solids in the vertical line (the static head of solids term). At high gas velocities the frictional terms dominate; and as the gas velocity is decreased from point C, the frictional terms begin to decrease in magnitude. As this occurs, the concentration of solids in the line starts to increase. At some gas velocity, the static head of solids term and the frictional pressure drop term are equal (the minimum point on the curve). As the gas velocity is decreased below the minimum point (point B), the static head of solids term begins to dominate as the concentration of solids in the line increases. The static head of solids pressure drop increases until it is no longer possible for the gas to fully support the solids in the line. The gas velocity at which the solids cannot be supported at solids flow rate $G_1$ for curve ABC is known as the choking velocity ($U_{ch}$) for solids mass flux, $G_1$. Curve RST is a pneumatic transport curve operating at a higher solids mass flux, $G_2$. It has a higher choking velocity than curve ABC. Because many Geldart Group A beds in the turbulent and all Geldart groups in the transport regime operate above the terminal velocity of some or all of the particles, a solids collection and return system is needed to maintain a stable fluidized bed with these regimes.

**Solids Concentration versus Height** As previously described, there are several fluidization regimes. In order of increasing gas velocity, these regimes are: the particulate fluidization regime ( for Geldart Group A *only*), the bubbling (aggregative) fluidization regime, the turbulent fluidization regime, the fast-fluidization regime, and the pneumatic transport regime. Each of these regimes has a characteristic solids concentration profile as shown in Fig. 17-6. Only the bubbling fluidization regime can be said to have a distinct top to its bed. The other regimes have essentially continuously changing solids concentrations as a function of height.

**Equipment Types** Fluidized-bed systems take many forms. Figure 17-7 shows some of the more common concepts and configurations with approximate ranges of gas velocities indicated in the legend.

**Minimum Fluidizing Velocity** $U_{mf}$, the minimum fluidizing velocity, is often used in fluid-bed calculations. This parameter is often measured experimentally in small-scale equipment at ambient conditions by measuring the pressure drop across the bed as a function of superficial gas velocity through the bed. The most accurate measurements of $U_{mf}$ are determined from a decreasing-velocity curve where the bed is first fluidized and then the gas velocity is decreased systematically. This type of curve avoids the problem of different packed-bed compactions experienced in an increasing-velocity curve. The correlation to predict $U_{mf}$ by Wen and Yu [*A.I.Ch.E.J.* **12:** 610–612 (1966)], shown below, can then be used to back-calculate an effective particle size, $d_{peff}$. This gives a particle size that takes into account the effects of size distribution and particle shape, or sphericity. The correlation can then be used to estimate $U_{mf}$ at process conditions using this effective particle size. If $U_{mf}$ cannot be determined experimentally, then it can be calculated using the following Wen and Yu correlation:

$$\mathrm{Re}_{mf} = (1135.7 + 0.0408\mathrm{Ar})^{0.5} - 33.7 \tag{17-1}$$

where $$\mathrm{Re}_{mf} = d_{peff}\rho_g U_{mf}/\mu \tag{17-2}$$

$$\mathrm{Ar} = d_{sv}\rho_g(\rho_p - \rho_g)g/\mu^2 \tag{17-3}$$

$$d_{sv} = 1/\sum(x_i/d_{pi}) \tag{17-4}$$

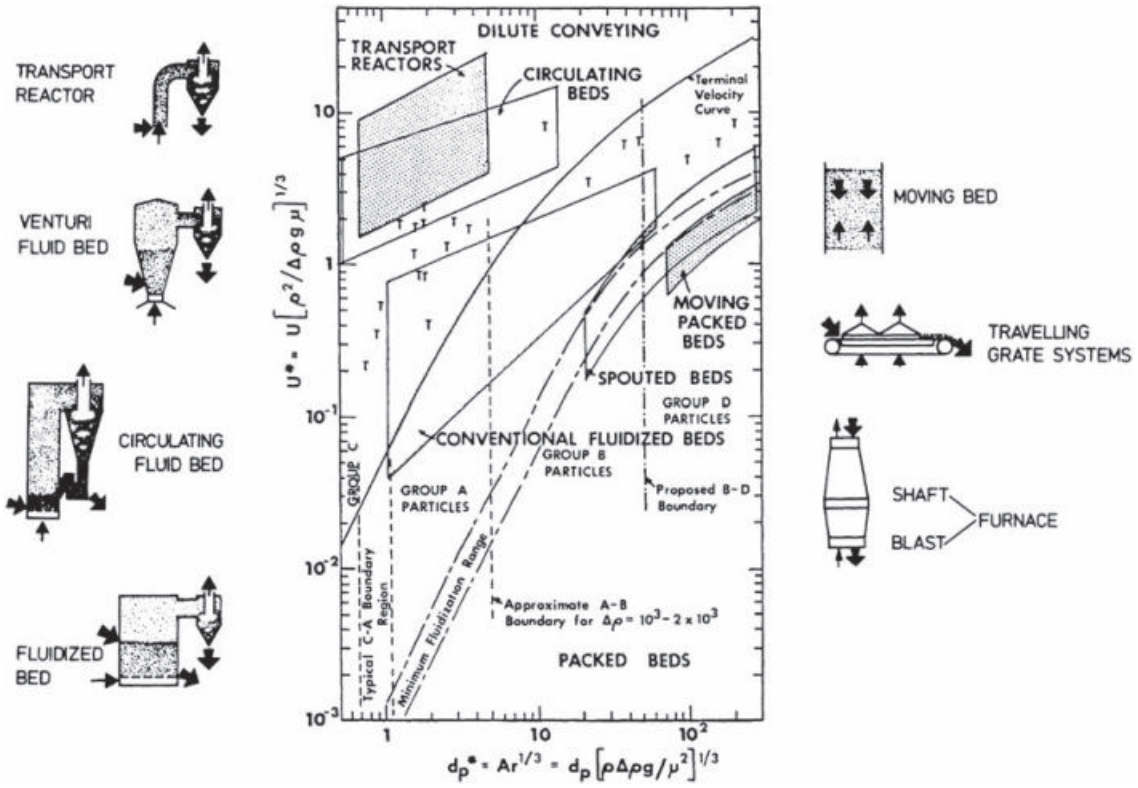

**FIG. 17-3** Simplified fluidized-bed regime plot. [From *Grace*, Can J. Chem. Eng. **64:** 353–363 (1986); *sketches from Reh*, Ger. Chem. Eng. **1:** 319–329 (1978).]

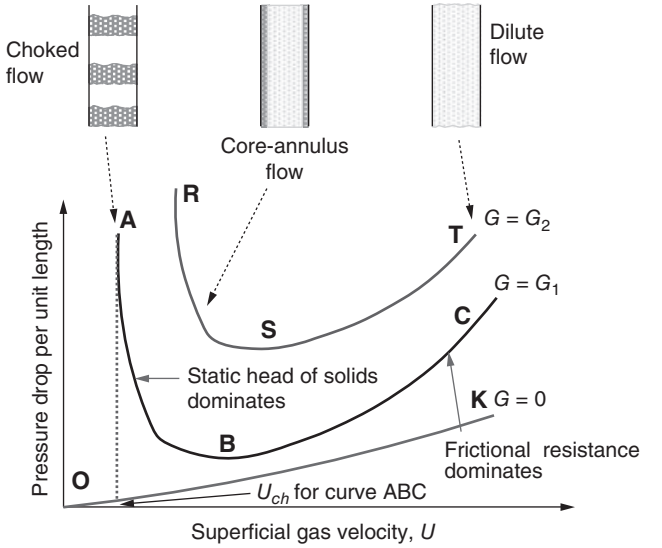

**FIG. 17-5** Pneumatic (dilute-phase) transport regime. (*Courtesy of PSRI, Chicago, Ill.*)

For wide particle-size distributions of group B and D materials, $U_{mf}$ does not apply. With these materials, the largest materials in the distribution may not be fluidized while most of the bed is fluidized. For materials such as this, the minimum velocity to completely fluidize the entire particle-size distribution is called the complete fluidization velocity, $U_{cf}$. This velocity can be estimated by applying the Wen and Yu correlation for $U_{mf}$ to the largest particle in the mixture, not the average particle size.

The gas velocity required to maintain a completely homogeneous bed of solids in which coarse or heavy particles will not segregate from the fluidized portion is very different from the minimum fluidizing velocity. The bed may be completely fluidized, but segregation can still occur. See Nienow and Chiba, *Fluidization,* 2d ed., Wiley, 1985, pp. 357–382, for a discussion of segregation or mixing mechanisms as well as the means of predicting this flow; also see Baeyens and Geldart, *Gas Fluidization Technology,* Wiley, 1986, 97–122.

**Particulate Fluidization** Fluid beds of Geldart Group A powders that are operated at gas velocities above the minimum fluidizing velocity ($U_{mf}$) but below the minimum bubbling velocity ($U_{mb}$) are said to be particulately fluidized. As the gas velocity is increased above $U_{mf}$, the bed further expands. Decreasing $(\rho_p - \rho_g)$, $d_p$ and/or increasing $\mu_f$ increases the spread between $U_{mf}$ and $U_{mb}$. Richardson and Zaki [*Trans. Inst. Chem. Eng.* **32:** 35 (1954)] showed that $U/U_i = \varepsilon^n$, where $n$ is a function of system properties, $\varepsilon$ = void fraction, $U$ = superficial fluid velocity, and $U_i$ = theoretical superficial velocity from the Richardson and Zaki plot when $\varepsilon = 1$.

**Vibrofluidization** It is possible to fluidize a bed mechanically by imposing vibration to throw the particles upward using a cyclical force. This enables the bed to operate with either no upward gas velocity or a vastly reduced gas flow. Entrainment can also be greatly reduced using this technique compared to unaided fluidization. This technique is used commercially in drying and other applications [Mujumdar and Erdesz, *Drying Tech.* **6:** 255–274 (1988)], and chemical reaction applications are also possible. See Sec. 12 for more on drying applications of vibrofluidization.

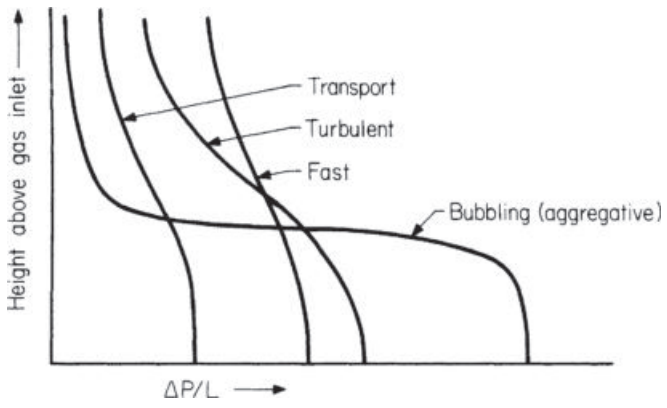

**FIG. 17-6** $\Delta P/L$ (proportional to solids concentration) versus height above the gas distributor for regimes of fluidization.

## DESIGN OF FLUIDIZED-BED SYSTEMS

The use of the fluidization technique requires (in almost all cases) the use of a fluidized-bed system rather than an isolated piece of equipment. Figure 17-8 illustrates the arrangement of components of some systems.

The major parts of a fluidized-bed system are:

1. Fluidization vessel
   - *a.* Fluidized-bed portion
   - *b.* Disengaging space or freeboard
   - *c.* Gas distributor
2. Solids feeder or flow control
3. Solids discharge
4. Dust separator for the exit gases
5. Instrumentation
6. Gas supply

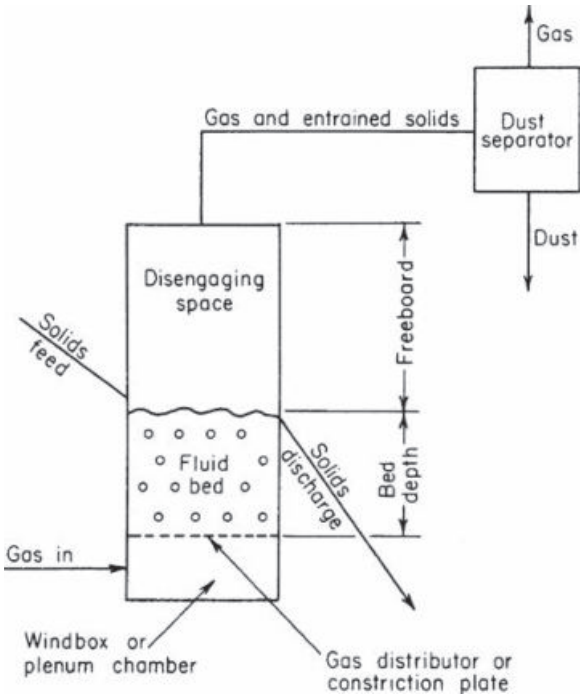

**FIG. 17-8** Noncatalytic fluidized-bed system.

**Fluidization Vessel** The most common shape for a fluidized-bed vessel is a vertical cylinder. Just as for a vessel designed for boiling a liquid, space must be provided in the vessel for vertical expansion of the solids and for disengaging splashed and entrained material. The volume above a bubbling fluidized bed is called the disengaging space. The cross-sectional area of the vessel is determined by the volumetric flow of gas and the allowable or required fluidizing velocity of the gas at operating conditions. In some cases the lowest permissible velocity of gas is used, and in others the greatest permissible velocity is used. The maximum volumetric flow is often determined by the carryover or entrainment of solids, and this is related to the dimensions of the disengaging space (cross-sectional area and height).

***Bed*** Bed height is determined by a number of factors, either individually or collectively, such as:

1. Gas-contact time
2. $L/D$ ratio required to provide staging
3. Space required for internal heat exchangers
4. Solids-retention time

Fluidized-bed heights can range from less than 0.3 m (12 in) to more than 25 m (82 ft).

Although the reactor is usually a vertical cylinder, generally there is really no limitation on shape. The specific design features vary with operating conditions, available space, and use. The lack of moving parts results in simple, clean designs.

Most fluidized-bed units operate at elevated temperatures. For this use, refractory-lined steel is the most economical design. The refractory (typically an insulting refractory with a hard, attrition-resistant layer in contact with the particles) serves two main purposes: (1) it insulates the metal shell from the elevated temperatures, and (2) it protects the metal shell from abrasion by the motion of the bed particles, and particularly the splashing solids at the top of the bed that result from bursting bubbles. Depending on specific conditions, several different refractory linings are used [Van Dyck, Chem. Eng. Prog. (December): 46–51 1979)]. Generally, for the moderate temperatures encountered in catalytic cracking of petroleum, a reinforced-gunnite lining has been found to be satisfactory. This also permits the construction of larger units than would be permissible if self-supporting ceramic domes were to be used for the roof of the reactor.

When heavier refractories are required because of operating conditions, insulating brick is installed next to the shell, and firebrick is installed to protect the insulating brick. Industrial experience in many fields of application has demonstrated that such a lining will successfully withstand the abrasive conditions in the bed for many years without replacement. Most serious refractory wear occurs with coarse particles at high gas velocities and is usually most pronounced near the operating level of the bubbling fluidized bed.

Gas leakage behind the refractory has plagued a number of units. Care should be taken in the design and installation of the refractory to reduce the possibility of the formation of "chimneys" in the refractories. A small flow of solids and gas behind the refractory can quickly erode large passages in soft insulating brick, or even in dense refractory. Gas stops are often attached to the shell and project into the refractory lining. Care in the design and installation of openings in shell and lining is also required.

In many cases, cold spots on the reactor shell will result in condensation and high corrosion rates. Sufficient insulation is needed to keep the shell and appurtenances above the dew point of the reaction gases. Hot spots can occur where refractory cracks allow heat to permeate to the shell. These can sometimes be repaired by pumping castable refractory into the hot area from the outside.

The violent motion of a bubbling or turbulent fluidized bed requires an ample foundation and a sturdy supporting structure for the reactor. Even a relatively small differential movement of the reactor shell with the lining will materially shorten refractory life. The lining and shell must be designed as a unit. Structural steel should not be supported from a vessel that is subject to severe vibration.

***Freeboard and Entrainment*** The freeboard, or disengaging height, is the distance between the top of the fluid bed and the gas-exit nozzle in bubbling- or turbulent-bed units. The distinction between bed and freeboard is difficult to determine in turbulent, fast, and transport units (see Fig. 17-6).

At least two actions can take place in the freeboard: (1) classification of solids and (2) reaction of solids and gases.

As a bubble reaches the upper surface of a fluidized bed, the bubble breaks through the thin upper envelope composed of solid particles and entrains some of these particles. The crater-shaped void formed by the erupting bubble is rapidly filled by flowing solids. When these solids meet at the center of the void, solids are geysered upward. The downward pull of gravity and the upward pull of the drag force of the upward-flowing gas act on the particles. The larger and denser particles return to the top of the bed, and the finer and lighter particles are carried upward. The distance above the bed at which the entrainment becomes constant with height is called the transport disengaging height (TDH). Cyclones and vessel gas outlets are usually located just above the TDH. Figure 17-9 graphically estimates how TDH changes as a function of superficial gas velocity in the freeboard and bed size.

The higher the concentration of an entrainable particle size in the bed, the greater its rate of entrainment. Finer particles have a greater rate of entrainment than coarse ones. These principles are embodied in the method of Geldart (*Gas Fluidization Tech.*, Wiley, 1986, pp. 123–153) via the equation, $E(i) = K^*(i)x(i)$, where $E(i)$ = entrainment flux for size $i$, kg/(m$^2 \cdot$ s); $K^*(i)$ = entrainment rate constant for particle size $i$; and $x(i)$ = weight fraction for particle size $i$. $K^*$ is a function of operating conditions given by $K^*(i)/(P_f u) = 23.7 \exp[-5.4\, U_t(i)/U]$. The composition and the total entrainment are calculated by summing over all of the entrainable size fractions. A different way to calculate the entrainment rate is to use the method of Zenz, as reproduced by Pell (*Gas Fluidization*, Elsevier, Amsterdam, 1990, pp. 69–72).

In batch classification, the removal of fines (particles less than any arbitrary size) can be correlated by treating carryover as similar to a second-order reaction $K = (F/\theta)[1/x(x - F)]$, where $K$ = rate constant, $F$ = fines removed in time $\theta$, and $x$ = original concentration of fines.

***Gas Distributor*** The gas distributor (also often called the grid of a fluidized bed) has a considerable effect on proper operation of the fluidized bed. For good fluidized-bed operation, it is absolutely necessary to have a properly designed gas distributor. Gas distributors can be used both when the gas is clean and when the gas contains a small loading of solids. The primary purpose of the gas distributor is to cause uniform gas distribution across the entire bed cross section. It should support the solids in the bed, operate for years without plugging or breaking, minimize sifting of solids back into the gas inlet to the distributor (called "weeping"), and minimize the attrition of the bed material. When the gas is clean, the gas distributor is often designed to prevent backflow of solids during normal operation, and in many cases it is designed to prevent backflow during shutdown. To provide good operation of the distributor, it has been found by experience that the grid should have a pressure drop equal to about one-third of the bed pressure drop. Because of pressure fluctuations in the bed caused by bubbles, the pressure fluctuations in the bed can be as much as about one-third of the bed pressure drop. If the grid pressure drop is not at least equal to the bed pressure fluctuations for upward-pointing grid nozzles, solids can be forced downward through these holes into the plenum below the grid. When the solids eventually flow back upward through the grid, excessive erosion of the grid holes can occur. Good gas distribution through the grid can be achieved a grid pressure drop of at least as low as one-tenth of the pressure drop across the bed. However, to prevent weeping of solids through the grid for upward-pointing nozzles, the grid pressure drop should be at least one-third of the bed pressure drop.

For gas distributors with downward-pointing nozzles, the grid pressure drop can be as low as one-tenth of the pressure drop across the bed to

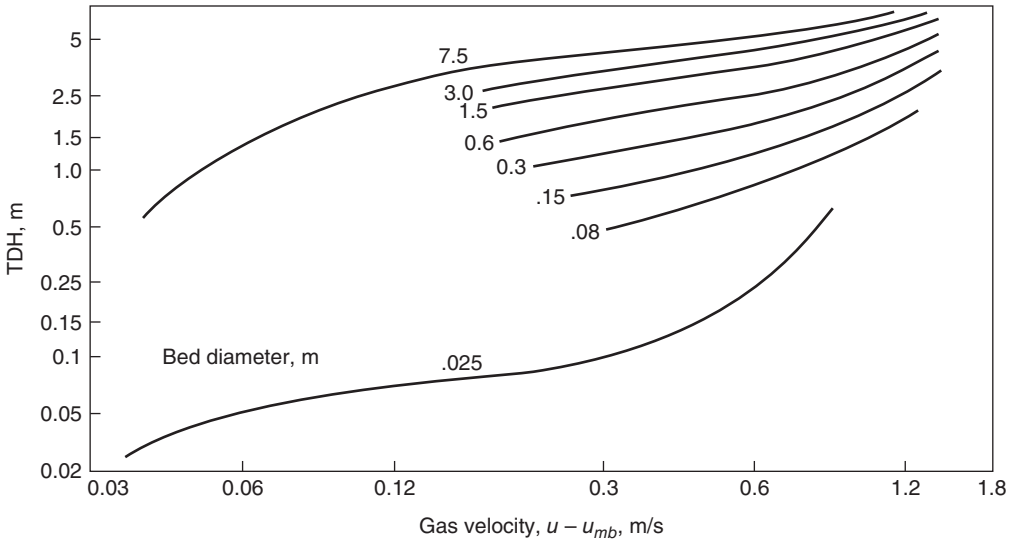

**FIG. 17-9** Estimating transport disengaging height (TDH).

prevent solids backflow into the distributor. If the pressure drop across the bed is extremely low, gas maldistribution can result, with the bed being fluidized in one area and not fluidized in another. In units with shallow beds, such as dryers, or where gas distribution is less crucial, lower gas distributor pressure drops can be used.

When both solids and gas pass through the distributor, such as in some fluidized catalytic cracking (FCC) units, a number of different gas distributor designs have been used. Because the inlet gas contains solids, it is much more erosive than gas alone, and care has to be taken to minimize the erosion of the grid openings as the solids flow through them. Generally, this is done by decreasing the inlet gas/solids velocity through the holes so that erosion of the grid openings is low. Some examples of grids that have been used with both solids and gases in the inlet gas are concentric rings in the same plane, with the annuli open (Fig. 17-10*a*); concentric rings in the form of a cone (Fig. 17-10*b*); grids of T bars or other structural shapes (Fig. 17-10*c*); flat metal perforated plates supported or reinforced with structural members (Fig. 17-10*d*); and dished and perforated plates concave both upward and downward (Fig. 17-10*e* and *f*). The distributors shown in Fig. 17-10*d*, *e*, and *f* also can be used with no solids in the gas to the distributor. The curved distributors of Fig. 17-10*d* and *e* are often used because they minimize thermal expansion effects.

There are three basic types of clean-gas distributors: (1) a perforated plate distributor, (2) a bubble cap type of distributor, and (3) a sparger or pipe-grid type of gas distributor. The perforated plate distributor (Fig. 17-10*d*) is the simplest type of gas distributor and consists of a flat or curved plate containing a series of vertical holes. The gas flows upward into the bed from a chamber below the bed called a plenum. This type of distributor is easy and economical to construct. However, when the gas is shut off, the solids can sift downward into the plenum and may cause erosion of the holes when the bed is started up again. The bubble cap type of distributor is designed to prevent backflow of solids into the plenum chamber or inlet line of the gas distributor on start-up or shutdown. The cap or tuyere type of distributor generally consists of a vertical pipe containing several small horizontal holes or holes angled downward from 30° to 45° from the horizontal (Fig. 17-11*a* and *b*). It is difficult for the solids to flow back through such a configuration when the fluidizing gas is shut off.

The pipe distributor (often called a sparger) differs from the other two distributor types because it consists of pipes with distribution holes in them that are inserted into the bed (Fig. 17-12). This type of distributor will often have solids below it that are not fluidized. If this is not acceptable for a process, then this type of distributor cannot be used. However, the pipe distributor has certain advantages. It does not require a large plenum, the holes in the pipe can be positioned at any angle (although most often they are pointed in downward at about a 45° angle), and it can be used in cases when multiple gas injections are required in a process (Fig. 17-12*c*). The most common type of pipe distributor is the multiple-pipe (manifold sparger) grid shown in Fig. 17-12*a*. Less common, but also used is the "wagon wheel" type of sparger distributor shown in Fig. 17-12*(b)*.

To generate a sufficient pressure drop for good gas distribution, a high velocity through the grid openings may be required. It is best to limit this velocity to less than about 45 m/s (150 ft/s) to minimize attrition of the bed material. The maximum hole velocity allowable may be even lower for very soft materials that attrit easily. The pressure drop and the gas velocity through the hole in the gas distributor are related by the equation

$$\Delta P = \frac{u^2 \rho_g}{2c^2 g_c} \quad \text{for fps units} \tag{17-5}$$

$$\Delta P = \frac{u^2 \rho_g}{2c^2} \quad \text{for SI units} \tag{17-6}$$

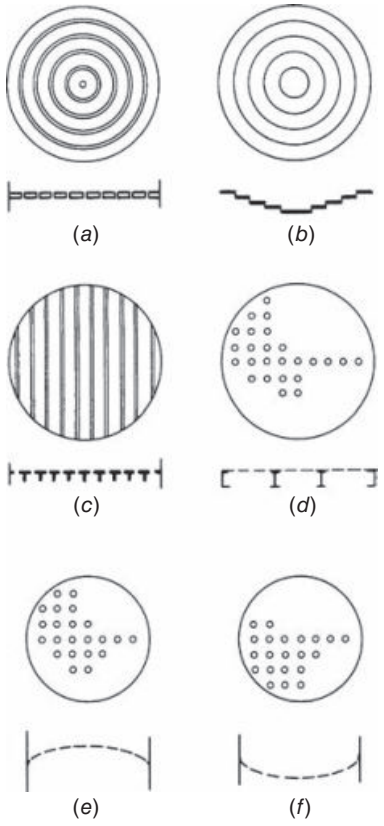

**FIG. 17-10** Gas distributors for gases containing solids.

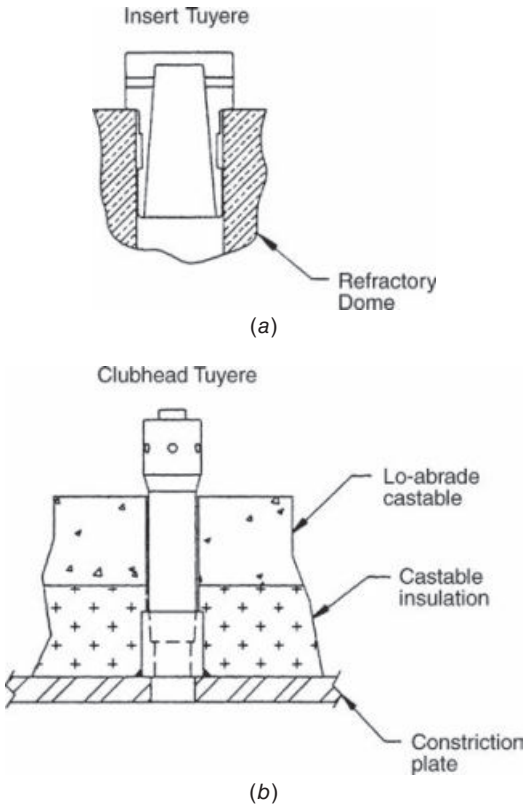

**FIG. 17-11** Gas inlet nozzles designed to prevent backflow of solids: (*a*) Insert tuyere; (*b*) clubhead tuyere. (*Dorr-Oliver, Inc.*)

where $u$ = superficial gas velocity in the grid hole at inlet conditions
$\rho_g$ = gas density in hole at conditions in inlet to hole, kg/m$^3$ or lb/ft$^3$
$\Delta P$ = pressure drop in consistent units, kPa or lb/ft$^2$
$C$ = orifice constant, dimensionless (typically 0.8 for gas distributors)
$g_c$ = gravitational conversion constant, ft-lb$_m$/(s$^2$ · lb$_f$)

Due to the pressure drop requirements across the gas distributor for good gas distribution, the velocity through the grid hole may be higher than desired in order to minimize or limit particle attrition. Therefore, it is common industrial practice to place a length of pipe (called a shroud) over the gas distributor hole such that the diameter of the pipe is larger than the diameter of the distributor hole. This technique effectively allows a smaller hole to give the required pressure drop, and the larger hole diameter of the shroud reduces the exit gas velocity into the bed so that particle attrition at the grid will be minimized. This technique is applied to both plate and pipe spargers.

Experience has shown that a concave-downward (Fig. 17-10*f*) gas distributor is a better arrangement than a concave-upward (Fig. 17-10*e*) gas distributor because it tends to increase the flow of gases in the outer portion of the bed. This counteracts the normal tendency of the gas to flow into the center of the bed after it exits the gas distributor. In addition, the concave-downward type of gas distributor tends to assist the general solids flow pattern in the bed, which is up in the center and down near the walls. The concave-upward gas distributor tends to have a slow-moving region at the bottom near the wall. If solids are large (or if they are slightly cohesive), they can build up in this region.

Structurally, distributors must withstand the differential pressure across the restriction during normal and abnormal flow conditions. In addition, during a shutdown, all or a portion of the bed will be supported by the distributor until sufficient backflow of the solids has occurred into the plenum to reduce the weight of solids above the distributor and to support some of this remaining weight by transmitting the force to the walls and bottom of the reactor. During start-up, a considerable upward thrust can be exerted against the distributor as the settled solids under the distributor are carried up into the normal reactor bed.

When the feed gas is devoid of or contains only small quantities of fine solids, more sophisticated designs of gas distributors can be used to realize economies in initial cost and maintenance. This is most pronounced when the inlet gas is cold and noncorrosive. When this is the case, the plenum chamber gas distributor and distributor supports can be fabricated of mild steel by using normal temperature design factors. The first commercial fluidized-bed ore roaster [Mathews, *Trans. Can. Inst. Min. Metall.* **L11:** 97 (1949)], supplied by the Dorr Co. (now Dorr-Oliver Inc.) in 1947 to Cochenour-Willans, Red Lake, Ontario, was designed with a mild steel constriction plate covered with castable refractory to insulate the plate from the calcine, and to provide cones in which refractory balls were placed to act as ball checks. The balls eroded unevenly, and the castable cracked. However, when the unit was shut down by closing the air control valve, the runback of solids was negligible because of bridging. If, however, the unit was shut down by de-energizing the centrifugal blower motor, the higher pressure in the reactor would relieve through the blower, and fluidizing gas plus solids would run back through the constriction plate. Figure 17-11 illustrates two designs of gas inlets that have been successfully used to prevent the flowback of solids. For best results, irrespective of the design, the gas flow should be stopped and the pressure relieved from the bottom upward through the bed. Some units have been built and successfully operated with simple slot-type distributors made of heat-resistant steel. This requires a heat-resistant plenum chamber but eliminates the often encountered problem of corrosion caused

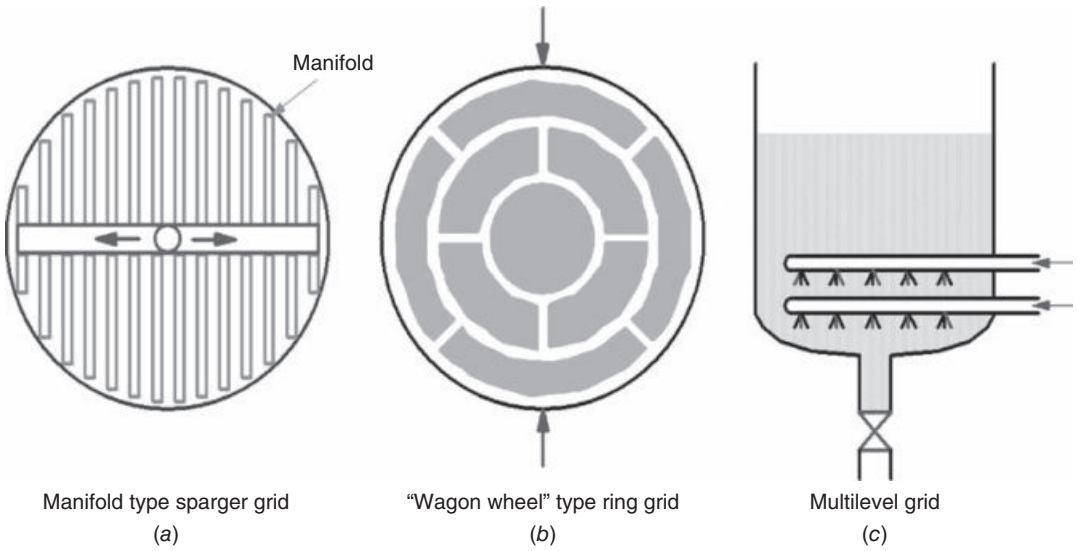

**FIG. 17-12** Manifold, wagon-wheel, and multilevel types of sparger distibutors: (*a*) multipipe manifold distributor; (*b*) wagon-wheel pipe distributor; (*c*) multilevel sparger distributor. (*Courtesy of PSRI, Chicago, Ill.*)

by condensation of acids and water vapor on the cold metal of the distributor. When the inlet gas is hot, such as in dryers or in the upper distributors of multibed units, ceramic arches or heat-resistant metal grates are generally used. Self-supporting ceramic domes have been in successful use for many years as gas distributors when temperatures range up to 1100°C. Some of these domes are fitted with alloy-steel orifices to regulate air distribution. However, the ceramic arch presents the same problem as the dished head positioned concave upward. Either the holes in the center must be smaller, so that the sum of the pressure drops through the distributor plus the bed is constant across the entire cross section, or the top of the arch must be flattened so that the bed depths in the center and outside are equal. This is especially important when shallow beds are used.

It is important to consider thermal effects in the design of the grid-to-shell seal. Bypassing of the grid at the seal point is a common problem caused by situations such as uneven expansion of metal and ceramic parts, a cold plenum and hot solids in contact with the grid plate at the same time, and start-up and shutdown scenarios. When the atmosphere in the bed is sufficiently benign, a sparger-type distributor may be used (Fig. 17-12). In some cases, it is impractical to use a plenum chamber under the constriction plate. This condition arises when a flammable or explosive mixture of gases is being introduced to the reactor. One solution is to pipe the gases to a multitude of individual gas inlets in the floor of the reactor. In this way it may be possible to maintain the gas velocities in the pipes above the flame velocity or to reduce the volume of gas in each pipe to the point at which an explosion can be safely contained. Another solution is to provide separate inlets for the different gases and to rely on the rapid axial mixing of the fluidized bed (Fig. 17-12*c*). The inlets should be fairly close to one another, as lateral gas mixing in fluidized beds is poor.

Much attention has been paid to the effect of gas distribution on bubble growth in the bed and the effect of this on catalyst utilization, space-time yield, etc., in catalytic systems. It would appear that the best gas distributor would be a porous membrane because of its even distribution. However, this type of distributor is seldom practical for commercial units because of structural limitations and the fact that it requires absolutely clean gas. Practically, the limitations on hole spacing in a gas distributor are dependent on the particle size of the solids, materials of construction, and type of distributor. If easily worked metals are used, then punching, drilling, and welding are not expensive operations, and they permit the use of a large number of holes. The use of tuyeres or bubble caps permits horizontal distribution of the gas so that a smaller number of gas inlet ports can still achieve good gas distribution. If a ceramic arch is used, generally only one hole per brick is permissible, and brick dimensions must be reasonable.

**Scale-Up**

***Bubbling or Turbulent Beds*** Scale-up problems in fluidized beds usually occur when the reaction rate is very fast. In this case, bubbling fluidized-bed hydrodynamics limit the rate of the reaction of gas and solids because the mass transfer of gas from the bubble to the emulsion (dense) phase is slower than the reaction rate. Therefore, hydrodynamics can limit the reaction, and it is of interest to try to increase the mass transfer rate. For Geldart Group A solids, most reactions are carried out in the turbulent fluidized-bed regime because of the increased mass transfer rate in that regime relative to the bubbling regime. For reactions that are slower than the mass transfer of bubble gas to the emulsion phase, scale-up fluidized beds is more straightforward, and this can sometimes be carried out on an area basis. However, scale-up even with slow reactions is not simple, and care must be taken at each step of the scale-up.

In a typical scale-up, small-scale tests are first made to determine reaction kinetics and physical limitations, such as sintering, agglomeration, and solids-holdup time required. Scale-up is typically conducted in several steps, from laboratory to commercial size. The hydrodynamics of gas–solids flow and contacting is quite different in small-diameter high-$L/D$ fluid beds as compared with large-diameter moderate-$L/D$ beds. In small-diameter beds, bubbles will be small, and they cannot grow larger than the vessel diameter. If they grow to a size approximately 2/3 of the bed diameter, the fluidized bed is said to be in a slugging mode, with large pressure fluctuations across it. In larger, deeper units, bubbles can grow very large. This is especially so for Geldart Group B and D particle beds.

The size of a bubble in the bed as a function of bed height was given by Darton et al. [*Trans. Inst. Chem. Eng.* **55:** 274–280 (1977)] as:

$$d_b = \frac{0.54(U - U_{mb})^{0.4}\left(h + 4\sqrt{A_t/N_0}\right)^{0.8}}{g^{0.2}} \tag{17-7}$$

where $d_b$ = bubble diameter, m
$h$ = height above the grid, m
$A_t/N_0$ = grid area per hole, $m^2$/hole
$U$ = superficial gas velocity, m/s
$U_{mf}$ = minimum bubbling velocity, m/s

Bubble growth in fluidized beds will be limited by the diameter of the containing vessel and bubble hydrodynamic stability. Bubbles in Geldart Group B and D systems can quickly grow to over 1 m in diameter if the gas velocity and the bed height are sufficient. Bubbles in Geldart Group A materials with a high percentage of fines (defined to be material less than 44 μm in size) will reach a maximum stable bubble size in a range of about 8 to 20 cm. Furthermore, solids and gas backmixing are much lower in deep (high-$L/D$) beds (whether they are slugging or bubbling) than in shallow (low-$L/D$) beds. Thus, the conversion or yield in large, unstaged reactors can sometimes be considerably lower than in small, high-$L/D$ units. To overcome some of the problems of scale-up, staged fluidized-bed units are often used (Fig. 17-13). A brief history of fluidization, fluidized-bed scale-up, and modeling will illustrate some problems involved with scaling up fluidized beds.

Fluidized beds were first used commercially in Germany in the late 1920s to gasify coal. Scale-up problems either were insignificant or were not publicized. During World War II, fluidized catalytic cracking of oil to produce gasoline was successfully commercialized by scaling up from pilot-plant size (a few centimeters in diameter) to commercial size (several meters in diameter). It is fortunate that the ratio of crude oil to catalyst is determined by thermal balance and the required catalyst circulation rates, and that the crude oil feed point was in the dilute-phase riser, which gives less

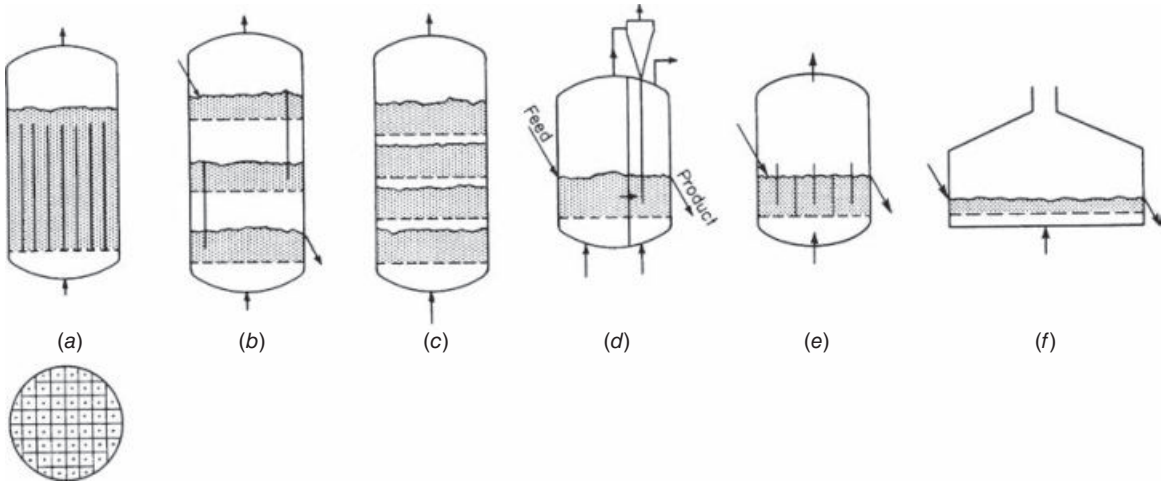

**FIG. 17-13** Methods of staging or minimizing backmixing in fluidized beds: (*a*) vertical, cross-hatched baffles to give high $L/D$; (*b*) staged beds with standpipes between stages; (*c*) staged beds with no standpipes between stages; (*d*) divided bed with small opening between the beds; (*e*) vertical baffles to give over/under solids flow pattern; (*f*) very shallow bed to minimize horizontal mixing.

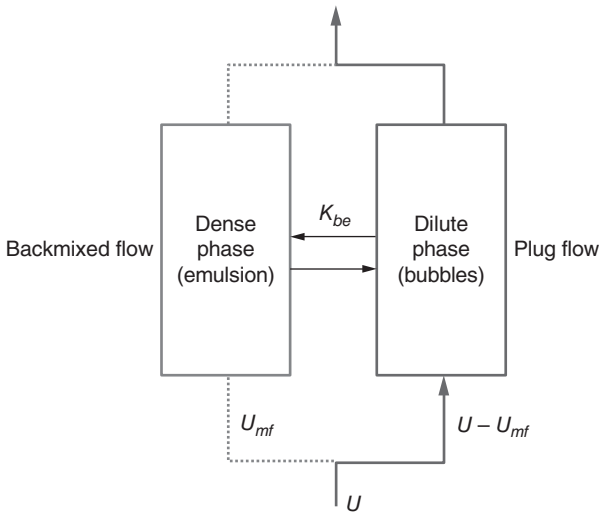

**FIG. 17-14** Two-phase model according to May [*Chem. Eng. Prog.* **55**(12): 49–55 (1959)] and Van Deemter [*Chem. Eng. Sci.* **13:** 143–154 (1961)]. $U$ = superficial gas velocity, $U_{mf}$ = minimum fluidizing velocity, $D_{ax}$ = axial dispersion coefficient, and $K_{be}$ = mass transfer coefficient. (*Courtesy of PSRI, Chicago, Ill.*)

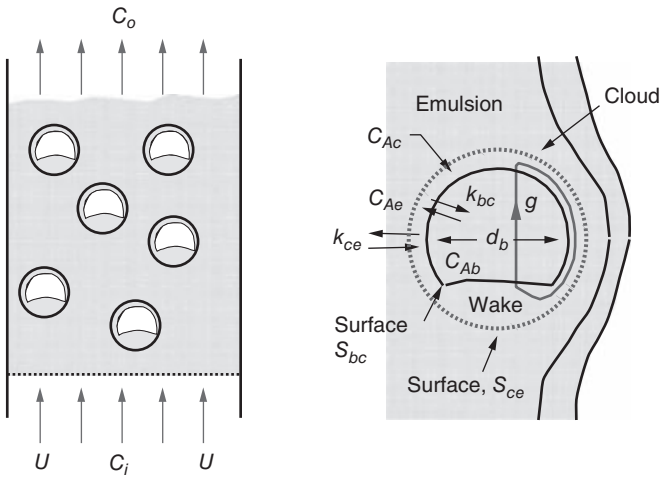

**FIG. 17-15** Bubbling-bed model of Kunii and Levenspiel. $d_b$ = effective bubble diameter, $C_{ab}$ = concentration of species A in emulsion, $q$ = volumetric gas flow rate into or out of bubble, $k_{bc}$ = mass-transfer coefficient between the bubble and the cloud, $k_{ce}$ = mass transfer coefficient between the cloud and the emulsion. (*From Kunii and Levenspiel,* Fluidization Engineering, *Wiley, New York, 1969.*) (*Courtesy of PSRI, Chicago, Ill.*)

backmixing than in a bubbling fluidized bed. The first experience of problems with scale-up of fluidized beds was associated with the production of gasoline from natural gas using the Fischer-Tropsch process. The results from a 0.10-m- (4-in-), 0.20-m- (8-in-), and 0.30-m- (12-in-) diameter pilot plants using a Group B iron catalyst were scaled to a 7-m-diameter commercial unit, where the yield was only about 50 percent of that achieved in the pilot units.

The problem was that the smaller reactors were operating in the slugging fluidized-bed mode (Fig. 17-4). In this mode, the slugs travel upward more slowly than in the bubbling fluidized-bed mode in the larger reactor, where the bubbles were much larger than the slugs and traveled much more rapidly through the bed. This resulted in a much shorter gas/solids contact time and the significantly lower conversion.

Immediately after this unfortunate experience, people were reluctant to use fluidized beds, and this slowed their development for some time. However, it was later shown that going to a smaller particle size (Geldart Group A material) and operating in the turbulent mode (for high mass transfer) solved most of the scale-up problems for the Fischer-Tropsch process.

Many bubbling fluidized-bed models have been developed; these basically are of two types, the two-phase model [May, *Chem. Eng. Prog.* **55**(12): 49–55 (1959); and Van Deemter, *Chem. Eng. Sci.* **13:** 143–154 (1961)] and the Kunii and Levenspiel bubble model (Kunii and Levenspiel, *Fluidization Engineering,* Wiley, New York, 1969). The two-phase model according to May and Van Deemter is shown in Fig. 17-14. In the two-phase model, all or most of the gas passes through the bed in plug flow in the bubble phase, which does not contain solids. The solids form a dense-suspension emulsion phase in which gas and solids mix according to an axial dispersion coefficient ($D_{ax}$). Cross-flow between the two phases is predicted by a mass-transfer coefficient, $K_{be}$.

Conversion of a gaseous reactant can be given by $C/C_0 = \exp[-Na \times Nr/(Na + Nr)]$, where $C$ = the exit concentration, $C_0$ = the inlet concentration, $Na$ = diffusional driving force, and $Nr$ = reaction driving force. Conversion is determined by both reaction and diffusional terms. It is possible for reaction to dominate in a lab unit with small bubbles, and for diffusion to dominate in a plant-size unit. It is this change of limiting regimes that makes scale-up so difficult. Refinements of the basic model and predictions of mass-transfer and axial-dispersion coefficients are the subject of many papers [Van Deemter, *Proc. Symp. Fluidization,* Eindhoven (1967); de Groot, ibid.; Van Swaaij and Zuidweg, *Proc. 5th Eur. Symp. React. Eng.*, Amsterdam, B9–25 (1972); DeVries, Van Swaaij, Mantovani, and Heijkoop, ibid., B9–59 (1972); Werther, *Ger. Chem. Eng.* **1:** 243–251 (1978); and Pell, *Gas Fluidization,* Elsevier, Amsterdam, 75–81 (1990)].

The Kunii and Levenspiel (K-L) bubbling bed model (Kunii and Levenspiel, *Fluidization Engineering,* Wiley, New York, 1969; Fig. 17-15) assumes constant-sized bubbles (with an effective bubble size $d_b$) rising through the emulsion phase. Gas is transferred from the bubble void to the cloud and wake with a mass-transfer coefficient of $k_{bc}$ and from the cloud to the emulsion phase with a mass-transfer coefficient $k_{ce}$. Experimental results have been fitted to theory by means of adjusting the effective bubble size. As mentioned previously, bubble size changes from the bottom to the top of the bed, and thus this model is not completely realistic, although it can be of considerable use in evaluating reactor performance. Several bubble models using bubbles of increasing size from the distributor to the top of the bed and gas interchange between the bubbles and the emulsion phase according to Kunii and Levenspiel have been proposed [Kato and Wen, *Chem. Eng. Sci.* **24:** 1351–1369 (1969); and Fryer and Potter, in *Fluidization Technology,* vol. I, ed. Keairns, Hemisphere, Washington, 1975, pp. 171–178].

There are several methods available to reduce scale-up loss. These are summarized in Fig. 17-16 for a process operating with Geldart Group A solids. The conversion efficiency of a fluid-bed reactor has been found to typically decrease as the size of the reactor increases. This decrease in reactor efficiency can be minimized by the use of a high gas velocity, fine solids, staging methods, and a high $L/D$. A high gas velocity maintains the reactor in the turbulent mode, where gas void breakup is rapid and frequent. A smaller particle size was found to lead to also promote turbulent fluidization. Maintaining a high $L/D$ minimizes backmixing, as does the use of baffles in the reactor. By using these techniques, Mobil was able to scale up its methanol to gasoline technology with little difficulty [Krambeck, Avidan, Lee, and Lo, *A.I.Ch.E.J.* **33:** 1727–1734 (1987)].

Another way to conduct the scale-up of bubbling fluidized-bed hydrodynamics is to build a cold and/or hot scale model of the commercial design and conduct testing in the models. Typically, a pilot plant reactor (typically 6 inches to 24 inches in diameter) will be built to obtain scale-up

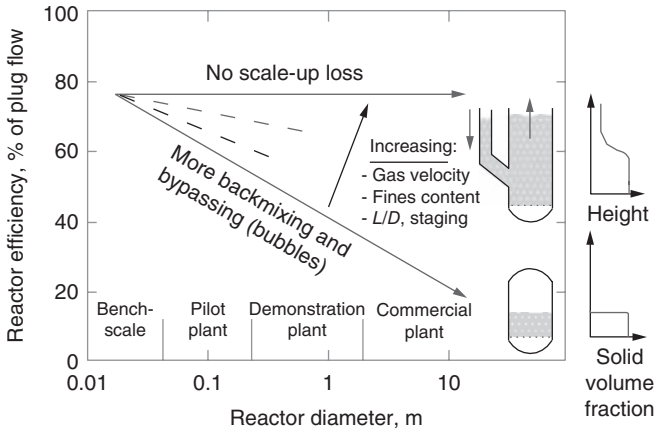

**FIG. 17-16** Reducing scale-up loss in group A fluidized beds. (*From Krambeck, Avidan, Lee and Lo,* A.I.Ch.E J., *1727–1734, 1987.*) (*Courtesy of PSRI, Chicago, Ill.*)

information in parallel with information from a relatively large cold model. Scaling parameters have also been developed such that dimensionless groups are the same in a small cold-flow model as well as with the high-temperature, large-scale units. However, designing a cold-flow model with dimensionless groups the same as in the large, high-temperature unit almost invariably results in the material in the cold model being different in particle size, particle density, or both.

***Circulating or Fast Fluidized Beds*** The circulating, or fast fluidized bed, is actually a misnomer in that it is not an extension of the turbulent bed, but is actually a part of the transport regime, as previously discussed. However, the fast fluidized bed operates in that part of the transport regime that is dominated by the static head of solids pressure drop term (the part of the regime where the solids concentration is the highest). The solids may constitute up to 10 percent of the volume of the system in this regime. There are no bubbles, mass-transfer rates are high, and there is little gas backmixing in the system. The high velocity in the system results in a high gas throughput, which minimizes reactor cost. Because there are no bubbles, scale-up is also less of a problem than with bubbling beds.

Many circulating systems (especially circulating fluidized-bed combustor systems) are characterized by an external cyclone return system that can have as large a footprint as the reactor itself. The axial solids density profile is relatively flat, as indicated in Fig. 17-6. There is a parabolic radial solids density profile in fast fluidized beds that is termed core annular flow. In the center of the reactor, the gas velocity and the solids velocity may be double the average. The solids in the center of the column (often termed a riser) are in dilute flow, traveling at their expected slip velocity $U_g - U_t$. Near the wall in the annulus, the solids are somewhat lower than their fluidized-bed density. The solids at the wall can flow either upward or downward. Whether they do so is determined primarily by the gas velocity used in the system. In circulating fluidized-bed combustor systems, the gas velocity in the rectangular riser is generally in the range of 4 to 6 m/s, and the solids flow downward at the wall. In fluid catalytic cracking, the velocity in the riser is typically in the range of 13 to 20 m/s, and the solids flow upward at the wall. Engineering methods for evaluating the hydrodynamics of the circulating bed are given by Kunii and Levenspiel (*Fluidization Engineering,* 2d ed., Butterworth, Oxford, UK, 1991, pp. 195–209), Werther (*Circulating Fluid Bed Technology IV,* Mobil Research and Development Corporation, Paulsboro Research Laboratory, 1994), and Avidan, Grace, and Knowlton, eds. (*Circulating Fluidized Beds,* Blackie Academic, New York, 1997).

***Pneumatic Conveying*** Pneumatic conveying systems can generally be scaled up on the principles of dilute-phase transport. Mass and heat transfer can be predicted on both the slip velocity during acceleration and the slip velocity at full acceleration. The slip velocity increases as the solids concentration is increased.

**Heat Transfer** Heat-exchange surfaces have been used to provide the means of removing or adding heat to fluidized beds. Usually, these surfaces are provided in the form of vertical or horizontal tubes manifolded at the tops and bottom or in a trombone shape manifolded exterior to the vessel. Horizontal tubes are extremely common as heat-transfer tubes. In any such installation, adequate provision must be made for abrasion of the exchanger surface by the bed. The prediction of the heat-transfer coefficient for fluidized beds is covered in Secs. 5 and 11.

Normally, the heat-transfer rate is between 5 and 25 times that for the gas alone. Bed-to-surface heat-transfer coefficients vary according to the type of solids in the bed. Group A solids have bed-to-surface heat-transfer coefficients of approximately 300 J/(m$^2$·s·K) [150 Btu/(h·ft$^2$·°F)]. Group B solids have bed-to-surface heat-transfer coefficients of approximately 100 J/(m$^2$·s·K) [50 Btu/(h·ft$^2$·°F)], while Group D solids have bed-to-surface heat-transfer coefficients of about 60 J/(m$^2$·s·K) [30 Btu/(h·ft$^2$·°F)]. These heat-transfer coefficients are approximate only, and they can vary considerably depending on gas velocity, system temperature, and pressure.

The large area of the solids per cubic foot of bed, 5000 m$^2$/m$^3$ (15,000 ft$^2$/ft$^3$) for 60-μm particles of about 600 kg/m$^3$ (40 lb/ft$^3$) bulk density, and the vast difference in heat capacity of the solids relative to the gas, results in the rapid approach of gas and solids temperatures near the bottom of the bed. Equalization of gas and solids temperatures generally occurs within 4 to 15 cm (1.5 to 6 in) of the top of the distributor in a bubbling fluidized bed.

Bed thermal conductivities in the vertical direction have been measured in the laboratory in the range of 40 to 60 kJ/(m$^2$·s·K) [20,000 to 30,000 Btu/(h·ft$^2$·°F·ft)]. Horizontal thermal conductivities for 3-mm (0.12-in) particles in the range of 2 kJ/(m$^2$·s·K) [1000 Btu/(h·ft$^2$·°F·ft)] have been measured in large-scale experiments. Except for extreme $L/D$ ratios or in some beds containing many horizontal baffles, the temperature in the fluidized bed is uniform—with the temperature at any point in the bed generally being within 5°C (10°F) or less of any other point. In fact, temperature difference is a good indicator of whether the bed is fluidized well. If two temperatures at any point in the bed differ by more than about 10°C (20°F), the bed is considered to have fluidization problems.

**Temperature Control** Because of the rapid equalization of temperatures in fluidized beds, temperature control can be accomplished in a number of ways:

1. *Adiabatic.* Control gas flow and/or solids feed rate so that the heat of reaction is removed as sensible heat in off-gases and solids or heat supplied by gases or solids.
2. *Solids circulation.* Remove or add heat by circulating solids.
3. *Gas circulation.* Recycle gas through heat exchangers to cool or heat.
4. *Liquid injection.* Add volatile liquid so that the latent heat of vaporization equals excess energy.
5. *Cooling or heating surfaces in bed.*

**Solids Mixing** Solids mixing in fluidized beds occurs because of bubbles. Solids are carried upward in the wake and the drift (or tail) of the bubble. When the bubble reaches the top of the bed, the solids are ejected upward and outward, and the solids are then circulated downward at the walls (Rowe and Patridge, "Particle Movement Caused by Bubbles in a Fluidized Bed," Third Congress of European Federation of Chemical Engineering, London, 1962). Thus, no mixing will occur at incipient fluidization, and solids mixing increases as the gas velocity through the bed is increased. Naturally, particles brought to the top of the bed must displace particles toward the bottom of the bed. Generally, solids upflow is upward in the center of the fluidized bed and downward at the wall.

At high ratios of fluidizing velocity to minimum fluidizing velocity, tremendous solids circulation from top to bottom of the bed assures rapid mixing of the solids. For all practical purposes, beds with $L/D$ ratios of from 0.1 to 4 can be considered to be completely mixed continuous-reaction vessels insofar as the solids are concerned.

Batch mixing using fluidization has been successfully employed in many industries. In this case there is practically no limitation on vessel dimensions.

All the foregoing pertains to solids of approximately the same physical characteristics. There is evidence that solids of widely different characteristics will classify one from the other at certain gas flow rates [Geldart, Baeyens, Pope, and van de Wijer, *Powder Technol.* **30**(2): 195 (1981)]. Two fluidized beds, one on top of the other, may be formed, or a lower static bed with a fluidized bed above may result. The latter often occurs when agglomeration takes place because of either fusion of particles in the bed or poor dispersion of sticky feed solids. Increased gas velocity in the bed sometimes overcomes this problem. However, improved feeding techniques or a change in operating conditions may be required. Another solution is to remove agglomerates either continuously or periodically from the bottom of the bed.

**Gas Mixing** The mixing of gases as they pass vertically up through the bed has never been considered a problem. However, horizontal mixing is often inadequate, and it requires effective distributors if two gases are to be mixed in the fluidized bed.

In bubbling beds operated at velocities of a few multiples of $U_{mf}$, the gases will flow upward in both the emulsion and the bubble phases. At higher gas velocities, the downward velocity of the solids in the emulsion phase is sufficient to carry the contained gas downward. The gas velocity where the gas in the emulsion begins to flow downward depends primarily on the particle size of the material. The back mixing of gases increases as $U/U_{mf}$ is increased until the circulating or fast regime is reached. In the fast fluidization regime gas back mixing decreases as the velocity is further increased.

**Size Enlargement** Under proper conditions, solid particles can be caused to increase in size in the bed. This can be advantageous or disadvantageous. Particle growth is usually associated with the melting or softening of some portion of the bed material (e.g., addition of soda ash to calcium carbonate feed in lime reburning, tars in fluidized-bed coking, or lead or zinc roasting causes agglomeration of dry particles in much the same way as binders act in rotary pelletizers). The motion of the particles, one against the other, in the bed results in spherical pellets. If the size of these particles is not controlled, rapid agglomeration and segregation of the large particles from the bed can occur. Control of agglomeration can be achieved by crushing a portion of the bed product and recycling it to form nuclei for new growth. Often, liquids or slurries are fed via a spray nozzle into the bed to cause particles to grow. In drying solutions or slurries of solutions, the location of the feed injection nozzle (spray nozzle) has a large effect on the size of the particles formed in the bed. Also of importance are the operating temperature, relative humidity of the off-gas, and gas velocity in the bed. Particle growth can occur as agglomeration (two or more particles sticking together) or by the particle growing in layers, often called *onion skinning.*

**Size Reduction** *Attrition* is the term used to describe particle reduction in the fluidized bed. Three major attrition mechanisms occur in the fluidized bed: particle abrasion, particle fragmentation (particle fracture), and particle thermal decrepitation. Particle abrasion occurs when the protruding edges on individual particles are broken off in the bed. These particle sizes are very small—usually on the order of 2 to 10 μm. Particle fragmentation

occurs when particle interaction is severe enough to cause the particles to break up into smaller individual pieces, but much greater than the particles produced by abrasion.

Particle attrition occurs near the grid because of particles being accelerated by the gas jets and then impacting the particles in the bed. Particle attrition in cyclones and risers occurs because the particles hit the cyclone wall or the bend at the top of the riser, respectively.

Because of the random motion of the solids, some abrasion of the particle surface occurs in the fluidized bed itself. However, this abrasion is extremely small relative to the particle breakup caused by the high-velocity jets at the distributor or the high inlet velocities in cyclones, and is often neglected. Typically, particle abrasion has been determined in some catalytic processes to be about 0.25 to 1 percent of the solids per day. Whether attrition occurs by abrasion or by fragmentation depends on the strength of the particles. In many catalytic processes, nearly all of the attrition occurring is due to abrasion. In other processes, fragmentation is the dominant mechanism. In the area of high gas velocities at the distributor, greater rates of attrition will occur because of fracture of the particles by impact. As mentioned previously, particle fracture of the grid is reduced by adding shrouds to the gas distributor.

Generally, particle attrition is unwanted. However, at times, controlled attrition is desirable. For example, in fluidized-bed coking units where agglomeration due to wet particles is frequent, jets are used to attrit particles to control particle size [Dunlop, Griffin, and Moser, *J. Chem. Eng. Prog.* **54:** 39–43 (1958)].

Thermal decrepitation occurs often when crystals are rearranged because of transition from one form to another, or when new compounds are formed (e.g., calcination of limestone). Sometimes the stresses on particles in cases such as this are sufficient to reduce the particle to almost the basic crystal size. All these mechanisms will cause the completion of fractures that were started before the introduction of the solids into the fluidized bed.

**Solids Feeders and Solids Flow Control** Several designs of valves for solids flow control are used. These should be chosen with care to suit the specific conditions. Figure 17-17 shows (schematically) some of the devices used for solids flow control. The devices shown are a slide valve, also known as a knife-gate valve (Fig. 17-17*a*), a rotary valve (Fig. 17-17*b*), a table feeder (Fig. 17-17*c*), a screw feeder (Fig. 17-17*d*), a cone valve (Fig. 17-17*e*), and an L-valve (Fig. 17-17*f*). All of the feeders are mechanical feeders except for the L-valve, which is a nonmechanical valve. This type of valve uses only injected aeration gas to control the flow of solids through it.

Not shown in Fig. 17-17 is the flow-control arrangement used in the Exxon Research & Engineering Co. model IV catalytic-cracking units. This device consists of a U-bend. A variable portion of regenerating air is injected into the riser leg. Changes in air-injection rate change the fluid density in the riser part of the U-bend and thereby achieve control of the solids flow rate. Catalyst circulation rates of 1200 kg/s (70 tons/min) have been reported using these bends.

When the solid is one of the reactants, such as in ore roasting, the flow must be continuous and precise in order to maintain constant conditions in the reactor. Feeding of free-flowing granular solids into a fluidized bed is not difficult. Standard commercially available solids-weighing and -conveying equipment can be used to control the rate and deliver the solids to the feeder. Screw conveyors (Fig. 17-17*d*), dip pipes, seal legs, and injectors are used to introduce the solids into a reactor. Difficulties arise and special techniques must be used when the solids are not free-flowing, as is the case with most filter cakes. One solution to this problem was developed at Cochenour-Willans. After much difficulty in trying to feed a wet and sometimes frozen filter cake into the reactor by means of a screw feeder, experimental feeding of a water slurry of flotation concentrates was attempted. This trial was successful, and this method has been used in almost all cases in which the heat balance, particle size of solids, and other considerations have permitted. Gilfillan et al. (*J. Chem. Metall. Min. Soc. S. Afr.,* May 1954) present complete details on the use of this system for feeding.

When slurry feeding is impractical, recycling of solids product to mix it with the feed, both to dry and to achieve a better-handling material, has been used successfully. Also, the use of a rotary table feeder mounted on top of the reactor, discharging through a mechanical disintegrator, has been successful. The wet solids generally must be broken up into discrete particles of very fine agglomerates either by mechanical action before entering the bed, or by rapidly vaporizing water. If lumps of dry or semidry solids are fed, the agglomerates do not break up but tend to fuse together. Because the size of the agglomerate is many times the size of the largest individual particle, these agglomerates will segregate out in the bed, and in time the whole of the fluidized bed may be replaced with a static bed of agglomerates.

**Standpipes** In a fluid catalytic cracking (FCC) unit, hot Group A catalyst is added to aspirated crude oil feed in a riser to crack the feed oil into gasoline and other light and heavy hydrocarbons. The catalyst activity is reduced by this contact as carbon is deposited on the catalyst. The catalyst is then passed through a steam stripper to remove the gas product in the interstices of the catalyst and is transported to a regenerator. The carbon on the catalyst is burned off in the fluidized-bed regenerator, and then the regenerated, hot catalyst is transported back to the bottom of the riser to crack the feed oil. Large FCC units have to control solids flow rates from 10 to 80 tons/min. The units require makeup catalyst to be added to replace solids losses due to attrition and other losses. The amount of catalyst makeup is small, and need not be continuous. Therefore, the makeup catalyst is fed into the commercial unit from pressurized hoppers into one of the conveying lines. However, the primary solids flow control problem in this FCC unit is to maintain the correct temperature in the riser reactor by controlling the flow of hot regenerated catalyst around the test unit. This is done by using large, 1.2-m (4-ft)-diameter slide valves (also known as knife-gate valves) located in standpipes to control the flow rates of catalyst.

In the FCC process, the solids are transferred out of the fluidized-bed regenerator into the bottom of the riser via a standpipe. The purpose of a standpipe is to transfer solids from a low-pressure region to a high-pressure region via gravity. The point of removal of the solids from the regenerator bed is at a lower pressure than the point of feed introduction into the riser. Therefore, the transfer of solids from the regenerator bed to the bottom of the riser is accomplished with a standpipe. The standpipes in FCC units can be as large as 1.5 m (5 ft) in diameter, and as long as about 30 m (100 ft). They can be either vertical or angled (generally approximately 60° from the horizontal). The pressure is higher at the bottom of a standpipe due to the relative flow of gas counter to the solids flow. The gas in the standpipe may be flowing either downward relative to the pipe wall, but more slowly than the solids (the most common occurrence), or upward relative to the pipe wall. The standpipe may be fluidized, or the solids may be in moving packed-bed flow.

There are two basic types of standpipe configurations: the overflow standpipe and the underflow standpipe (Fig. 17-18). The overflow standpipe is so named because the solids "overflow" from the top of the fluidized bed into the standpipe, and there is no bed of solids above the standpipe. In the underflow standpipe, the solids are introduced into the standpipe from the underside, or bottom, of the bed or hopper, and a bed of solids is present above the standpipe. With this definition, a cyclone dipleg is classified as an overflow standpipe because there is no bed of solids above the entrance to the dipleg.

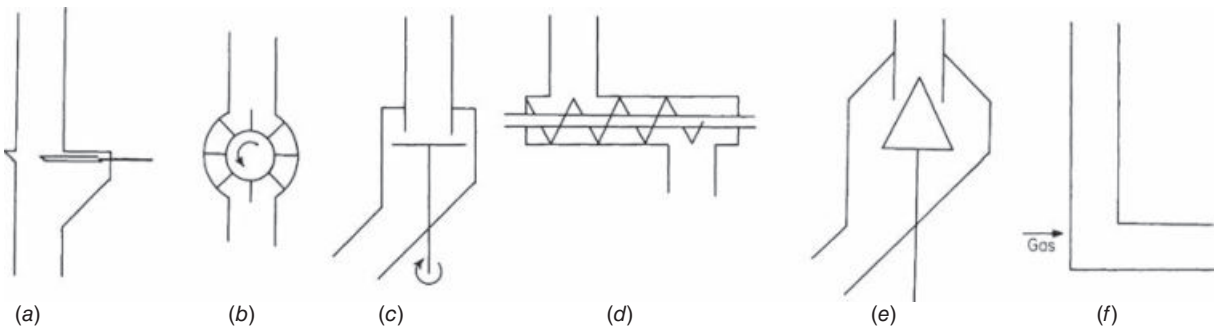

**FIG. 17-17** Solids flow control devices: (*a*) slide valve, (*b*) rotary valve, (*c*) table feeder, (*d*) screw feeder, (*e*) cone valve, (*f*) L-valve.

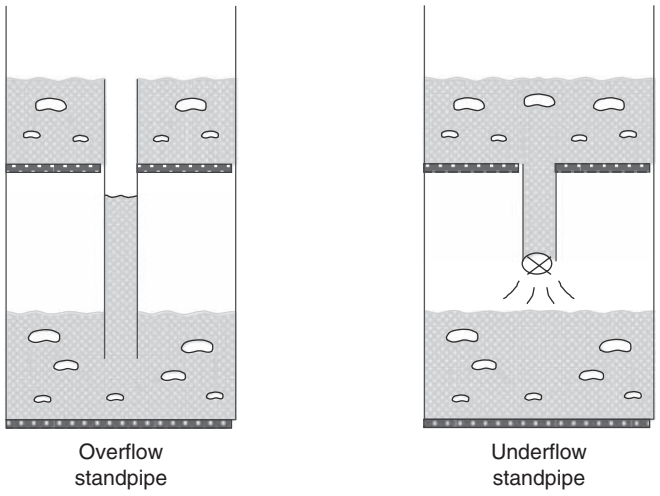

**FIG. 17-18** Schematic depiction of overflow and underflow standpipes. (*Courtesy of PSRI, Chicago, Ill.*)

With the two types of standpipe configurations and the two typical standpipe flow regimes ( fluidized and packed bed), there are four different types of standpipes:

1. An underflow packed-bed standpipe
2. An underflow fluidized-bed standpipe
3. An overflow fluidized-bed standpipe
4. An overflow packed-bed standpipe

All of these standpipes are used extensively in industry except for the overflow packed-bed standpipe. It is possible for this type of standpipe to operate, but it is much harder to operate and control than the others. Therefore, it is not used.

Fluidized standpipes can accommodate a much higher solids flow rate than moving packed-bed standpipes because the friction of the solids flow on the wall of the standpipe is much less in fluidized standpipes.

One of the most common standpipes in industry is the fluidized underflow standpipe (Fig. 17-19). With the fluidized underflow standpipe, aeration gas is added to the standpipe to maintain the solids in a fluidized state as they flow down the standpipe. As the solids flow down the fluidized underflow standpipe from a low pressure to a higher pressure, the gas in the standpipe is compressed, which causes the solids to move closer together. When the standpipe is operating at low pressures, the percentage change in gas density from the top of the standpipe to the bottom can be significant. If aeration is not added to the standpipe to prevent this, the solids can defluidize near the bottom of the standpipe. Defluidization of solids in this standpipe results in less pressure buildup in the standpipe and a reduction in the solids flow rate through it.

To keep the solids in a fluidized underflow standpipe in a fluidized state, aeration gas is added to the standpipe. Adding the correct amount of gas uniformly (every 1.5 to 2 m) in a commercial fluidized underflow standpipe will prevent defluidization at the bottom of the standpipe. If the material flowing in the standpipe is a Geldart Group A material, it is required that the aeration be added uniformly along the standpipe. If the aeration is added at only one location (e.g., at the bottom of the standpipe), a large bubble will form in the standpipe at the aeration point (Fig. 17-20*a*). If the bubble is large enough, it can restrict the flow of solids down the standpipe. The large bubble forms because it is difficult for the aeration gas to permeate the very fine solids moving through the standpipe. Therefore, it requires a significant area for the gas to dissipate through the very fine particles at the same rate that it is being added through the aeration tap. If the aeration gas is added at several locations, then the bubble size is significantly reduced, and standpipe operation is significantly improved (Fig. 17-20*b*). Aeration bubbles extend downward from the aeration point in the direction of flow of the solids (Fig. 17-20*b*). This occurs because the momentum of the solids is much greater than the buoyancy force of the bubble, and it elongates the aeration bubble in the direction of flow.

Typically, the pressure drop across the solids control valve in a commercial fluidized underflow standpipe should be designed for a minimum of approximately 2 psi (14 kPa) for good control. A maximum of no more than 10 to 12 psi (70 to 84 kPa) is recommended to prevent excessive erosion of the valve at high pressure drops [Zenz, *Powder Technol.* **2:** 105–113 (1986)].

For Geldart Group B solids, it is often unnecessary to add aeration at several locations along the standpipe to maintain the standpipe in fluidized flow. Adding aeration at the bottom of the standpipe operating with Group B solids is generally sufficient. This is because the gas can permeate through the larger Group B particles more easily than through the Group A particles (Group A particles have a significantly larger surface area and produce more drag for the same gas flow conditions).

The amount of aeration required to maintain solids in a fluidized state throughout a fluidized underflow standpipe was presented by Karri and Knowlton [*Circulating Fluidized Bed Technology* **IV:** 253 (1993)] to be:

$$Q = 2000\left[\frac{P_b}{P_t}\left(\frac{1}{\rho_{mf}} - \frac{1}{\rho_{sk}}\right) - \left(\frac{1}{\rho_t} - \frac{1}{\rho_{sk}}\right)\right] \tag{17-8}$$

where $Q$ is the aeration required in actual cubic feet per ton of solids flowing in the standpipe, $P_b$ is the pressure at the bottom of the standpipe in psia, $P_t$ is the pressure at the top of the standpipe in psia, $\rho_{mf}$ is the fluidized bed density at minimum fluidization in lb/ft$^3$, $\rho_{sk}$ is the skeletal density of the particles in lb/ft$^3$, and $\rho_t$ is the density at the top of the standpipe in lb/ft$^3$.

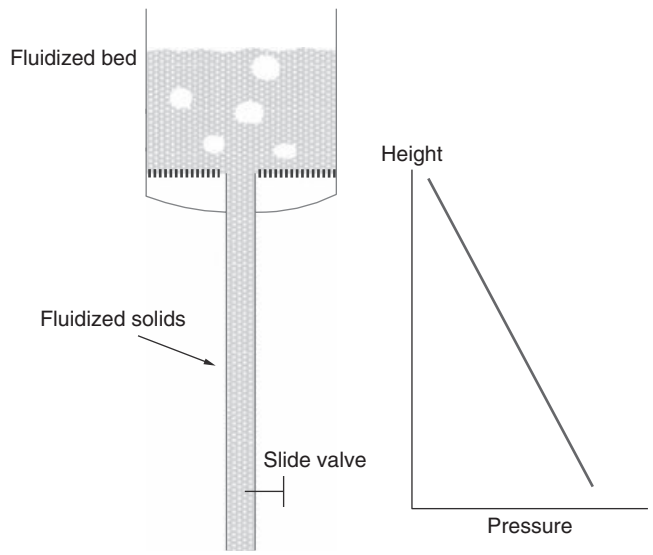

**FIG. 17-19** Schematic depiction of a fluidized, underflow standpipe. (*Courtesy of PSRI, Chicago, Ill.*)

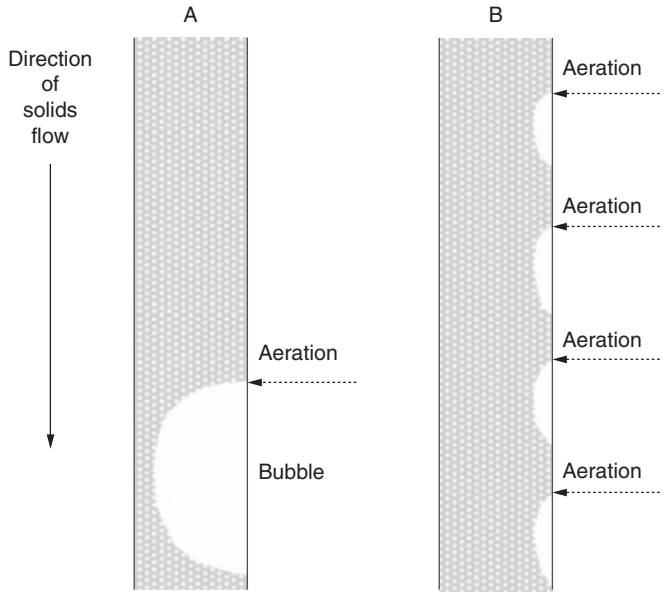

**FIG. 17-20** The effect of adding aeration at a single point or multiple points in a Geldart group A underflow fluidized standpipe. (*Courtesy of PSRI, Chicago, Ill.*)

This is an estimate of the theoretical amount of aeration that should be added to the standpipe. In practice, it has been found that about 70 percent of the theoretical amount is a better estimate of the actual aeration required. In a commercial fluidized underflow standpipe, the amount of aeration theoretically required is added in equal increments via aeration taps located approximately 1.5 to 2 m apart. Care should be taken not to overaerate the standpipe. If this occurs, large bubbles are generated in the standpipe that hinder solids flowing down the standpipe. Thus, standpipes can be overaerated as well as underaerated.

As indicated above, it is detrimental to have bubbles in standpipes. For fluidized-bed underflow standpipes with the standpipe entrance in the fluidized bed, bubbles can be "sucked" down the standpipe at its entrance if nothing is done to prevent this from occurring. This is especially true when the bed consists of Geldart Group A solids. When solids flow from a fluidized bed into the top of an underflow fluidized-bed standpipe, the solids are accelerated from a low velocity near 0 ft/s in the bed to as much as 6 ft/s in the standpipe. This sudden increase in solids velocity can carry bubbles with the solids down into the standpipe and degrade standpipe operation. To prevent this, a cone (Fig. 17-21) is often added to the top of the standpipe to minimize the solids velocity at the standpipe entrance and minimize bubble "carryunder." Experience has shown that the diameter of the standpipe inlet cone should be four to six times the area of the standpipe [King, *Fluidization VII:* 15, (1991)]. Standpipe inlet cones typically have an included angle of from 25° to 35°.

In many fluidized beds, a sparger type of gas distributor is used to fluidize the bed. The sparger consists of a pipe with nozzles in it inserted into the bottom of the fluidized bed. Solids flow down through the distributor and into the standpipe. Another technique to prevent bubbles from entering the top of the standpipe can be used with sparger grids. Instead of having the standpipe entrance in the bed, the standpipe entrance is located below the sparger grid. As the solids flow between the sparger grid and the standpipe entrance, the bubbles dissipate and do not enter the standpipe. Generally, an aeration ring is added around the standpipe to ensure that the solids are fluidized as they enter the standpipe. With this configuration, a cone at the entrance of the standpipe is not required.

Underflow fluidized standpipes are operated in either a vertical configuration, a completely angled configuration, or a hybrid configuration in which both vertical and angled sections are present (Fig. 17-22). Angling a standpipe is a very convenient way to transfer solids between two points that are separated horizontally as well as vertically. However, it has been found by Karri and Knowlton [*Circulating Fluidized Bed Technology* **IV:** 253 (1993)] and Yaslik [*Circulating Fluidized Bed Technology* **IV:** 484 (1993)] that long, angled underflow fluidized standpipes do not perform as well as vertical standpipes.

Sauer et al. [*AIChE Symposium Series 234* **80:** 1 (1984)] and Karri and Knowlton [*Circulating Fluidized Bed Technology* **IV:** 253 (1993)] studied hybrid angled standpipe operation using transparent standpipes to allow visual observation of the flow. Both found that the gas and solids separated in the standpipe, with the gas bubbles flowing up along the upper portion

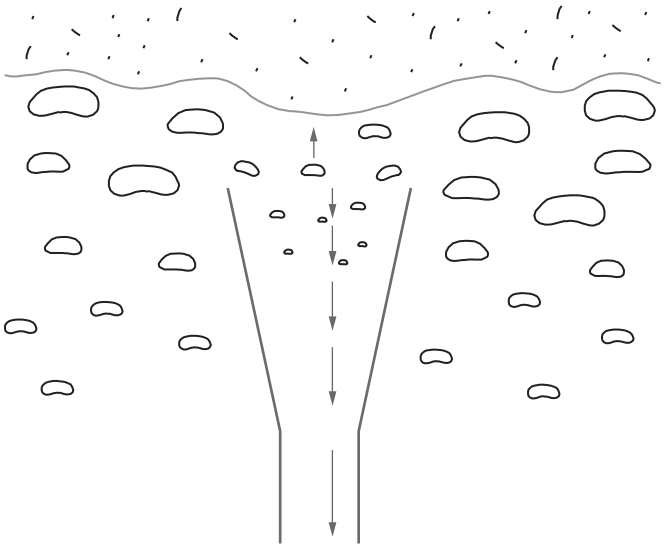

**FIG. 17-21** Schematic depiction of an inlet cone for a fluidized underflow standpipe. (*Courtesy of PSRI, Chicago, Ill.*)

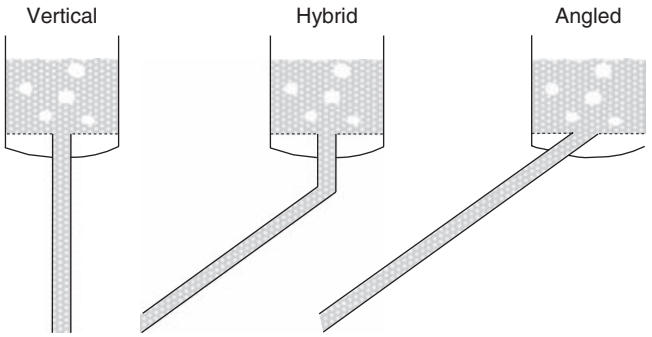

**FIG. 17-22** Schematic depiction of vertical, angled, and hybrid standpipes. (*Courtesy of PSRI, Chicago, Ill.*)

of the standpipe while the solids flowed down along the bottom portion of the standpipe (Fig. 17-23). The pressure buildup in the hybrid standpipe was lower than that in the vertical standpipe, and Karri and Knowlton [*Circulating Fluidized Bed Technology* **IV:** 253 (1993)] reported that the maximum solids mass flux possible in a hybrid angled underflow fluidized standpipe was less than that attainable in a vertical underflow fluidized standpipe. The principal reason for this is that the rising bubbles in the angled section of the standpipe become relatively large at a low solids flow rate (and low aeration rate). At a certain solids mass flux, the bubbles become large enough to bridge across the vertical section at the top of the standpipe, hindering the solids flow. When this occurs, the maximum solids flow rate in the hybrid angled standpipe has been achieved.

Karri et al. [*Fluidization* **VII:** 1075 (1995)] showed that the solids flow rate through a hybrid angled standpipe can be increased if a bypass line is added between the top of the angled section of the standpipe and the freeboard of the bed above it. The bypass line allows the bubble gas from the angled section to bypass the vertical section of the pipe so that large bubbles are not formed there. Thus, the solids flow rate can be increased. Karri et al. [*Fluidization* **VII:** 1075 (1995)] reported that if the bypass was used, the solids flow rate could be increased to such a value that the solids velocity in the hybrid standpipe became greater than the bubble rise velocity, and the bubbles were carried down the standpipe with the solids. When the bubbles were being carried down the standpipe by the solids, the bypass line could then be closed, and the standpipe would operate without slugging in the vertical section.

Even though vertical standpipes can transfer solids more efficiently than hybrid angled standpipes, true angled standpipes (those containing no vertical section) are commonly operated satisfactorily in large FCC units with Geldart Group A catalyst. However, these standpipes are relatively short, and they are designed so that the mass flux through them is not too high so that they can be operated satisfactorily. Yaslik [*Circulating Fluidized Bed Technology* **IV:** 484 (1993)] found that a long, angled standpipe had a limited solids circulation rate relative to vertical standpipes. Thus, when operating a hybrid angled standpipe or a true angled standpipe it is essential to: (1) keep the solids mass flux through the standpipe below a value which will lead to slugging, and (2) keep the line as short as possible so that the large gas slugs will not have as great a length in which to form.

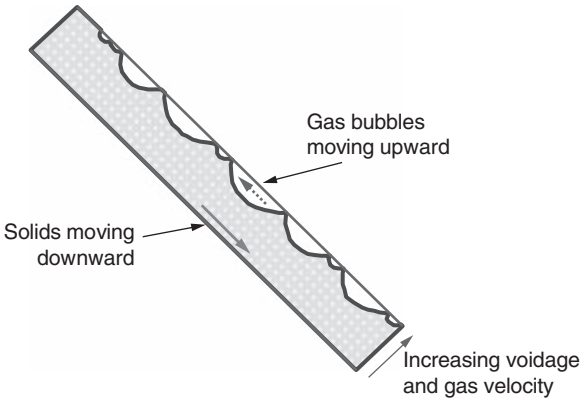

**FIG. 17-23** Depiction of gas and solids flow in an angled standpipe. (*Courtesy of PSRI, Chicago, Ill.*)

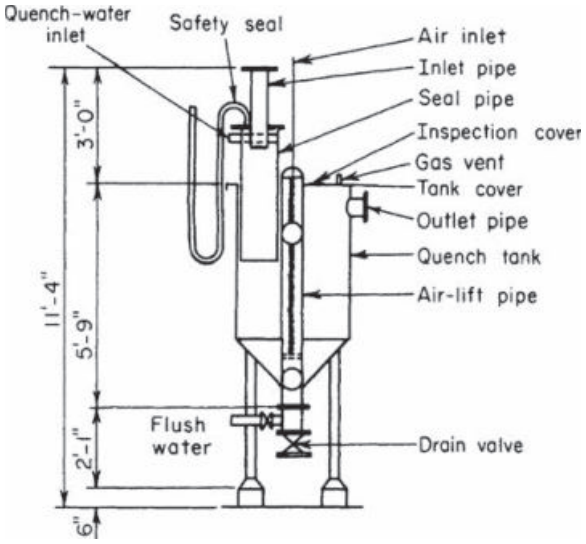

**FIG. 17-24** Quench tank for overflow or cyclone solids discharge. [*Gilfillan et al., "The FluoSolids Reactor as a Source of Sulphur Dioxide,"* J. Chem. Metall. Min. Soc. S. Afr. (*May 1954*).]

**Solids Discharge** The type of fluidized-bed discharge mechanism used is dependent on the necessity of sealing the atmosphere inside the fluidized-bed reactor and the subsequent treatment of the solids. One of the simplest solids discharge types is an overflow weir. This can be used only when the escape of fluidizing gas does not present any hazards due to its nature or dust content, or when the leakage of gas into the fluidized-bed chamber from the atmosphere into which the bed is discharged is permitted. Solids will overflow from a fluidized bed through a port even though the pressure above the bed is maintained at a slightly lower pressure than the exterior pressure. When it is necessary to restrict the flow of gas through the opening, a simple flapper valve can sometimes be used. Overflow to a combination seal and quench tanks (Fig. 17-24) is used when it is permissible to wet the solids and when disposal or subsequent treatment of the solids in slurry form is desirable. The fluidized seal pot and a loop seal (sometimes called a FluoSeal) are simple and effective ways of sealing and purging gas from the solids when an overflow-type discharge standpipe is used (Fig. 17-25). The upleg of the loop seal must be fluidized in order for it to work properly. A more recent loop seal design has the downleg angled at about 45° to 60° from the horizontal (Fig. 17-26) so that it connects directly with the upleg. This angled design eliminates the horizontal flow section of the loop seal.

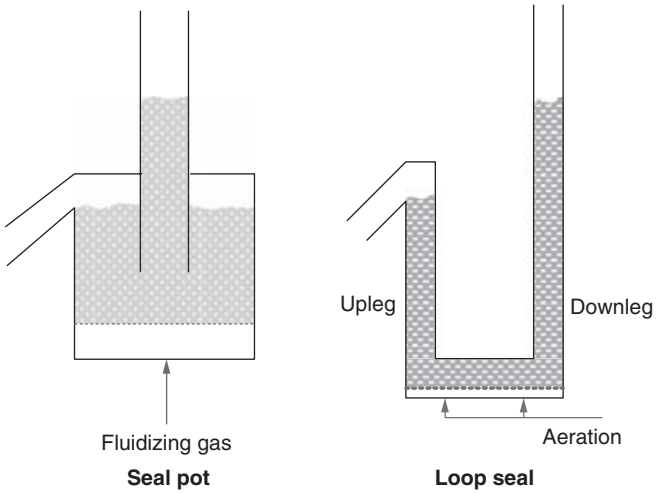

**FIG. 17-25** Schematic drawing of a seal pot and a loop seal. (*Courtesy of PSRI, Chicago, Ill.*)

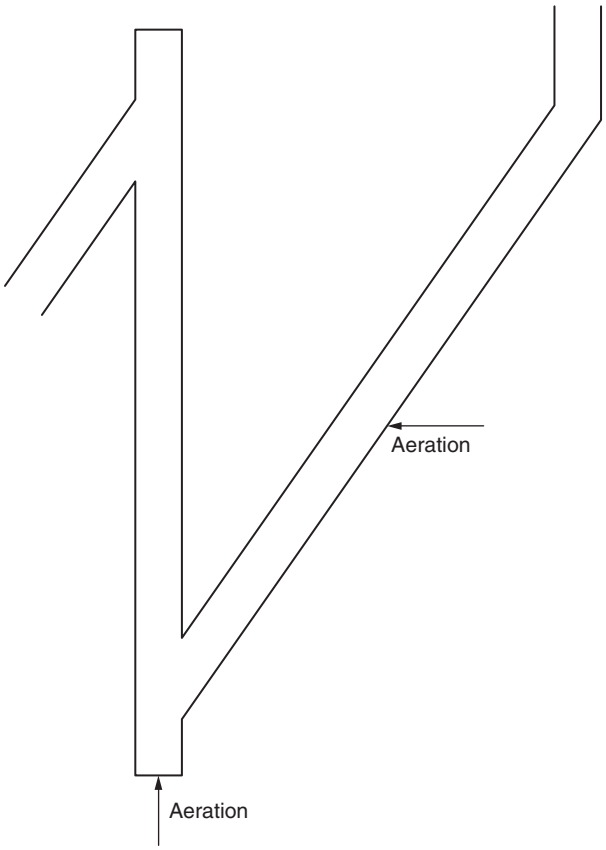

**FIG. 17-26** Angled loop seal. (*Courtesy of PSRI, Chicago, Ill.*)

A star (rotary) valve is an effective sealing device for solids discharge. It functions well with a head of solids above it. Bottom-of-the-bed discharge is also acceptable via a slide valve with a head of solids.

Seal legs are often used in conjunction with both mechanical and nonmechanical solids-flow-control valves to equalize pressures and to strip trapped or adsorbed gases from the solids. The operation of a seal leg is shown schematically in Fig. 17-27. The solids flow by gravity from the fluidized bed into the seal leg or standpipe. Seal and/or stripping gas is introduced near the bottom of the leg. If designed properly, this gas flows both upward and downward. Pressures indicated in the illustration have no absolute value but are only relative. The seal legs can be designed for either fluidized or nonfluidized solids.

The L-valve is shown schematically in Fig. 17-28. The L-valve can increase or decrease the flow rate of solids through it by adding more or less aeration gas to it, respectively. In the control mode, the standpipe above the L-valve must be an underflow, moving (nonfluidized) bed [Knowlton, T. M., *Standpipes and Nonmechanical Valves*, chap. 21 in *Handbook of Fluidization and Fluid-Particle Systems,* ed. W. C. Yang, Marcel Dekker, New York, (2003), p. 575].

The L-valve can also act like a nonsolids flow control seal where it does not control the flow rate of solids through it. When operating in this mode, the standpipe above it should be an overflow, fluidized-bed standpipe [Knowlton, T. M., *Standpipes and Nonmechanical Valves*, chap. 21 in *Handbook of Fluidization and Fluid-Particle Systems,* ed. W. C. Yang, Marcel Dekker, New York, (2003), p. 575]. In this mode it is called an "automatic" L-valve. Thus, the L-valve can act both as a seal and as a solids-flow control valve. When used to control the solids flow rate, it is only practical to use the L-valve for solids that deaerate quickly (Geldart Group B and D solids). Generally, the average particle size of the solids must be greater than about 100 to 120 μm for the L-valve to work well. The height at which aeration is added to the L-valve in Fig. 17-28 is usually 1.5 pipe diameters above the centerline of the horizontal section of the L-valve. For L-valve design equations, see Yang and Knowlton [*Powder Tech.***77:** 49–54 (1993)] and [Knowlton, T. M., *Standpipes and Nonmechanical Valves*, chap. 21 in *Handbook of Fluidization and Fluid-Particle Systems,* ed. W. C. Yang, Marcel Dekker, New York, (2003), p. 575].

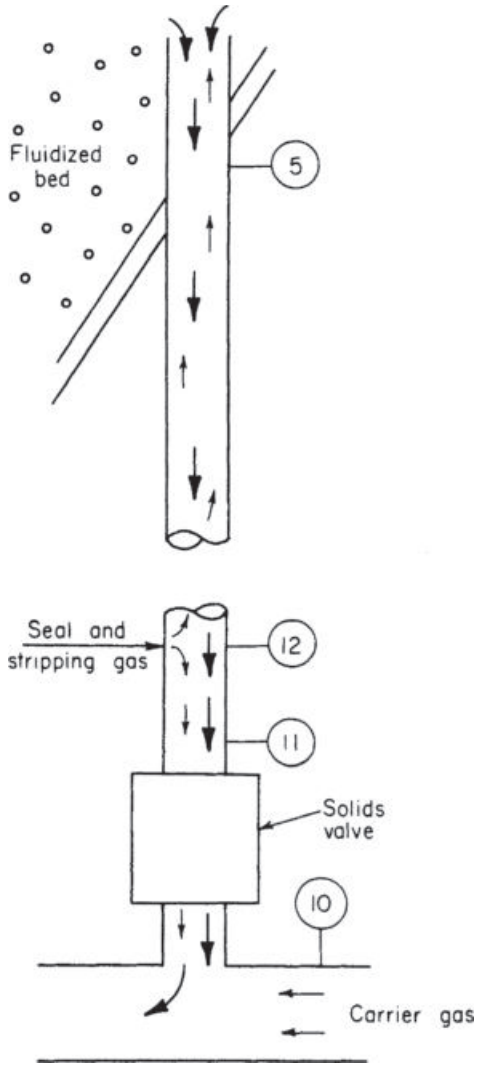

**FIG. 17-27** Schematic drawing of a fluidized seal leg. Circled numbers refer to pressure taps.

In the sealing mode, the standpipe above the L-valve (a dipleg if the "automatic" L-valve is located below a cyclone) should be fluidized as indicated previously. Gas introduced below the normal solids level and above the discharge port will usually flow upward and downward—but this depends on the solids velocity in the standpipe. The relative flow in each direction is self-adjusting, depending on the differential pressure between the point of solids feed and discharge and the level of solids in the leg. The length and diameter of the horizontal section of the L-valve are selected so that the undisturbed angle of repose of the solids will prevent discharge of the solids. As solids rate into the dipleg increases, the height, *H,* of solids in the standpipe increases. This increase in the solids level in the standpipe reduces the flow of gas in the upward direction and increases the flow of gas in the downward direction. When the flow of gas downward through the "automatic" L-valve increases, it causes more solids to flow around the automatic L-valve. Usually, the level of solids above the point of gas introduction will float.

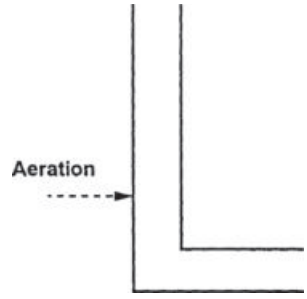

**FIG. 17-28** Schematic drawing of an L-valve.

**Dust Separation** It is usually necessary to recover the solids carried by the gas leaving the disengaging space or freeboard of the fluidized bed and return them to the bed. Generally, cyclones are used to collect these solids (see the subsection Gas–Solids Separation). However, in a few cases, filters are employed without the use of cyclones to reduce the loading of solids in the off-gas. For high-temperature usage, either porous ceramic or sintered metal filters have been employed. Multiple units must be provided so that one or more units can be blown back with clean gas while one or more are filtering.

Cyclones are arranged generally in any one of the arrangements shown in Fig. 17-29. The effect of cyclone arrangement on the height of the vessel and the overall height of the system is apparent. Details regarding cyclone design and collection efficiencies are to be found in another part of this section.

Discharging of the solids collected by a cyclone back into the fluidized bed requires some care. It is necessary to pressure seal the bottom of the cyclone so that the collection efficiency of the cyclone will not be impaired by the passage of appreciable quantities of gas up through the dipleg and into the bottom of the cyclone. This is usually done by (1) sealing the dipleg in the fluid bed, or (2) adding a trickle or flapper valve to the bottom of the dipleg if the dipleg is terminated in the freeboard of the fluidized bed.

Many processes start up their fluidized beds from an empty bed. Solids are added to the bed gradually as the unit temperature is gradually increased. There is usually no problem with primary cyclone diplegs during this period because the solids flux through the primary dipleg is very high, and it carries gas downward with the solids. However, the secondary cyclone diplegs have a very low flux through them, and the gas can travel back up the secondary dipleg, preventing solids from making the pressure seal in the secondary dipleg. To prevent too much gas from flowing up the secondary dipleg at start-up, secondary cyclone termination devices are used. The most common of these termination devices are shown in Fig. 17-30.

Because the solids fluxes through primary cyclone diplegs can be very high [up to 150 lb/s/ft$^2$ (750 kg/s/m$^2$)] a horizontal plate called a splash plate (somewhat larger in diameter than the dipleg) is often attached to the bottom of the primary cyclone dipleg to (1) help disperse the solids, and (2) shield internals from being eroded due to the momentum of the solids exiting the primary cyclone dipleg. Care must be taken to ensure that the horizontal plate (sometimes called a "dollar" plate) is located far enough away from the dipleg outlet that the solids discharge from the dipleg is not constricted.

In addition to an open dipleg (a dipleg with no termination device) immersed into a fluidized bed, various other devices have been used to seal cyclone dipleg returns, especially for second-stage cyclones. Several of these are shown in Fig. 17-30. One of the most often used is the trickle valve (Fig. 17-30*a*). Trickle valves work best when they are immersed in the fluidized bed. Dipleg operation is more stable when the trickle valve is immersed, and solids losses are generally reduced. However, trickle valves can discharge solids into the freeboard if necessary.

Another common dipleg termination device is the flapper valve (Fig. 17-30*b*). This device is similar to the trickle valve, but has its "flapper plate" located horizontally instead of vertically. A counterweight is used to ensure that the fluidized solids leg above the flapper can cause the flapper to open relative easily.

An "automatic" L-valve (Fig. 17-30*c*) can also be used as a dipleg termination. These devices are most commonly used at the bottom of external cyclone diplegs. It is necessary to add aeration gas to the automatic L-valve to ensure the best performance.

The loop seal is shown in Fig. 17-30*d.* This device is very common at the bottom of the external cyclone dipleg for circulating fluidized-bed combustors. This device works smoothly to transfer the solids from the cyclone back into the fluidized bed. The upleg of the loop seal must be fluidized in order for it to function properly. The downleg should be fluidized as well for practical, effective operation, but it is not absolutely necessary that it be fluidized.

A simple open-ended dipleg is shown in Fig. 17-30*d.* The open-ended dipleg can be used at the bottom of primary cyclone diplegs, but not general secondary cyclone diplegs. It is the simplest of all of the dipleg/termination devices. A splash plate is shown below the open-ended dipleg in the figure. The splash plate is used to disperse the solids into the bed more evenly, and to protect any bed internals that may be located immediately below the dipleg discharge.

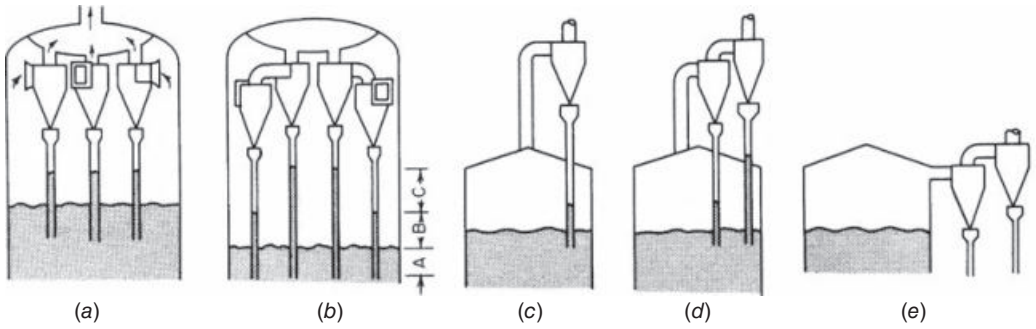

**FIG. 17-29** Fluidized-bed cyclone arrangements. (*a*) Single-stage internal cyclone. (*b*) Two-stage internal cyclone. (*c*) Single-stage external cyclone; dust returned to bed. (*d*) Two-stage external cyclone; dust returned to bed. (*e*) Two-stage external cyclone; dust collected externally.

In any event, the diplegs must be large enough to accommodate momentarily high rates of solids flows (primary dipleg) and must provide solid seals to overcome cyclone pressure drops as well as to allow for differences in fluid density of solids in the bed and the solids in the diplegs. It has been reported that, in the case of catalytic processes operating with Geldart group A solids, the fluid density of the solids collected by the primary cyclone is essentially the same as that in the fluidized bed. This is so because in most of these processes, the bed fluidizing velocity is so high and the particles in the bed are so small that generally all are entrained. However, as a general rule, the fluidized density of solids collected by the second-stage cyclone is significantly less than the fluidized density of the bed. Each succeeding cyclone collects finer solids, and the smaller the solids, the lower the fluidized density.

The dipleg of both the primary and secondary cyclone must be long enough to seal the imposed pressure drop across them. A representative calculation showing the length of dipleg required for one specific installation is given in Example 17-1.

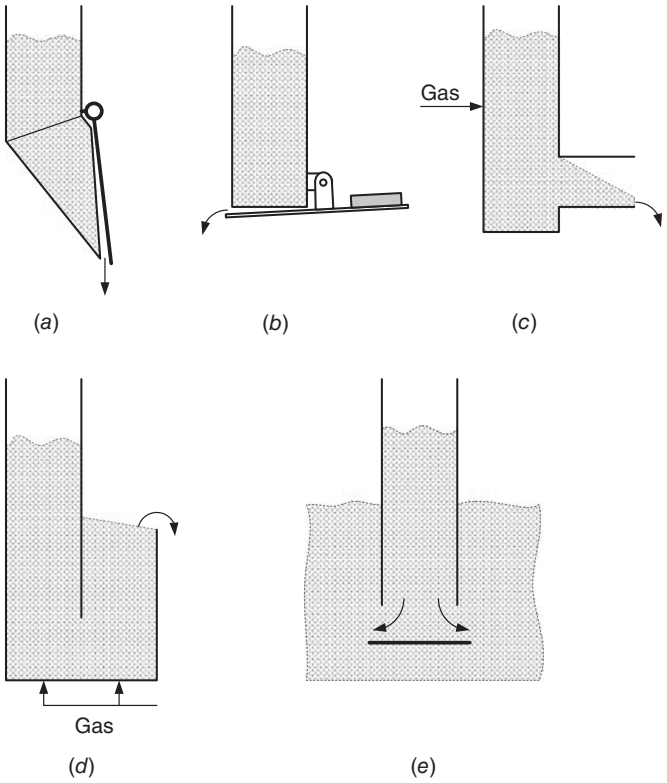

**FIG. 17-30** Common cyclone dipleg terminations. (*a*) trickle valve, (*b*) flapper valve, (*c*) "automatic" L-valve, (*d*) loop seal, (*e*) open-ended dipleg with splash plate. (*Courtesy of PSRI, Chicago, Ill.*)

***Example 17-1*** ***Calculation of Required Length of Cyclone Seal Leg (Dipleg)*** The length of the required cyclone solids seal height in the seal leg (dipleg) for a single cyclone can be calculated as shown here.

Given:

Fluidized density of the fluidized bed = 1100 kg/m$^3$ (68.8 lb/ft$^3$)

Fluidized density of solids in the cyclone dipleg = 650 kg/m$^3$ (40.6 lb/ft$^3$)

Settled bed depth = 1.5 m (5 ft)

Fluidized bed depth = 2.4 m (8 ft)

Pressure drop through the cyclone = 1.4 kPa (0.2 lbf/in$^2$)

In order to ensure that the dipleg is sealed at start-up, the bottom of the seal leg (dipleg) is submerged 0.9 m (2.95 ft) in the fluidized bed.

From the information given, the total pressure differential to be balanced by the fluidized seal leg in the cyclone dipleg is:

$$(0.9 \times 1100 \times 9.81)/1000 + 1.4 = 11.1 \text{ kPa} \qquad \text{(in SI units)}$$

$$[(2.95 \times 68.8)/144 + 0.2 = 1.61 \text{ lb/in}^2] \qquad \text{(in fps units)}$$

To balance this differential pressure, the height of solids in the dipleg must be = $(11.1 \times 1000)/(650 \times 9.81) = 1.74$ m [$(1.61 \times 144)/40.6 = 5.7$ ft]; therefore, the bottom of the separator pot on the cyclone must be at least 1.74 + 1.5 or 3.24 m (5.7 + 5 or 10.7 ft) above the gas distributor. To take into account various contingencies, upsets, changes in size distribution, etc., this distance should be increased. Normally, the calculated solids height should be approximately 1.5 m (5 feet) below the bottom of a commercial cyclone. Therefore, the cyclone discharge level should be at least 3.24 + 1.5 = 4.74 m (10.7 + 5 = 15.7 ft) above the gas distributor.

Cyclones are less effective as the particle size entering them decreases, so secondary collection units are often required, such as filters, electrostatic precipitators, and scrubbers. When dry collection is not required, elimination of cyclones is possible using scrubbers if allowance is made for heavy solids loads in the scrubber (see the subsection Gas–Solids Separations; see also Sec. 14).

### Instrumentation

***Temperature Measurement*** Temperature measurement in fluidized beds is usually simple, and standard temperature-sensing elements (usually thermocouples) are adequate for continuous use. Because of the high abrasion wear on horizontal thermocouple protection tubes, vertical installations are often used. In highly corrosive atmospheres in which metallic protection tubes cannot be used, short, heavy ceramic tubes have been used successfully.

***Pressure Measurement*** Although successful pressure measurement probes or taps have been fabricated by using porous materials, the most universally-accepted pressure tap consists of a purged tube projecting into the bed. Minimum internal diameters of the tube are 0.6 to 1.2 cm (0.25 to 0.5 in). A purge velocity of 2 to 4 m/s (6 to 12 ft/s) is usually required to prevent solids from plugging the signal lines. Bubbling fluidized-bed density is determined directly from $\Delta P/L$, the pressure drop inside the bed itself ($\Delta P/L$ in units of weight/area $\times$ $1/L$). The overall bed weight of a bubbling fluidized bed is obtained from a $\Delta P$ taken between a point just above the gas distributor and a point in the freeboard. This $\Delta P$ reading is equal to the weight of the bed ($W$) divided by the bed area ($A$). Multiplying the overall bed pressure drop by the area yields the weight of the bed. Nominal bed height of a bubbling fluidized bed is determined by dividing the $\Delta P$ across the entire bed by the $\Delta P/L$ over a section of the bed length. Splashing of the solids by bubbles bursting at the bed surface will eject solids well above the nominal bed height in most cases. The pressure drop signal from fluidized beds fluctuates due to bubble effects and the generally statistical nature of fluid-bed flow parameters. A fast Fourier transform of the pressure drop signals from the bed transforms the pressure perturbations to a frequency-versus-amplitude plot with a maximum at about 3 to 5 Hz. Changes in frequency and amplitude are associated with changes in the quality of the fluidization.

Experienced operators of fluidized beds can often predict what is happening in the bed from changes in the $\Delta P$ fluctuation signal. However, one of the best indications of whether a fluidized bed is operating properly is to monitor the temperatures inside the bed. If the difference between any two thermocouple readings is greater than 20°F (about 10°C), then one should be worried about the nature of the fluidization of the bed.

***Flow Measurements*** Measurement of flow rates of clean gases entering the fluidized bed presents no problem. Flow measurement of gas streams containing solids is almost always avoided. The flow of solids in very large fluidized-bed processes is usually controlled, but not measured, except for the solids flows added to or taken from the system. This is because measuring solids flows is very difficult even in laboratory units, and it is not practical in larger units using present technology. Solids flows in the system are usually adjusted and determined on an inferential basis using variables such as temperature, pressure level, catalyst activity, gas analysis, and heat balance. In many roasting operations, the color of the calcine discharge material indicates whether the solids feed rate is too high or too low.

## USES OF FLUIDIZED BEDS

There are many uses of fluidized beds. A number of applications have become commercial successes; others are in the pilot-plant stage, and others in bench-scale stage. Generally, the fluidized bed is used for gas–solids contacting. Uses of fluidized beds are listed below:

I. Chemical reactions
  *A.* Catalytic
  *B.* Noncatalytic
    1. Homogeneous
    2. Heterogeneous
II. Physical contacting
  *A.* Heat transfer
    1. To and from fluidized bed
    2. Between gases and solids
    3. Temperature control
    4. Between points in the bed
  *B.* Solids mixing
  *C.* Gas mixing
  *D.* Drying
    1. Solids
    2. Gases
  *E.* Size enlargement
  *F.* Size reduction
  *G.* Classification
    1. Removal of fines from solids
    2. Removal of fines from gas
  *H.* Adsorption-desorption
  *I.* Heat treatment
  *J.* Coating

**Chemical Reactions**

***Catalytic Reactions*** The use of fluidized beds to optimize chemical catalytic reactions has provided the greatest impetus for the use of fluidized solids. Some of the details pertaining to this use are to be found in the preceding pages of this section. Reference should also be made to Sec. 21. Several of the catalytic process that use fluidized beds are described in the following text.

*Fluidized Catalytic Cracking* The fluidized catalytic cracking (FCC) process using Geldart Group A solids is the oldest and, still today, the most important commercial application of fluidized beds. The evolution of fluidized catalytic cracking since the early 1940s has resulted in several fluidized-bed process configurations. The high solids transfer rate between the fluidized-bed regenerator and the riser reactor in this process permits a balancing of the exothermic burning of carbon and tars in the regenerator and the endothermic cracking of petroleum in the reactor. Therefore, the temperature in both units can usually be controlled without resorting to auxiliary heat control. The high catalyst circulation rate also permits the maintenance of the catalyst at a constantly high activity. The early fluidized-bed regenerators were considered to be completely backmixed units. Newer processes now have staged regenerators to improve conversion (see Fig. 17-31). The use of the riser reactor operating in the fast fluid-bed mode also results in much lower gas and solids backmixing due to the more plug-flow nature of the riser. Staging and operating in the fast fluidized-bed mode facilitates cracking of the oil in the riser, and it allows for much more efficient operation in the regenerator.

The first fluid catalytic cracking unit was operated by Exxon and was called the Model I. It started operation in Baytown, Texas, in 1942. This was a low-pressure, 14- to 21-kPa (2- to 3-psig) unit operating in what is now called the turbulent fluidized-bed mode with a gas velocity of 1.2 to 1.8 m/s (4 to 6 ft/s). Before the start-up of the Model I cracker, it was realized that by lowering the gas velocity in the bed, a dense, bubbling, or turbulent fluidized bed, with a bed density of 300 to 400 kg/m$^3$ (20 to 25 lb/ft$^3$), would be formed. The increased gas–solids contacting time in the denser bed allowed completion of the cracking reaction. System pressure was eventually increased to 140 to 210 kPa (20 to 30 psig) over the years.

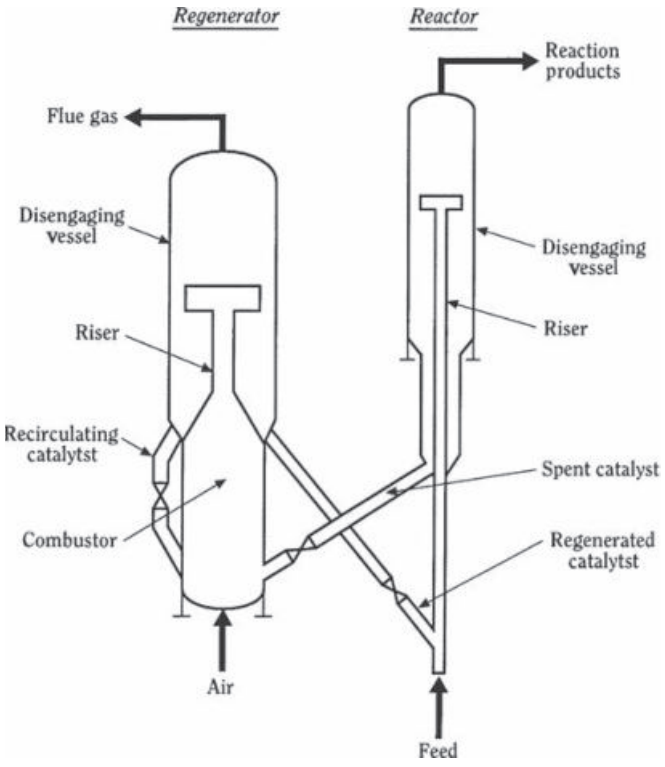

**FIG. 17-31** UOP fluid catalytic cracking unit. (*Reprinted with permission of UOP.*)

In the 1970s, extremely active zeolite catalysts were developed so that the cracking reaction could be conducted in the transport riser itself and not in a dense, fluidized bed. Recently, heavier crude feedstocks have resulted in higher coke production in the cracker. The extra coke causes higher temperatures in the regenerator than are desired. This has resulted in the addition of catalyst cooling to the regeneration step, as shown in Fig. 17-32.

Many companies have participated in the development of the fluid catalytic cracker, including ExxonMobil Research & Engineering Co., UOP, Kellogg Brown and Root, Chevron, Gulf Research Development Co., and Shell Oil Company. Many of these companies provide designs and/or licenses to operate these units to others. For further historical and technical details, see Luckenbach et al., "Cracking, Catalytic," in *Encyclopedia of Chemical Processing and Design,* vol. 13, ed. McKetta, Marcel Dekker, New York, 1981, pp. 1–132.

*Alkyl Chloride* In this process, olefins are chlorinated to alkyl chlorides in a single fluidized bed. HCl reacts with $O_2$ over a copper chloride catalyst to form chlorine. The chlorine reacts with the olefin to form alkyl chloride. The process was developed by the Shell Development Co., and uses a recycle of catalyst fines in aqueous HCl to control the temperature [*Chem. Proc.* **16:** 42 (1953)].

*Phthalic Anhydride* To produce phthalic anhydride, naphthalene is oxidized by air to phthalic anhydride in a bubbling/turbulent fluidized reactor. Even though the naphthalene feed is in liquid form, the reaction is highly exothermic. Temperature control is achieved by removing heat by placing vertical tubes in the bed to raise steam [Graham and Way, *Chem. Eng. Prog.* **58:** 96 (January 1962)].

*Acrylonitrile* Acrylonitrile is produced by reacting propylene, ammonia, and oxygen (air) in a single fluidized bed using a complex catalyst. Known as the SOHIO process, this process was first operated commercially in 1960. In addition to acrylonitrile, significant quantities of HCN and acetonitrile are produced. This process is also exothermic, and temperature control is achieved by raising steam inside vertical tubes immersed in the bed [Veatch, *Hydrocarbon Process. Pet. Refiner* **41:** 18 (November 1962)].

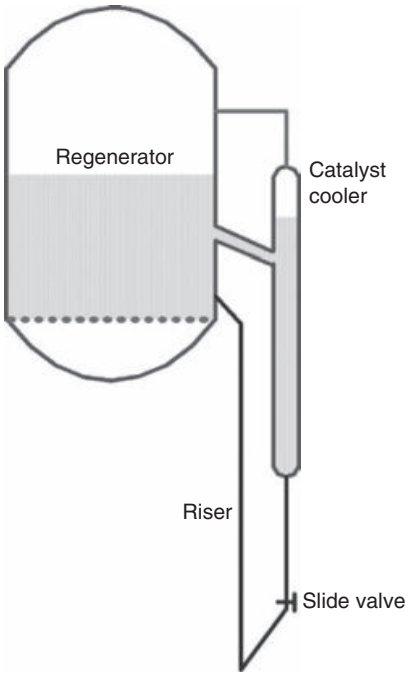

**FIG. 17-32** Schematic drawing of a catalyst cooler attached to a regenerator in an FCC unit. (*Courtesy of PSRI, Chicago, Ill.*)

*Fischer-Tropsch Synthesis* One of the early attempts to scale up a bubbling bed reactor to produce gasoline from CO and $H_2$ was unsuccessful (see Scale-Up in the subsection Design of Fluidized-Bed Systems). However, Kellogg Co. later developed a successful Fischer-Tropsch synthesis reactor based on a dilute-phase transport-reactor concept. Kellogg, in its design, prevented excessive gas bypassing by using a transport (riser) reactor and maintained temperature control of the exothermic reaction by inserting heat exchangers in the transport line. This process has been very successful, and has been repeatedly improved upon at the South African Synthetic Oil Limited (SASOL) plant in the Republic of South Africa, where politics and economics favored the conversion of coal to gasoline and other hydrocarbons. Refer to Jewell and Johnson, U.S. Patent 2,543,974, Mar. 6, 1951 for more information. The process has been successfully modified to use a simpler, less expensive turbulent bed catalytic reactor system (Silverman, R. W., et al., in *Fluidization V,* ed. K. Østergaard and A. Sørensen, Engineering Foundation, New York, 1986, pp. 441–448).

*Polyethylene* The first commercial fluidized-bed polyethylene plant was constructed by Union Carbide in 1968. Modern units operate at a temperature of approximately 100°C and a pressure of about 2500 kPa (360 psig). The bed is fluidized with ethylene at about 0.5 to 0.7 m/s (1.65 to 2.3 ft/s) and operates in the turbulent fluidization regime. Small catalyst is added to the bed, and the ethylene polymerizes on the catalyst to form polyethylene particles of approximately 600- to 1000-μm average size, depending on the type of polyethylene product being produced. The excellent mixing provided by the fluidized bed is necessary to prevent hot spots, since the unit is operated just slightly below the melting point of the product. A model of the reactor (Fig. 17-33) that couples polyethylene reaction kinetics to the hydrodynamics in the fluidized reactor bed was given by Choi and Ray [*Chem. Eng. Sci.* **40:** 2261 (1985)].

*Additional Catalytic Processes* Nitrobenzene is hydrogenated to aniline (U.S. Patent 2,891,094). Melamine and isophthalonitrile are produced in catalytic fluidized-bed reactors. Badger developed a process to produce maleic anhydride by the partial oxidation of butane (Schaffel, Chen, and Graham, "Fluidized Bed Catalytic Oxidation of Butane to Maleic Anhydride," presented at Chemical Engineering World Congress, Montreal, Canada, 1981). Du Pont developed a circulating bed process for production of maleic anhydride (Contractor, *Circulating Fluidized Bed Tech. II,* Pergamon, Oxford, UK, 1988, pp. 467–474). Mobil developed a commercial process to convert methanol to gasoline (Grimmer et al., *Methane Conversion,* Elsevier, Amsterdam, 1988, pp. 273–291).

***Noncatalytic Reactions***

*Homogeneous Reactions* Homogeneous noncatalytic reactions are normally carried out in a fluidized bed to achieve good mixing of the gases and for good temperature control. The solids in the bed act as a heat sink (or source) and facilitate heat transfer from or to the gas or from or to heat-exchange surfaces. Reactions of this type include chlorination of hydrocarbons or oxidation of gaseous fuels.

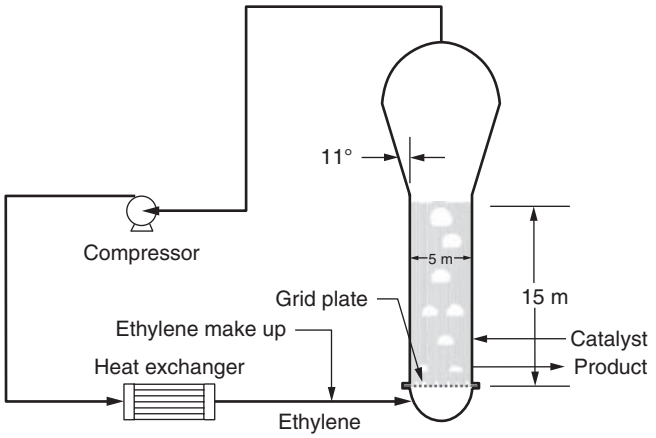

**FIG. 17-33** High-pressure polyethylene reactor.

*Heterogeneous Reactions* This category covers the greatest commercial use of fluidized beds other than fluid catalytic cracking. Roasting of ores in fluidized beds is very common. Roasting of sulfide, arsenical, and/or antimonial ores to facilitate the release of gold or silver values; the roasting of pyrite, pyrrhotite, or naturally occurring sulfur ores to provide $SO_2$ for sulfuric acid manufacture; and the roasting of copper, cobalt, and zinc sulfide ores to solubilize the metals are the major metallurgical uses. Figure 17-34 shows the basic items in the roasting process.

Thermally efficient calcination of lime, dolomite, and clay can be carried out in a multicompartment fluidized bed (Fig. 17-35). Fuels are burned in a fluidized bed of the product to produce the required heat. Bunker C oil, natural gas, and coal are used in commercial units as the fuel. Temperature control is accurate enough to permit production of lime of very high quality with close control of slaking characteristics. Also, half calcination of dolomite is an accepted practice in fluidized beds. The requirement of large crystal size for the limestone limits this application. Small crystals in the limestone result in low yields due to high dust losses from the fluidized bed.

Phosphate rock is calcined to remove carbonaceous material before being digested with sulfuric acid. Several different fluidized-bed processes have been commercialized for the direct reduction of hematite to high-iron,

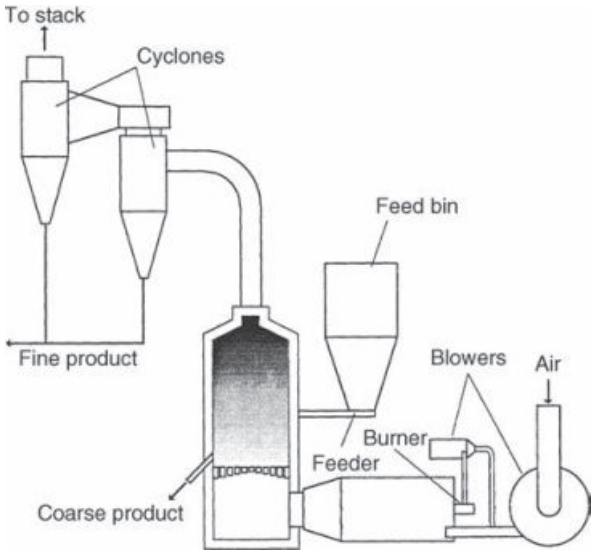

**FIG. 17-34** Single-stage FluoSolids roaster or dryer. (*Dorr-Oliver, Inc.*)

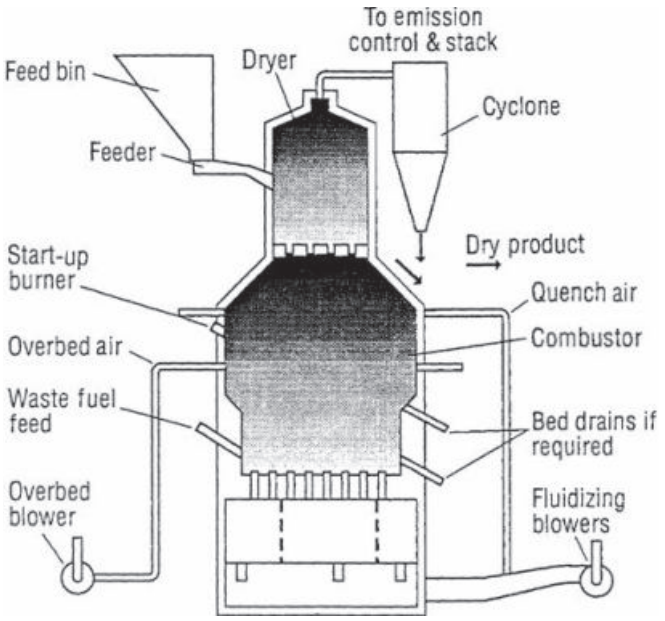

**FIG. 17-35** FluoSolids multicompartment fluidized bed. (*Dorr-Oliver, Inc.*)

low-oxide products. Foundry sand is also calcined to remove organic binders and release fines. The calcination of $Al(OH)_3$ to $Al_2O_3$ in a circulating fluidized process produces a high-grade product. The process combines the use of circulating, bubbling, and transport beds to achieve high thermal efficiency (see Fig. 17-36).

An interesting feature of these high-temperature-calcination applications is the direct injection of heavy oil, natural gas, or fine coal into the fluidized bed. Combustion takes place at well below flame temperatures without atomization. Considerable care in the design of the fuel and air supply system is necessary to take full advantage of the fluidized bed, which serves to mix the air and fuel.

Coal can be burned in fluidized beds in an environmentally acceptable manner by adding limestone or dolomite to the bed to react with the $SO_2$ to form $CaSO_4$. Because of moderate combustion temperatures, about 800°C to 900°C, $NO_x$ formation, which results from the oxidation of nitrogen compounds contained in the coal, is kept at a low level. $NO_x$ is increased by higher temperatures and higher excess oxygen contents. Two-stage air addition reduces $NO_x$. Several concepts of fluidized-bed combustion have been or are being developed. Atmospheric fluidized-bed combustion (AFBC), in which most of the heat-exchange tubes are located in the bed, is illustrated in Fig. 17-37. This type of unit is most commonly used for industrial applications up to about 50 t/h of steam generation. Larger units are generally of the circulating bed type, as shown in Fig. 17-37. Circulating fluidized-bed combustors have many advantages. The gas velocity is significantly higher than in bubbling or turbulent beds, which results in greater throughput. Since all the solids are recycled, fine limestone and coal can be fed to the combustor, which gives better limestone utilization and greater latitude in specifying coal sizing. Because of erosion due to high-velocity coarse solids, heat-transfer surface is usually not designed into the bottom of the combustion zone.

Pressurized fluidized-bed combustion (PFBC) is, as the name implies, operated at above atmospheric pressures. The beds and heat-transfer surfaces are stacked to conserve space and to reduce the size of the pressure vessel. This type of unit is usually conceived as a cogeneration unit. Steam raised in the boilers is employed to drive turbines or for other uses. The hot pressurized gases after cleaning are let down through an expander coupled to a compressor to supply the compressed combustion air and/or electric generator. Also see Sec. 24, Energy Resources, Conversion, and Utilization.

***Incineration*** There are hundreds of units in operation that are used for the incineration of biological sludges. These units can be designed to operate autogenously with wet sludges containing as little as 6 MJ/kg (2600 Btu/lb) heating value (Fig. 17-38). Depending on the calorific value of the feed, heat can be recovered as steam either by means of waste heat boilers or by a combination of waste heat boilers and the heat-exchange surface in the fluid bed. Several units are used for sulfite papermill waste liquor disposal. Several units are used for oil refinery wastes, which sometimes include a mixture of liquid sludges, emulsions, and caustic waste [Flood and Kernel, *Chem. Proc.* (Sept. 8, 1973)]. Miscellaneous uses include the incineration of sawdust, carbon-black waste, pharmaceutical waste, grease from domestic sewage, spent coffee grounds, and domestic garbage.

Toxic or hazardous wastes can be disposed of in fluidized beds by either chemical capture or complete destruction. In the former case, bed material, such as limestone, will react with substances such as halides, sulfides, and metals to form stable compounds that can be landfilled. Contact times of up to 5 to 10 s at 1200 K (900°C) to 1300 K (1000°C) ensure complete destruction of most compounds.

**Physical Contacting**

***Drying*** Fluidized-bed units for drying solids, particularly coal, cement, rock, and limestone, are in wide use. Economic considerations make these units particularly attractive when large tonnages of solids are to be handled. Fuel requirements are 3.3 to 4.2 MJ/kg (1500 to 1900 Btu/lb of water removed), and total power for blowers, feeders, etc., is about 0.08 kWh/kg of water removed. The maximum coal feed size is approximately 6 cm (2.4 in) × 0. One of the major advantages of this type of dryer is the close control of operating conditions so that a predetermined amount of free moisture may be left with the solids to prevent dusting of the product during subsequent material handling operations. The fluidized-bed dryer is also used as a classifier so that drying and classification operations are accomplished simultaneously. Wall and Ash [*Ind. Eng. Chem.* **41:** 1247 (1949)] state that in drying 4.8-mm (−4-mesh) dolomite with combustion gases at a superficial velocity of 1.2 m/s (4 ft/s), the following removals of fines were achieved:

| Particle size | % removed |
|---|---|
| −65 + 100 mesh | 60 |
| −100 + 150 mesh | 79 |
| −150 + 200 mesh | 85 |
| −200 + 325 mesh | 89 |
| −325 mesh | 89 |

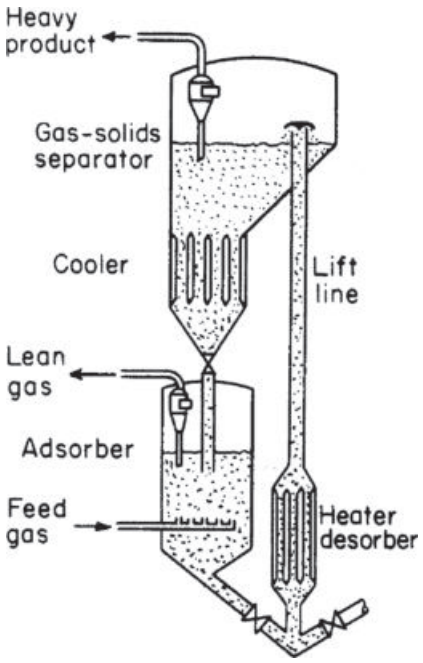

**FIG. 17-39** Fluidized bed for gas fractionation. [*Sittig.* Chem. Eng. (*May 1953*).]

***Classification*** The separation of fine particles from coarse particles can be accomplished by the use of a fluidized bed (see Drying). However, for economic reasons (e.g., initial cost, power requirements for compression of fluidizing gas), it is doubtful, except in special cases, that a fluidized-bed classifier would be built for this purpose alone.

It has been proposed that fluidized beds be used to remove fine solids from a gas stream. This is possible under special conditions.

***Adsorption-Desorption*** An arrangement for gas fractionation is shown in Fig. 17-39.

The effects of adsorption and desorption on the performance of fluidized beds are discussed elsewhere. Adsorption of carbon disulfide vapors from airstreams is as great as 300 $m^3/s$ (540,000 $ft^3/min$) in a 17-m- (53-ft-) diameter unit as reported by Avery and Tracey ("The Application of Fluidized Beds of Activated Carbon to Recover Solvent from Air or Gas Streams," Tripartate Chemical Engineering Conference, Montreal, Sept. 24, 1968).

***Heat Treatment*** Heat treatment can be divided into two types: treatment of fluidizable solids and treatment of large, usually metallic objects in a fluid bed. The former is generally accomplished in multicompartment units to conserve heat. The heat treatment of large metallic objects is accomplished in long, narrow, heated beds. The objects are conveyed through the beds by an overhead conveyor system. Fluid beds are used because of the high heat-transfer rate and uniform temperature. See Reindl, "Fluid Bed Technology," *American Society for Metals,* Cincinnati, Sept. 23, 1981; Fennell, *Ind. Heat.* **48:** 9, 36 (September 1981).

***Coating*** Fluidized beds of thermoplastic resins have been used to facilitate the coating of metallic parts. A properly prepared, heated metal part is dipped into the fluidized bed, which permits complete immersion in the dry solids. The heated metal fuses the thermoplastic, forming a continuous uniform coating.

# GAS–SOLIDS SEPARATIONS

This subsection is concerned with the application of particle mechanics (see Sec. 6, Fluid and Particle Dynamics) to the design and application of dust-collection systems. It includes wet collectors, or scrubbers, for particle collection. Scrubbers designed for purposes of mass transfer are discussed in Secs. 14 and 18. Equipment for removing entrained liquid mist from gases is described in Sec. 18.

### Nomenclature

Except where otherwise noted here or in the text, either consistent system of units (SI or U.S. customary) may be used. Only SI units may be used for electrical quantities, since no comparable electrical units exist in the U.S. customary system. When special units are used, they are noted at the point of use.

| Symbols | Definition | SI units | U.S. customary system units | Special units |
|---|---|---|---|---|
| $A_{in}$ | Area of cyclone inlet duct | $m^2$ | $ft^2$ | |
| $A_{out}$ | Area of cyclone outlet pipe | $m^2$ | $ft^2$ | |
| $B_c$ | Width of rectangular cyclone inlet duct | m | ft | |
| $B_e$ | Spacing between wire and plate, or between rod and curtain, or between parallel plates in electrical precipitators | m | ft | |
| $B_s$ | Width of gravity settling chamber | m | ft | |
| $C^*$ | Dry scrubber pollutant gas equilibrium concentration over sorbent | | | |
| $C_1$ | Dry scrubber pollutant gas inlet concentration | | | |
| $C_2$ | Dry scrubber pollutant gas outlet concentration | | | |
| $c_d$ | Dust concentration in gas stream | $g/m^3$ | $lb/ft^3$ | $grains/ft^3$ |
| $c_h$ | Specific heat of gas | $J/(kg \cdot K)$ | $Btu/(lb_m \cdot °F)$ | |
| $c_{hb}$ | Specific heat of collecting body | $J/(kg \cdot K)$ | $Btu/(lb_m \cdot °F)$ | |
| $c_{hp}$ | Specific heat of particle | $J/(kg \cdot K)$ | $Btu/(lb_m \cdot °F)$ | |
| $D_b$ | Diameter or other representative dimension of collector body or device | m | ft | |
| $D_{b1}$, $D_{b2}$ | Other characteristic dimensions of collector body or device | m | ft | |
| $D_c$ | Cyclone diameter | m | ft | |
| $D_d$ | Outside diameter of wire or discharge electrode of concentric-cylinder type of electrical precipitator | m | ft | |
| $D_e$ | Diameter of cyclone gas exit duct | m | ft | |
| $D_o$ | Volume/surface-mean-drop diameter | | | µm |
| $D_p$ | Diameter of particle | m | ft | µm |
| $d_{pth}$ | Cut diameter, diameter of particles of which 50 percent of those present are collected | m | ft | µm |
| $d_P$ | Particle diameter of fraction number $c'$ | m | ft | |
| $D_t$ | Inside diameter of collecting tube of concentric-cylinder type of electrical precipitator | m | ft | |
| $D_v$ | Diffusion coefficient for particle | $m^2/s$ | $ft^2/s$ | |
| DI | Decontamination index = $\log_{10}[1/(1-\eta)]$ | Dimensionless | Dimensionless | |
| $e$ | Natural (napierian) logarithmic base | 2.718 . . . | 2.718 . . . | |
| $E$ | Potential difference | V | | |
| $E_c$ | Potential difference required for corona discharge to commence | V | | |
| $E_d$ | Voltage across dust layer | V | | |
| $E_s$ | Potential difference required for sparking to commence | V | | |
| $E_L$ | Cyclone collection efficiency at actual loading | | | |
| $E_O$ | Cyclone collection efficiency at low loading | | | |
| $F_E$ | Effective friction loss across wetted equipment in scrubber | kPa | | in water |
| $F_k$ | Packed-bed friction loss | | | |
| $g$ | Acceleration due to gravity | $m/s^2$ | $ft/s^2$ | |
| $g_c$ | Conversion factor | | 32.17 $(lb_m/lb_f)(ft/s^2)$ | |
| $H_c$ | Height of rectangular cyclone inlet duct | m | ft | |
| $H_s$ | Height of gravity settling chamber | m | ft | |
| $I$ | Electrical current per unit of electrode length | A/m | | |
| $j$ | Corona current density at dust layer | $A/m^2$ | | |
| $J_c$ | Cyclone solids discharge diameter, or dipleg diameter | m | ft | |
| $k\rho$ | Density of gas relative to its density at 0°C, 1 atm | (–) | (–) | (–) |
| $k_t$ | Thermal conductivity of gas | $W/(m \cdot K)$ | $Btu/(s \cdot ft \cdot °F)$ | |
| $k_{tb}$ | Thermal conductivity of collecting body | $W/(m \cdot K)$ | $Btu/(s \cdot ft \cdot °F)$ | |
| $k_{tp}$ | Thermal conductivity of particle | $W/(m \cdot K)$ | $Btu/(s \cdot ft \cdot °F)$ | |
| $K$ | Empirical proportionality constant for cyclone pressure drop or friction loss | (–) | (–) | (–) |
| $K_1$ | Resistance coefficient of "conditioned" filter fabric | kPa/(m/min) | in water/(ft/min) | |
| $K_2$ | Resistance coefficient of dust cake on filter fabric | $\frac{kPa}{(m/min)(g/m^2)}$ | $\frac{in\ water}{(ft/min)(lb_m/ft^2)}$ | |
| $K_a$ | Proportionality constant, for target efficiency of a single fiber in a bed of fibers | (–) | (–) | (–) |
| $K_c$ | Resistance coefficient for "conditioned" filter fabric | | | $\frac{in\ water}{(ft/min)(cP^2)}$ |
| $K_d$ | Resistance coefficient for dust cake on filter fabric | | $\frac{in\ water}{(ft/min)(gr/ft^2)(cP)}$ | |
| $K_e$ | Electrical-precipitator constant | s/m | s/ft | |
| $K_F$ | Resistance coefficient for clean filter cloth | | | $\frac{in\ water}{(ft/min)(cP)}$ |
| $K_o$ | "Energy-distance" constant for electrical discharge in gases | m | | |
| $K_m$ | Stokes-Cunningham correction factor | (–) | (–) | (–) |
| $L$ | Thickness of fibrous filter or of dust layer on surface filter | m | ft | |
| $L_c$ | Barrel length | m | ft | |
| $L_e$ | Length of collecting electrode in direction of gas flow | m | ft | |
| $L_s$ | Length of gravity settling chamber in direction of gas flow | m | ft | (–) |
| ln | Natural logarithm (logarithm to the base $e$) | (–) | (–) | |
| $M$ | Molecular weight | kg/mol | $lb_m/mol$ | |

**Nomenclature** (*Continued*)

| Symbols | Definition | SI units | U.S. customary system units | Special units |
|---|---|---|---|---|
| $n$ | Exponent | (–) | (–) | (–) |
| $N_{Kn}$ | Knudsen number = $\lambda_m/D_b$ | (–) | (–) | (–) |
| $N_{Ma}$ | Mach number | (–) | (–) | (–) |
| $N_o$ | Number of elementary electrical charges acquired by a particle | (–) | (–) | (–) |
| $N_{Re}$ | Reynolds number = $(D_p\rho V_o/\mu)$ or $(D_p\rho u_t/\mu)$ | (–) | (–) | (–) |
| $N_{sc}$ | Interaction number = $18\,\mu/K_m\rho_p D_v$ | (–) | (–) | (–) |
| $N_{sd}$ | Diffusional separation number | (–) | (–) | (–) |
| $N_{sec}$ | Electrostatic-attraction separation number | (–) | (–) | (–) |
| $N_{sei}$ | Electrostatic-induction separation number | (–) | (–) | (–) |
| $N_{sf}$ | Flow-line separation number | (–) | (–) | (–) |

| $N_{si}$ | Inertial separation number | (–) | (–) | (–) |
| $N_{st}$ | Thermal separation number | (–) | (–) | (–) |
| $N_t$ | Number of transfer units = $\ln[1/(1-\eta)]$ | (–) | (–) | (–) |
| $N_s$ | Number of turns made by gas stream in a cyclone separator | (–) | (–) | (–) |
| $\Delta p$ | Gas pressure drop | kPa | $lb_f/ft^2$ | in water |
| $\Delta p_i$ | Gas pressure drop in cyclone or filter | | | in water |
| $p_F$ | Gauge pressure of water fed to scrubber | kPa | | $lbf/in^2$ |
| $P_G$ | Gas-phase contacting power | $MJ/1000\ m^3$ | | $hp/(1000\ ft^3/min)$ |
| $P_L$ | Liquid-phase contacting power | $MJ/1000\ m^3$ | | $hp/(1000\ ft^3/min)$ |
| $P_M$ | Mechanical contacting power | $MJ/1000\ m^3$ | | $hp/(1000\ ft^3/min)$ |
| $P_T$ | Total contacting power | $MJ/1000\ m^3$ | | $hp/(1000\ ft^3/min)$ |
| $q$ | Gas flow rate | $m^3/s$ | $ft^3/s$ | |
| $Q_G$ | Gas flow rate | | $ft^3/s$ | $ft^3/min$ |
| $Q_L$ | Liquid flow rate | | $ft^3/s$ | gal/min |
| $Q_p$ | Electrical charge on particle | C | | |
| $r$ | Radius; distance from centerline of cyclone separator; distance from centerline of concentric-cylinder electrical precipitator | m | ft | |
| $t_m$ | Time | | | min |
| $S_c$ | Gas outlet tube distance below the bottom of the inlet | m | ft | |
| $T$ | Absolute gas temperature | K | °R | |
| $T_b$ | Absolute temperature of collecting body | K | °R | |
| $u_s$ | Velocity of migration of particle toward collecting electrode | m/s | ft/s | |
| $u_t$ | Terminal settling velocity of particle under action of gravity | m/s | ft/s | ft/s |
| $v_m$ | Average cyclone inlet velocity, based on area $A_c$ | m/s | ft/s | ft/s |
| $v_p$ | Actual particle velocity | m/s | ft/s | |
| $V_f$ | Filtration velocity (superficial gas velocity through filter) | m/min | | ft/min |
| $V_o$ | Gas velocity | m/s | ft/s | |
| $V_s$ | Average gas velocity in gravity settling | m/s | ft/s | |
| $V_{ct}$ | Tangential component of gas velocity in cyclone | m/s | ft/s | |
| $w$ | Loading of collected dust on filter | $g/m^2$ | $lb_m/ft^2$ | $gr/ft^2$ |
| $Z_c$ | Cyclone cone length | m | ft | |
| | Greek symbols | | | |
| $\alpha$ | Empirical constant in equation of scrubber performance curve | $\left[\frac{MJ}{100\ m^3}\right]^{-\gamma}$ | | $\left[\frac{hp}{100\ ft^3/min}\right]^{-\gamma}$ |
| $\gamma$ | Empirical constant in equation of scrubber performance curve | (–) | (–) | (–) |
| $\delta$ | Dielectric constant | (–) | (–) | (–) |
| $\delta_g$ | Dielectric constant at 0°C, 1 atm | (–) | (–) | (–) |
| $\delta_o$ | Permittivity of free space | F/m | | |
| $\delta_b$ | Dielectric constant of collecting body | (–) | (–) | (–) |
| $\delta_p$ | Dielectric constant of particle | (–) | (–) | (–) |
| $\Delta$ | Fractional free area ( for screens, perforated plates, grids) | (–) | (–) | (–) |
| $\varepsilon$ | Elementary electrical charge | $1.60210\times10^{-19}$ C | | |
| $\varepsilon_b$ | Characteristics potential gradient at collecting surface | V/m | | |
| $\varepsilon_v$ | Fraction voids in bed of solids | (–) | (–) | (–) |
| $\zeta$ | $=1+2\frac{\delta-1}{\delta+2}$ ranges from a value of 1 for materials with a dielectric constant of 1 to 3 for conductors | (–) | (–) | (–) |
| $\eta$ | Collection efficiency, weight fraction of entering dispersoid collected | (–) | (–) | (–) |
| $\eta_o$ | Target efficiency of an isolated collecting body, fraction of dispersoid in swept volume collected on body | (–) | (–) | (–) |
| $\eta_t$ | Target efficiency of a single collecting body in an array of collecting bodies, fraction of dispersoid in swept volume collected on body | (–) | (–) | (–) |
| $\lambda_i$ | Ionic mobility of gas | (m/s)/(V/m) | | |
| $\lambda_p$ | Particle mobility = $u_e/E$ | (m/s)/(V/m) | | |
| $\mu$, $\mu_g$ | Gas viscosity | Pa·s | $lb_m/(s\cdot ft)$ | cP |
| $\mu_L$ | Liquid viscosity | | | cP |
| $\rho$, $\rho_g$ | Gas density | $g/m^3$ | $lb/ft^3$ | |
| $\rho_d$ | Resistivity of dust layer | Ω·m | | |
| $\rho_L$ | Liquid density | $kg/m^3$ | $lb_m/ft^3$ | $lb_m/ft^3$ |

**Nomenclature** (*Continued*)

| Symbols | Definition | SI units | U.S. customary system units | Special units |
|---|---|---|---|---|
| $\rho_s$, $\rho_p$ | True (*not* bulk) density of solids or liquid drops | kg/m$^3$ | lb$_m$/ft$^3$ | lb$_m$/ft$^3$ |
| $\rho'$ | Density of gas relative to its density at 25°C, 1 atm | (–) | (–) | (–) |
| $\sigma$ | Ion density | Number/m$^3$ | | |
| $\sigma_{avg}$ | Average ion density | Number/m$^3$ | | |
| $\sigma_L$ | Liquid surface tension | | | dyn/cm |

## PURPOSE OF GAS–SOLIDS SEPARATION

Gas–solids separation is concerned with the removal or collection of solids dispersed in gases for purposes of:

1. Air pollution control, as in fly ash removal from power plant flue gases, dust control for dryer effluent air, diesel particulates from internal combustion engines
2. Equipment maintenance reduction, as in filtration of engine intake air or pyrites furnace gas treatment prior to its entry to a contact sulfuric acid plant
3. Safety, or health hazard elimination, as in collection of siliceous and metallic dusts around grinding and drilling equipment and in some metallurgical operations and flour dusts from milling or bagging operations; filtration of particulate matter from ambient air to improve indoor air quality, removal of combustible dust from air
4. Product quality improvement, as in air cleaning in the production of pharmaceutical products and photographic film, and manufacturing of microelectronics
5. Recovery of a valuable product in dry state, as in collection of dusts from dryers and smelters
6. Powdered-product collection, as in pneumatic conveying; the spray drying of milk, eggs, and soap; and manufacture of high-purity zinc oxide and carbon black; separation of catalyst in FCC reactors and separation of elutriated solids from fluidized-bed processes

## PROPERTIES OF DISPERSED SOLIDS

An understanding of the fundamental properties and characteristics of solids dispersed in gas is essential to the design of industrial dust-control equipment. Figure 17-40 shows characteristics of dispersed solids and other particles together with the types of gas-cleaning equipment that are applicable to their control. Two types of solid dispersed in gases are shown: (1) dust, which is composed of particles larger than 1 μm in diameter; and (2) fume, which consists of particles generally smaller than 1 μm in diameter. Dusts usually result from mechanical disintegration of matter. They may be redispersed from the settled, or bulk, condition by an air blast. Fumes are submicrometer dispersed solids formed by processes such as combustion, sublimation, and condensation. Once collected, they cannot be redispersed from the settled condition to their original state of dispersion by air blasts or mechanical dispersion equipment.

The primary distinguishing characteristic of solids dispersed in gas is the particle size. The generally accepted unit of particle size is the micrometer, μm. (Prior to the adoption of the SI system, the same unit was known as the micron and was designated by μ.) The size of a spherical particle is unambiguously defined by its diameter, which can be considered the characteristic dimension. However, particles encountered in nature and industrial processes are rarely spherical or regular (e.g., cuboid, ellipsoid, cylindrical) in shape. The characteristic dimension of an irregular particle can be obtained by relating the relevant process response or geometric feature to an "equivalent" sphere (see Fig. 17-41). Therefore, each derived equivalent diameter represents a mechanism or characteristic relevant to the behavior of the particle in the process of interest (Trottier and Dhodapkar, *Chemical Engineering Progress*, July 2014). It should not simply be based on the dominant physical dimension of the particle. A summary of equivalent diameters is shown in Table 17-1.

From the standpoint of gas–solid separation, the most important size-related property of a dust particle is its dynamic behavior. Particles larger than 100 μm are readily collectible by simple inertial or gravitational methods. For particles under 100 μm, the range of principal difficulty in dust collection, the resistance to motion in a gas is viscous (see Sec. 6, Fluid and Particle Dynamics), and for such particles, the most useful size specification is commonly the Stokes settling diameter, which is the diameter of the spherical particle of the same density that has the same terminal velocity in viscous flow as the particle in question. It is yet more convenient in many circumstances to use the "aerodynamic diameter," which is the diameter of the particle of unit density (1000 kg/m$^3$ or 1 g/cm$^3$) that has the same terminal settling velocity. Use of the aerodynamic diameter permits direct comparisons of the dynamic behavior of particles that are actually of different sizes, shapes, and densities [Raabe, *J. Air Pollut. Control Assoc.* **26:** 856 (1976); Cooper and Alley, *Air Pollution Control—A Design Approach*, Waveland Press, Long Grove, Ill., 2011]. The Stokes diameter and the aerodynamic diameter are equal for particles of unit density (1000 kg/m$^3$ or 1 g/cm$^3$).

When the size of a particle approaches the same order of magnitude as the mean free path of the gas molecules, the settling velocity is greater than predicted by Stokes' law because of molecular slip. The mean free path for air at standard conditions is about 0.065 μm. Submicron particles in an air suspension can therefore slip by without impacting the molecules. The slip-flow correction is appreciable for particles smaller than 1 μm and is allowed for by the Cunningham correction for Stokes' law (Cooper in *Handbook of Powder Science & Technology*, ed. Fayed and Otten, Chapman and Hall, London, 1997; Cooper and Alley, *Air Pollution Control*, 4th ed., Waveland Press, Long Grove, Ill., 2011). The correction factors for particle sizes of 0.01, 0.1, 1.0, and 10.0 mm at 1 atm and 25°C are 22.5, 2.89, 1.17, and 1.02, respectively (Cooper and Alley, *Air Pollution Control*, 4th ed., Waveland Press, Long Grove, Ill., 2011). The effect of operating temperature and pressure must also be taken into account. The Cunningham correction is applied in calculations of the aerodynamic diameters of particles that are in the appropriate size range.

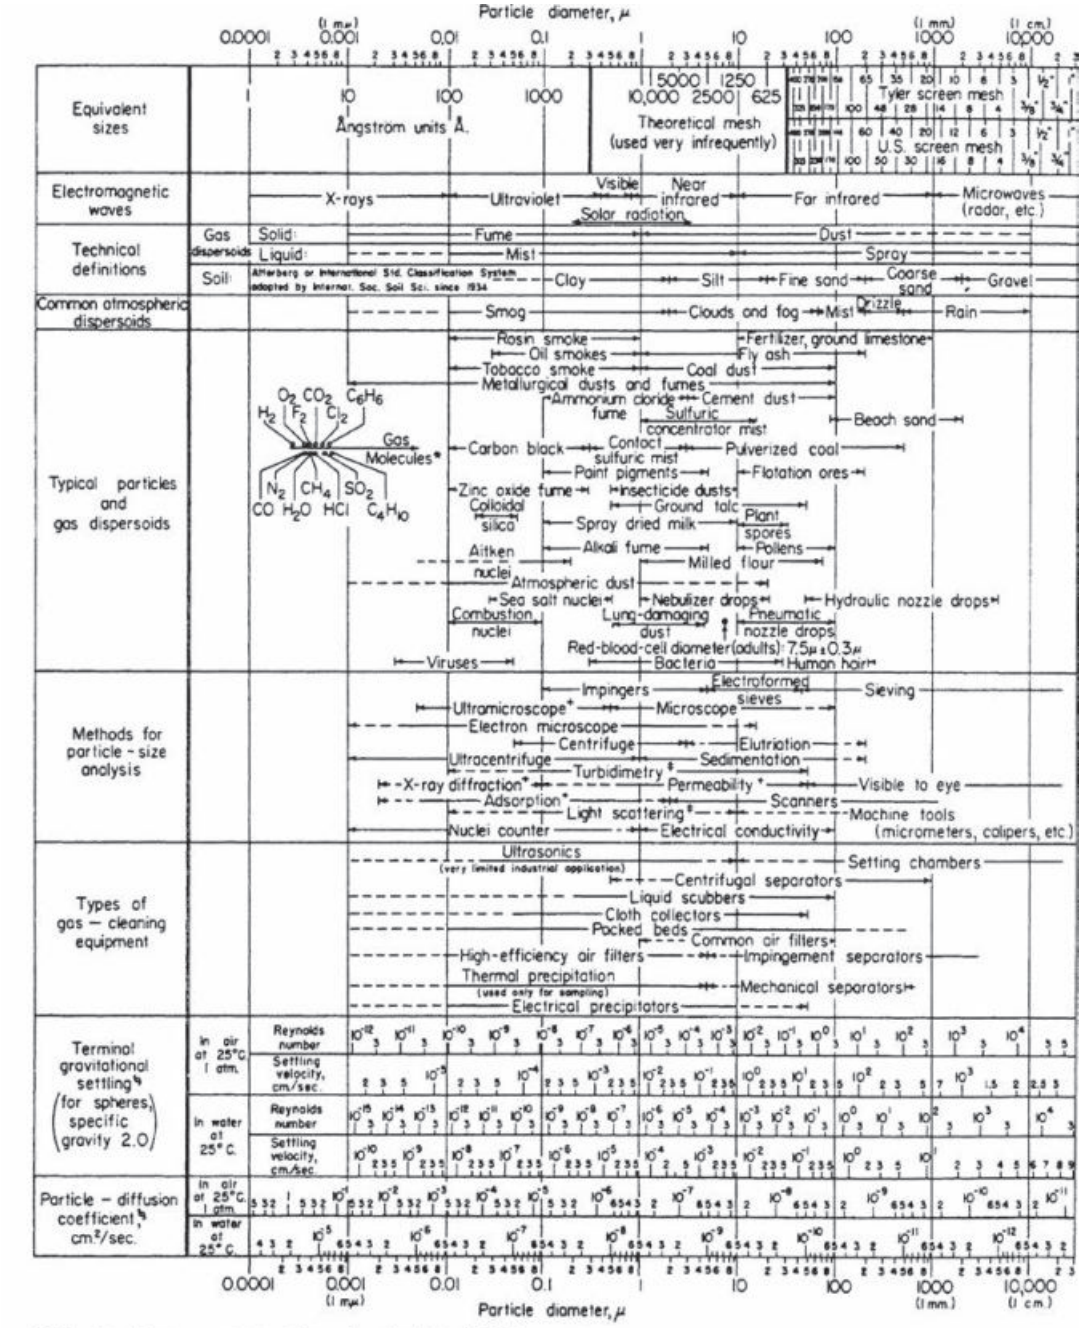

**FIG. 17-40** Characteristics of particles and particle dispersoids. (*Courtesy of the Stanford Research Institute; prepared by C. E. Lapple.*)

Although solid fume particles may range in size down to perhaps 0.001 μm, fine particles effectively smaller than about 0.1 μm are not of much significance in industrial dust and fume sources because their aggregate mass is only a very small fraction of the total mass emission. At the concentrations present in such sources (e.g., production of carbon black) the coagulation, or flocculation, rate of the ultrafine particles is extremely high, and the particles speedily grow to sizes of 0.1 μm or greater. The most difficult collection problems are thus concerned with particles in the range of about 0.1 to 2 μm, in which forces for deposition by inertia are small. For collection of particles under 0.1 μm, diffusional deposition becomes increasingly important as the particle size decreases.

In a gas stream carrying dust or fume, some degree of particle flocculation will exist, so both discrete particles and clusters of adhering particles will be present. The discrete particles composing the clusters may be only loosely attached to each other, as by van der Waals forces [Lapple, *Chem. Eng.* **75**(11): 149 (1968)]. Flocculation tends to increase with increases in particle concentration and may strongly influence collector performance.

## PARTICLE MEASUREMENTS

Measurements of the concentrations and characteristics of dust dispersed in air or other gases may be necessary (1) to determine the need for control

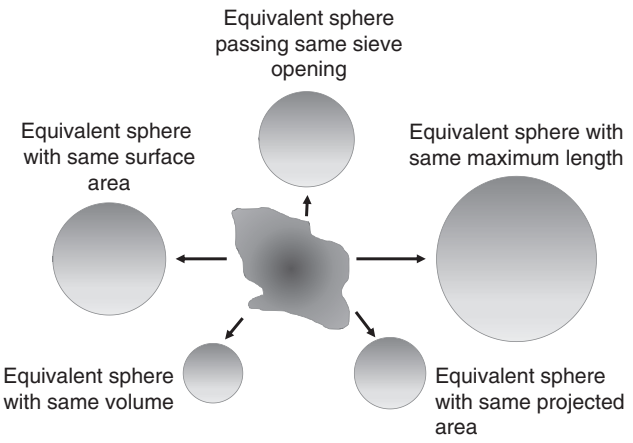

**FIG. 17-41** Examples of equivalent sphere diameters for an irregular particle.

measures, (2) to establish compliance with legal requirements, (3) to select appropriate gas cleaning technology, (4) to obtain information for collector design, and (5) to determine collector performance.

**Atmospheric-Pollution Measurements** The dust-fall measurement is one of the common methods for obtaining a relative long-period evaluation of particulate air pollution. Stack-smoke densities are often graded visually by means of the Ringelmann chart. Plume opacity may be continuously monitored and recorded by a photoelectric device which measures the amount of light transmitted through a stack plume. Equipment for local atmospheric dust concentration measurements fall into five general types: (1) the impinger, (2) the hot-wire or thermal precipitator, (3) the electrostatic precipitator, (4) the filter, and (5) impactors and cyclones. The filter is the most widely used, in the form of either a continuous tape, or a number of filter disks arranged in an automatic sequencing device, or a single, short-term, high-volume sampler. Samplers such as these are commonly used to obtain mass emission and particle-size distribution. Impactors and small cyclones are commonly used as size-discriminating samplers and are usually followed by filters for the determination of the finest fraction of the dust (Lundgren et al., *Aerosol Measurement,* University of Florida, Gainesville, 1979; and Dennis, *Handbook on Aerosols,* U.S. ERDA TID-26608, Oak Ridge, Tenn., 1976; Willeke and Baron, *Aerosol Measurement*, Van Nostrand Reinhold, New York, 1993).

**Process-Gas Sampling** In sampling process gases either to determine dust concentration or to obtain a representative dust sample for composition, particle size, or density measurements, it is necessary to take special precautions to avoid inertial segregation of the particles. To prevent such classification, a traverse of the duct may be required, and at each point the sampling nozzle must face directly into the gas stream with the velocity in the mouth of the nozzle equal to the local gas velocity at that point. This is called isokinetic sampling. If the sampling velocity is too high, the dust sample will contain a lower concentration of dust than the mainstream, with a greater percentage of fine particles; if the sampling velocity is too low, the dust sample will contain a higher concentration of dust with a greater percentage of coarse particles. The sampling probe must be maintained parallel to the streamlines if concentration is being measured. The sampling point should be located such that classification or separation caused by bends, valves, or transitions does not affect the measurements. The measurement can be made upstream of these elements or at least 8 to 10 diameters downstream. The critical elements of a sampling system are nozzle design, dust extraction system, and sample collector. However, it is not always possible to achieve isokinetic and isoaxial sampling conditions in the field. Specific corrections must then be made to the measured data (Allen, *Particle Size Measurement*, 4th ed., Chapman and Hall, London, 1990). Additional details can be found in these references [Lapple, *Heat. Piping Air Cond.* **16:** 578 (1944); *Manual of Disposal of Refinery Wastes,* vol. V, American Petroleum Institute, New York, 1954; and Dennis, *Handbook on Aerosols,* U.S. ERDA TID-26608, Oak Ridge, Tenn., 1976; EPA Report, *Principles and Practices of Air Pollution Control—Student Manual,* APTI Course 452, U.S. EPA, July 2003; EPA Report, *Quality Assurance Handbook for Air Pollution Measurement System*, 454/B-13-003, May 2013; Allen, *Particle Size Measurement*, 4th ed., Chapman and Hall, London, 1990].

**Particle-Size Analysis** Methods for particle-size analysis are shown in Fig. 17-40, and various techniques for particle-size analysis are summarized in Table 17-2. More detailed information may be found in Lapple, *Chem. Eng.* **75**(11): 140 (1968); Lapple, "Particle-Size Analysis," in *Encyclopedia of Science and Technology,* 5th ed., McGraw-Hill, New York, 1982; Cadle, *The Measurement of Airborne Particles,* Wiley, New York, 1975; Lowell, *Introduction to Powder Surface Area,* 2d ed., Wiley, New York, 1993; Allen, *Particle Size Measurement,* 4th ed, Chapman and Hall, London, 1990; Allen, *Powder Sampling and Particle Size Determination*, Elsevier, 2003; and Baron et al., *Aerosol Measurement: Principles, Techniques, and Applications,* 3d ed., John Wiley & Sons, Inc., 2011.

**TABLE 17-1 Commonly Used Equivalent Diameters**

| Basis | Equivalent diameter | Symbol* | Definition |
|---|---|---|---|
| Volume-based diameter | Volume diameter | $d_v$ | Diameter of a sphere having the same volume as the particle |
| | Surface diameter | $d_s$ | Diameter of a sphere having the same external surface area as the particle |
| | Surface volume diameter (Sauter diameter) | $d_{sv}$ | Diameter of a sphere having the same external surface-area-to-volume ratio as the particle |
| | Sieve diameter | $d_A$ | Diameter of a sphere equivalent to the size of the minimum square aperture through which the particle will pass |
| | Drag diameter | $d_d$ | Diameter of a sphere that has the same resistance to motion in the same fluid (having same viscosity), moving at the same velocity as the particle |
| | Free-falling diameter | $d_f$ | Diameter of a sphere having the same density and the same free-falling speed as the particle in the same fluid |
| | Stokes' diameter | $d_{St}$ | Diameter of a free-falling sphere in laminar region |
| | Aerodynamic diameter | $d_a$ | Stokes' diameter of a sphere of unit specific gravity (water) |
| Equivalent circle | Projected area diameter | $d_{ps}$ | Diameter of a circle having the same area as the projected area of the particle at rest in a stable position |
| | Projected area diameter | $d_{pr}$ | Diameter of a circle having the same area as the projected area of the particle at rest in a random position |
| | Perimeter diameter | $d_c$ | Diameter of a circle having the same perimeter as the projected area (outline) of the particle, irrespective of the particle orientation |
| Statistically derived | Feret's diameter | $d_F$ | Mean value of the distance between pairs of parallel tangents to the projected outline of the particle |
| | Martin's diameter | $d_M$ | The mean chord length of the projected outline of the particle |
| | Unrolled diameter | $d_R$ | The mean chord length through the center of gravity of the particle |
| | Maximum chord diameter | $d_{CH}$ | The maximum length of a line limited by the particle contour |
| | Shear diameter | $d_{SH}$ | Particle width obtained with an image shearing device |

*It is a standard practice in the United States to use the letter $d$ for particle size, whereas European literature, including ISO standards, uses the letter $x$.

With the exception of image analysis techniques, every particle sizing technique measures some type of equivalent diameter, which is then reported as the particle diameter. In the past 25 years, the particle-size measurement devices have become sophisticated and yet easier to use. Often, the users do not understand the underlying principles and take the results as absolute values. A direct comparison of particle-size distributions obtained from instruments based on different measurement techniques should be avoided.

Particle-size distribution may be presented on either a frequency or a cumulative basis; the various methods are discussed in the references just cited. The most common method presents a plot of particle size versus the cumulative weight percent of material larger or smaller than the indicated size. The distributions can be reported by number, surface, or volume. However, the conversion between number, surface, and volume distributions done by the instrument software does usually take the particle shape into account. For nonspherical particles, the measurement techniques must always be reported along with the particle size analysis.

As discussed earlier, the dynamic response of a particle in a fluid medium is best represented by the Stokes diameter, the aerodynamic diameter, or the Sauter mean diameter. For determination of the aerodynamic diameters of particles, the most commonly applicable methods for particle-size analysis are those based on inertia: aerosol centrifuges, cyclones, and inertial impactors (Lundgren et al., *Aerosol Measurement,* University of Florida, Gainesville, 1979; Liu, *Fine Particles—Aerosol Generation, Measurement, Sampling, and Analysis,* Academic, New York, 1976; and Baron et al., *Aerosol Measurement: Principles, Techniques, and Applications,* 3d ed., John Wiley & Sons, Inc., 2011), and time of flight aerodynamic particle sizers. Cascade impactors are most commonly used. It should be noted that the impactor measurements are subject to many errors [Rao and Whitby, *Am. Ind. Hyg. Assoc. J.* **38:** 174 (1977); Marple and Willeke, "Inertial Impactors," in *Aerosol Measurement,* Lundgren et al., University of Florida, Gainesville, 1979; and Fuchs, "Aerosol Impactors," in *Fundamentals of Aerosol Science,* Shaw, Wiley, New York, 1978]. Reentrainment due to particle bouncing and blowoff of deposited particles makes a dust appear finer than it actually is, as does the breakup of flocculated particles. The processing of cascade-impactor data also presents possibilities for substantial errors (Fuchs, *The Mechanics of Aerosols,* Pergamon, Oxford, 1964) and is laborious as well. Lawless (Rep. No. EPA-600/7-78-189, U.S. EPA, 1978) discusses problems in analyzing and fitting cascade-impactor data to obtain dust-collector efficiencies for discrete particle sizes.

The measured diameters of particles should as nearly as possible represent the effective particle size of a dust as it exists in the gas stream. The ideal, but also the most challenging, approach would be on-line sampling and particle-size analysis. However, most particle sizing methods are suitable for off-line analysis of the collected samples. When the sample is redispersed for particle-size analysis, the agglomerates of fine particles, which might exist in the process stream, will be broken down to their constituent particles. The fines fraction from such analysis would report a higher value than actually observed in the process stream.

For dust-control work, it is recommended that a preliminary qualitative examination of the dust first be made without a detailed particle count. A visual estimate of particle-size distribution will often provide sufficient guidance for a preliminary assessment of requirements for collection equipment.

***Sampling*** It is often assumed that the sample obtained and analyzed from the process is a representative sample. Care and expertise expended on analyzing a nonrepresentative sample will not yield useful data. To obtain a representative sample for particle-size analysis, one must follow good sampling practices (Allen, *Particle Size Measurement*, 4th ed., Chapman and Hall, 1990; Allen, *Powder Sampling and Particle Size Determination,* Elsevier, Amsterdam, 2003; NIST Practice Guide, *Particle Size Characterization*, Special Publication 960-1, 2001). The gross sample so obtained is usually much larger than the sample required for analysis (Table 17-2). Further reduction in the sample size from gross sample to laboratory sample, and finally the analytical sample, must be done without introducing bias or random variability. Various methods, such as cone and quartering, scoop sampling, table sampling, chute riffling, and spin riffling, are commonly practiced. Allen and Khan [*Chem. Engr.* 238 (1970)] have suggested that a spinning riffler is the most reproducible technique for sample subdivision. More details can be found in Allen (*Powder Sampling and Particle Size Determination,* Elsevier, Amsterdam, 2003).

## MECHANISMS OF GAS–SOLIDS SEPARATION

The basic operations in dust collection by any device are (1) separation of the gas-borne particles from the gas stream by deposition on a collecting surface, (2) retention of the deposit on the surface, and (3) removal of the deposit from the surface for recovery or disposal. The separation step

**TABLE 17-3 Summary of Mechanisms and Parameters in Aerosol Deposition**

*This has also commonly been termed "direct interception" and in conventional analysis would constitute a physical boundary condition imposed upon the particle path induced by action of other forces. By itself it reflects deposition that might result with a hypothetical particle having finite size but no mass or elasticity.

†This parameter is an alternative to $N_{sf}$, $N_{si}$, or $N_{ad}$ and is useful as a measure of the interactive effect of one of these on the other two. It is comparable with the Schmidt number.

‡When applied to the inertial deposition mechanism, a convenient alternative is $(K_m \rho_s/18\rho) = N_{si}/(N_{sf}^2 N_{Re})$.

§In cases in which the body charge distribution is fixed and known, $\epsilon_b$ may be replaced with $Q_{bs}/\delta_o$.

¶Not likely to be significant contributions.

requires (1) application of a force that produces a differential motion of a particle relative to the gas and (2) a gas retention time sufficient for the particle to migrate to the collecting surface. The principal mechanisms of aerosol deposition that are applied in dust collectors are (1) gravitational deposition, (2) flow-line interception, (3) inertial deposition, (4) diffusional deposition, and (5) electrostatic deposition. Thermal deposition is only a minor factor in practical dust-collection equipment because the thermophoretic force is small. Table 17-3 lists these six mechanisms and presents the characteristic parameters of their operation [Lunde and Lapple, *Chem. Eng. Prog.* **53:** 385 (1957)]. The actions of the inertial-deposition, flow-line-interception, and diffusional-deposition mechanisms are illustrated in Fig. 17-42 for the case of a collecting body immersed in a particle-laden gas stream.

Two other deposition mechanisms, in addition to the six listed, may be in operation under particular circumstances. Some dust particles may be collected on filters by sieving when the pore diameter is less than the particle diameter. Except in small membrane filters, the sieving mechanism is probably limited to surface-type filters, in which a layer of collected dust is itself the principal filter medium.

The other mechanism appears in scrubbers. When water vapor diffuses from a gas stream to a cold surface and condenses, there is a net hydrodynamic flow of the noncondensable gas directed toward the surface. This flow, termed the Stefan flow, carries aerosol particles to the condensing surface (Goldsmith and May, in Davies, *Aerosol Science*, Academic, New York, 1966) and can substantially improve the performance of a scrubber. However, there is a corresponding Stefan flow directed away from a surface at which water is evaporating, and this will tend to repel aerosol particles from the surface.

In addition to the deposition mechanisms themselves, methods for preliminary conditioning of aerosols may be used to increase the effectiveness of the deposition mechanisms subsequently applied. One such conditioning method consists of imposing on the gas high-intensity acoustic vibrations to cause collisions and flocculation of the aerosol particles, producing large particles that can be separated by simple inertial devices such as cyclones. This process, termed *sonic* (or *acoustic*) *agglomeration*, has attained only limited commercial acceptance.

Another conditioning method, adaptable to scrubber systems, consists of inducing condensation of water vapor on the aerosol particles as nuclei, increasing the size of the particles and making them more susceptible to collection by inertial deposition.

Most forms of dust-collection equipment use more than one of the collection mechanisms, and in some instances the controlling mechanism may change when the collector is operated over a wide range of conditions. Consequently, collectors are most conveniently classified by type rather than according to the underlying mechanisms that may be operating.

## PERFORMANCE OF GAS–SOLIDS SEPARATORS

The performance of a gas–solids separation device is most commonly expressed as the collection efficiency $\eta$, the weight ratio of the dust collected to the dust entering the apparatus. However, the collection efficiency is usually related exponentially to the properties of the dust and gas and the operating conditions of most types of collectors and hence is an insensitive function of the collector operating conditions as its value approaches 1.0. Performance in the high-efficiency range is better expressed by the penetration $1 - \eta$, the weight ratio of the dust escaping to the dust entering. Particularly in reference to collection of radioactive aerosols, it is common to express performance in terms of the reciprocal of the penetration $1/(1 - \eta)$, which is termed the *decontamination index* (DI). The number of transfer units $N_t$, which is equal to $\ln [1/(1 - \eta)]$ in the case of dust collection, was first proposed for use by Lapple (Wright, Stasny, and Lapple, "High Velocity Air Filters," WADC Tech. Rep. 55-457, ASTIA No. AD-142075, October 1957) and is more commonly used than the DI. Because of the exponential form of the relationship between efficiency and process variables for most dust collectors, the use of $N_t$ (or DI) is particularly suitable for correlating collector performance data.

In comparing alternative collectors for a given service, a figure of merit is desirable for ranking the different devices. Since power consumption is one of the most important characteristics of a collector, the ratio of $N_t$ to power consumption is a useful criterion. Another is the ratio of $N_t$ to capital investment.

Gas–solids separation devices are often installed in series to achieve the highest possible efficiency and performance reliability. A precleaner may be installed to reduce the solids loading in the primary collector to improve collection efficiency and reduce abrasive wear. A secondary collector downstream may be installed to mitigate chances of emissions during a process upset in the primary collector. The overall efficiency of the combined system can be calculated by multiplying the penetration value of each device that is connected in series (Fig. 17-43).

$$Pt_{\text{system}} = Pt_1, Pt_2, Pt_3 \tag{17-9}$$

$$\eta_{\text{system}} = 1 - Pt_{\text{system}} \tag{17-10}$$

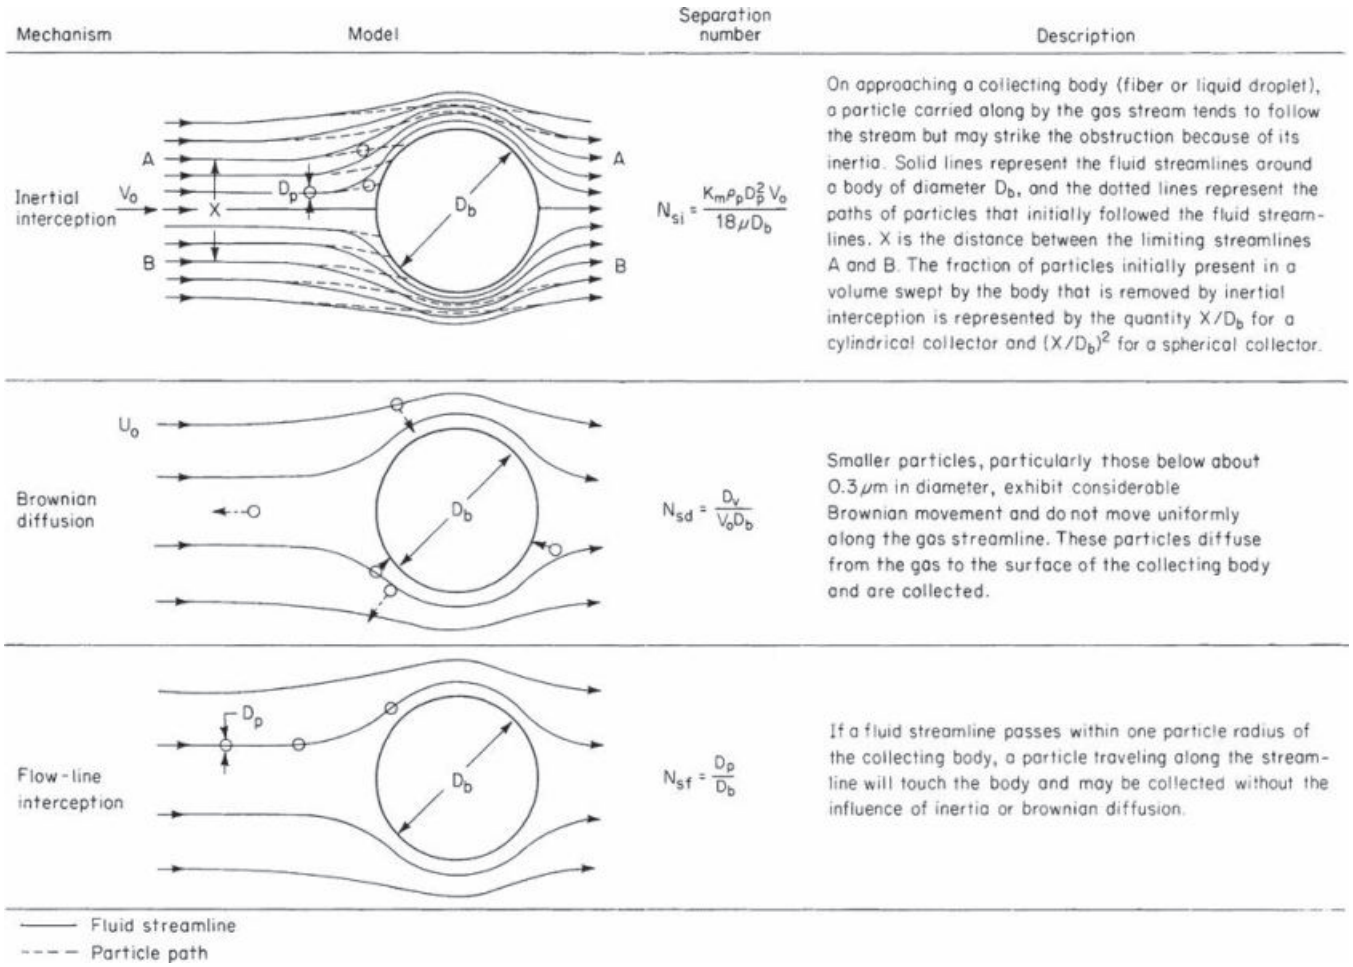

**FIG. 17-42** Particle deposition on collector bodies.

***Gravimetric Grade (or Fractional) Efficiency*** The performance of gas–solids separation devices is quantified by the overall collection efficiency or the fraction of the total mass of incoming dust that is separated from the gas stream. The overall collection efficiency depends on performance characteristics of the separator and the particle-size distribution of the incoming dust. It is possible for a coarse dust to be collected at 100 percent efficiency, whereas a fine dust may be separated with lower efficiency in the same unit operating at exactly the same conditions. Therefore, specification of an efficiency without qualifying the operating conditions and inlet dust characteristics is misleading.

The performance characteristics of a separator are represented by the gravimetric grade (or fractional) efficiency, or simply the grade efficiency. Grade efficiency can be conceptualized as a probabilistic function where every incoming particle has a certain chance of being removed from the gas stream. The flow path of various particles, even at identical operating conditions, will not be identical. Larger particles have a higher probability of being collected, while the smaller particles have a lower probability. The grade efficiency curve ($G(d_p)$) is typically S-shaped (Fig. 17-44*a*). The characteristic particle size for the abscissa should be relevant to the principle of separation. Stokes' diameter, Sauter mean diameter, or aerodynamic diameter are commonly used. The particle size corresponding to 50 percent efficiency is called the cut size ($d_{p50}$). It represents the size fraction which has equal probability of being collected or elutriated. A step-function at the cut size, which is often assumed but rarely realized, would represent the ideal shape

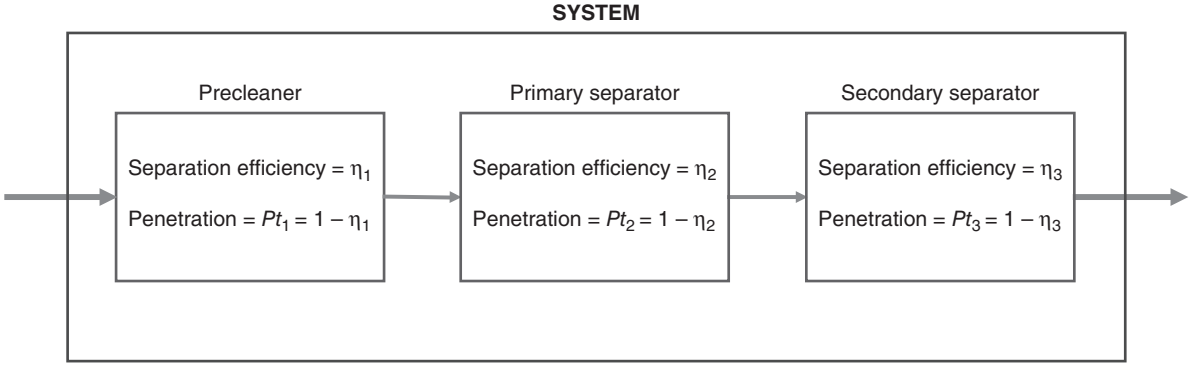

**FIG. 17-43** Overall efficiency of separation devices connected in series.

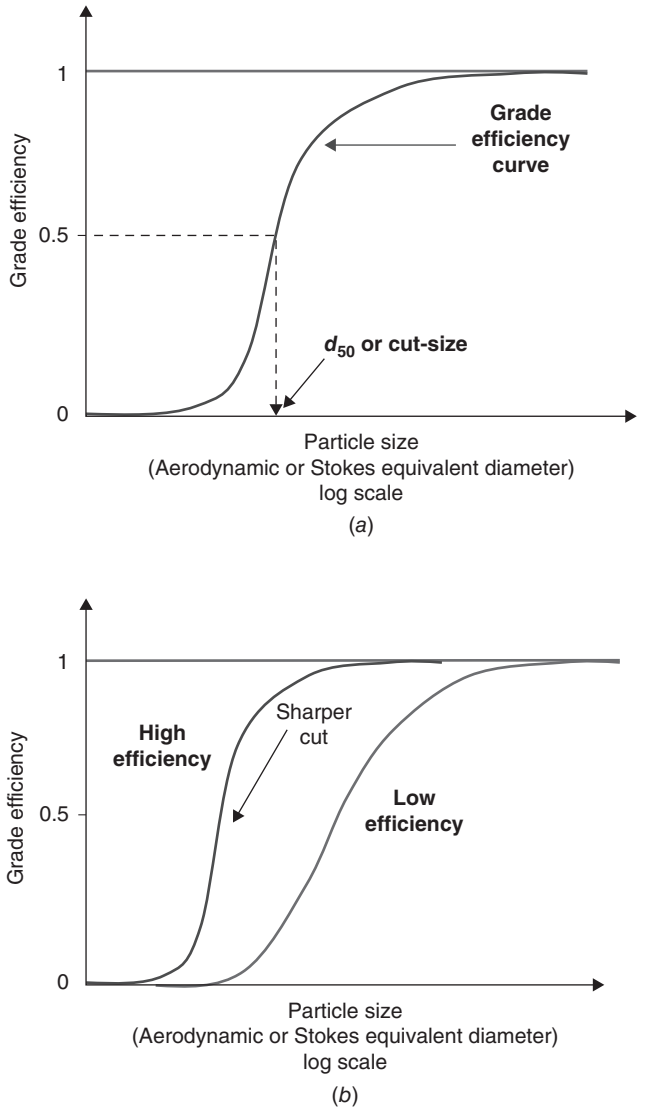

**FIG. 17-44** (*a*) Grade efficiency curve and cut size. (*b*) Comparison of different grade efficiency curves.

of a grade or fractional efficiency curve. The departure from ideality can be attributed to turbulent dispersion, reentrainment, fines agglomeration, attrition, and other nonidealities within the separator.

Each curve is specific for a given design, size, and the operating conditions. Grade efficiency curves of two different devices can be plotted on the same basis for comparison (see Fig. 17-44*b*).

The overall gravimetric efficiency (or collection efficiency, $\eta$) is a product of grade efficiency and the weight fraction of incoming dust for various particle size fractions (Fig. 17-45).

$$\eta = \sum G(d_{pi}) w(d_{pi}) * 100 \qquad (17\text{-}11)$$

where $\eta$ = overall collection efficiency, %
$G(d_{pi})$ = grade (or fractional) efficiency at particle size $d_{pi}$ $(0-1)$
$w(d_{pi})$ = weight fraction of particles corresponding to particle size $d_{pi}$ $(0-1)$

The grade efficiency curve reaches an asymptotic limit on both ends, at smaller and larger particles. It is difficult to determine the particle size that has a 100 percent chance of separation (limit of separation). Therefore, 98 or 99 percent is usually chosen as the upper limit. On the lower end of the particle size, the curve can terminate at a finite value on the abscissa for separators with defined purge streams (e.g., uniflow cyclones, baffle separators) or for other inefficiencies in the operation (e.g., leakage in cyclones and bypassing in electrostatic precipitators).

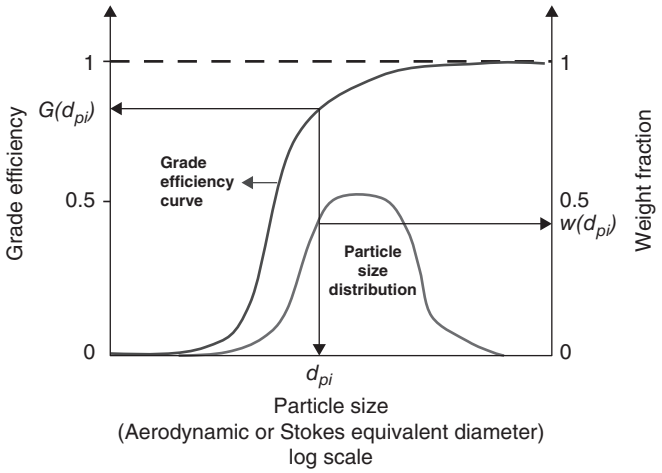

**FIG. 17-45** Calculation of overall efficiency from grade efficiency and particle size distribution.

While this concept is very useful, and is equally applicable to solid–liquid separation and solid–solid separation, it is limited to unit operations where the mechanism of separation does not change with time or during operation. The performances of gravity settling chambers, inertial collectors, cyclones, electrostatic precipitators, and scrubbers are well represented by this concept, whereas filters ( fabric, granular, media) are unsuitable due to changing mechanisms during operation.

For design and performance prediction, one must estimate (experimentally or theoretically) the grade efficiency curve of a device. In practice, experimental data are used to validate and adjust the parameters in a model. A generalized schematic of gas–solids separation is shown in Fig. 17-46.

The three streams are feed, coarse, and fines. Each stream is described by the solids rate and the particle-size distribution. Only two out of three streams must be defined, and the third one can be calculated from the mass balance. Unless there is a process advantage for measurements, Svarovsky (*Solid–Gas Separation, Handbook of Powder Technology*, vol. 3, Elsevier, Amsterdam, 1981) has shown that estimation based on fines and coarse streams yields the best results, or at least one of the streams should be the fines stream (Hoffman and Stein, *Gas Cyclones and Swirl Tubes—Principles, Design and Operation*, Springer, Berlin, 2002). The overall efficiency of separation can be estimated by Eq. (17-11).

For selection purposes, the entire efficiency curve need not be estimated. Approximations based on cut size and analytical cut diameter, which represent equipment performance and inlet dust characteristics respectively, can provide a useful guide.

***Cut Size ($d_{p50}$):*** As discussed earlier, it is the particle size corresponding to 50 percent on the grade efficiency curve (Fig. 17-44*a*). Since a grade efficiency curve depends on operating conditions and equipment size/geometry, the family of curves can be condensed into a range of cut sizes for a given technology. These ranges are available from manufacturers and are well documented for commonly practiced devices. It is essential to understand the definition of particle size and its associated measurement method used to generate these grade efficiency curves.

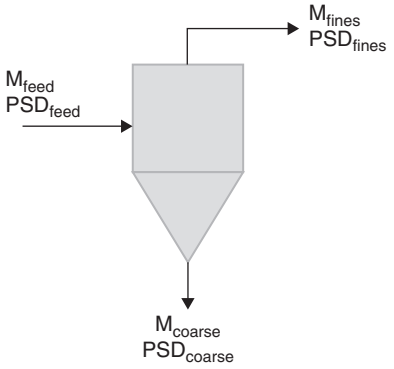

**FIG. 17-46** Generalized description of a gas–solid separation device.

***Analytical Cut Diameter ($d_{p\text{-}ac}$):*** This is the particle size on a cumulative weight percent oversize distribution curve that is *numerically* equal to the desired overall collection efficiency of the gas–solid separation device. Again, the selection of a characteristic particle size for the abscissa must be relevant to the principle of separation and the same as the grade efficiency curves under consideration.

The suitability of a technology for gas–solid separation is determined by its ability to achieve the desired collection or separation efficiency. For preliminary selection, the analytical cut diameter can be estimated from the particle-size distribution of the incoming dust. The analytical cut diameter is compared against typical ranges for various technologies (e.g., gravity settling, cyclones, scrubbers, electrostatic precipitators). The choice is acceptable if $d_{50}$ is smaller than $d_{p\text{-}ac}$; otherwise the choice is unacceptable. There is an inherent assumption of the ideal shape of the curve. Nonetheless, it is a useful concept for preliminary process selection since it allows comparison of performances for a specific dust.

***Particle Density*** In addition to the particle size, the density of particulate matter (PM) plays an important role in its ability to be entrained and remain in suspension. The particle density may be a function of particle size if the mechanism of particle formation for various size fractions is different. Very fine particles tend to agglomerate into a loose, porous structure, whereas coarse particles may be nonporous and dense. The density of nonporous solids can unambiguously be defined in the classical sense (mass per unit volume), and measured with pycnometers. On the other hand, porous particles will exhibit different dynamic behavior in fluids as compared to nonporous particles of the same size and composition. The equivalent or effective density, also known as the envelope density, is a measure that includes the pores and reflects the dynamic response of the particle in the fluid. True density or skeletal density is the density of the matter the particles are composed of. For gas–solids separation operations, we are interested in measuring the effective or envelope density of the particulate matter.

## DESIGN OF GAS–SOLID SEPARATORS

For any separation device, the relative contribution of various collection mechanisms (Fig. 17-42) depends on the particle and gas characteristics, the geometry of the equipment, and the fluid-flow pattern. Although the general case is exceedingly complex, it is usually possible in specific instances to determine which mechanism or mechanisms may be controlling. Nevertheless, the difficulty of theoretical treatment of dust-collection phenomena has made necessary simplifying assumptions, with the introduction of corresponding uncertainties. Theoretical studies have been hampered by a lack of adequate experimental techniques for verification of predictions. Although theoretical treatment of collector performance has been greatly expanded in the past 30 years with the widespread application of computational fluid dynamics (CFD) coupled with the discrete element method (DEM), few of the resulting performance models have received adequate experimental confirmation because of experimental limitations. CFD is increasingly used to understand the gas and particle dynamics within the collector and for applying the learnings to optimize and troubleshoot systems.

The best-established models of collector performance are those for fibrous filters and fixed-bed granular filters, in which the structures and fluid-flow patterns are reasonably well defined. These devices are also adapted to small-scale testing under controlled laboratory conditions. Realistic modeling of full-scale electrostatic precipitators and scrubbers is incomparably more difficult. Confirmation of the models has been further limited by a lack of monodisperse aerosols that can be generated on a scale suitable for testing equipment of substantial sizes. When a polydisperse test dust is used, the particle-size distributions of the dust both entering and leaving a collector must be determined with extreme precision to avoid serious errors in the determination of the collection efficiency for a given particle size.

The design of industrial-scale collectors still rests essentially on empirical or semiempirical methods, although it is increasingly guided by concepts derived from theory. Existing theoretical models often embody constants that must be evaluated by experiment and may actually compensate for deficiencies in the models.

## COMMON GAS–SOLID SEPARATORS

**Gravity Settling Chambers** The gravity settling chamber is probably the simplest and earliest type of dust-collection equipment, consisting of a chamber in which the gas velocity is reduced to enable dust to settle out by the action of gravity. Its simplicity lends it to almost any type of construction. Practically, however, its industrial utility is limited to removing particles larger than 325 mesh (43-μm diameter). For removing smaller particles, the required chamber size is generally excessive. As precleaners, gravity settling chambers can handle heavy dust loading and can process coarse abrasive particles at high temperatures and with low pressure drop.

Gravity collectors are generally built in the form of long, empty, horizontal, rectangular chambers with an inlet at one end and an outlet at the side or top of the other end. The dust-laden gas stream traverses the length of the settling chamber at low velocities (0.3 m/s typical, 3 m/s maximum), thereby allowing sufficient time for the coarse fraction to settle and to prevent reentrainment. The grade efficiency of gravity settling chambers can be calculated based on particle trajectory within the unit. Svarovsky [*Solid–Gas Separation, Handbook of Powder Technology*, vol. 3, Elsevier, Amsterdam, 1981] has outlined three calculation approaches, depending on the nature of flow:

- Laminar flow (Re < 2300)
- Turbulent flow with lateral mixing
- Turbulent flow with lateral and longitudinal mixing

***Laminar Flow*** By assuming a low degree of turbulence relative to the settling velocity of the dust particle in question, the performance (grade efficiency) of a gravity settling chamber is given by

$$G(d_p)=\frac{B_s L_s}{q}U_t(d_p)=\frac{L_s}{V_s H_s}U_t(d_p)=\frac{\rho_s g d_p^2}{18\mu}\frac{L_s}{V_s H_s}B \qquad (17\text{-}12)$$

where $V_s$ = average gas velocity. The dimensionless group $B$ allows comparison of models for laminar and turbulent mixing. Expressing $U_t$ in terms of particle size (equivalent spherical diameter), the smallest particle that can be completely separated out corresponds to $\eta = 1.0$ and, assuming Stokes' law, is given by

$$d_{p,\min}=\sqrt{\frac{18\mu H_s V_s}{g L_s(\rho_s-\rho)}} \qquad (17\text{-}13)$$

where $\rho$ = gas density and $\rho_s$ = particle density. For a given volumetric airflow rate, collection efficiency depends on the total plan cross section of the chamber and is independent of the height. The height needs to be made only large enough so that the gas velocity $V_s$ in the chamber is not so high as to cause reentrainment of separated dust.

***Turbulent Flow*** The footprint of a gravity settling chamber can become excessively large if laminar flow must be maintained. In practice, turbulent flow (Re > 2300) is often observed in these units. Turbulent mixing will reduce the collection efficiency, however, and a balance between economics (footprint) and efficiency must be sought. Simple mechanistic models proposed by Svarovsky [*Solid–Gas Separation, Handbook of Powder Technology*, vol. 3, Elsevier, Amsterdam, 1981] provide insight into the effect of turbulent mixing on performance. For an assumption of turbulent flow with complete lateral mixing and no longitudinal mixing, the grade efficiency is given by

$$G(d_p)=1-\exp\left(-\frac{U_t(d_p)L_s}{V_s H_s}\right)=1-\exp[-B]=1-\exp\left(-\frac{U_t(d_p)B_s L_s}{q}\right) \qquad (17\text{-}14)$$

For the case of lateral and longitudinal mixing in the settling chamber, the efficiency can be calculated by

$$G(d_p)=\frac{B}{1+B} \qquad (17\text{-}15)$$

As shown in Fig. 17-47, the performance is progressively diminished with increased mixing. These models do not account for reentrainment or recirculation flows within the unit. As the models suggest, reducing the settling height ($H_s$) will increase the collection efficiency. Horizontal plates arranged as shelves within the chamber will give a marked improvement in collection. This arrangement is known as the Howard dust chamber (Fume Arrester, U.S. Patent 896,111, 1908). The disadvantage of the unit is the difficulty of cleaning owing to the close shelf spacing and warpage at elevated temperatures.

The pressure drop through a settling chamber is small, consisting primarily of entrance and exit losses. Because low gas velocities are used, the chamber is not subject to abrasion and may, therefore, be used as a precleaner to remove very coarse particles and thus minimize abrasion on subsequent equipment.

**Impingement Separators** Impingement separators are a class of inertial separators in which particles are separated from the gas by inertial impingement on collecting bodies arrayed across the path of the gas stream. Fibrous-pad inertial impingement separators for the collection of wet particles are the main applications for this technology. With the growing need for very high-performance dust collectors, there is little application anymore for dry impingement collectors.

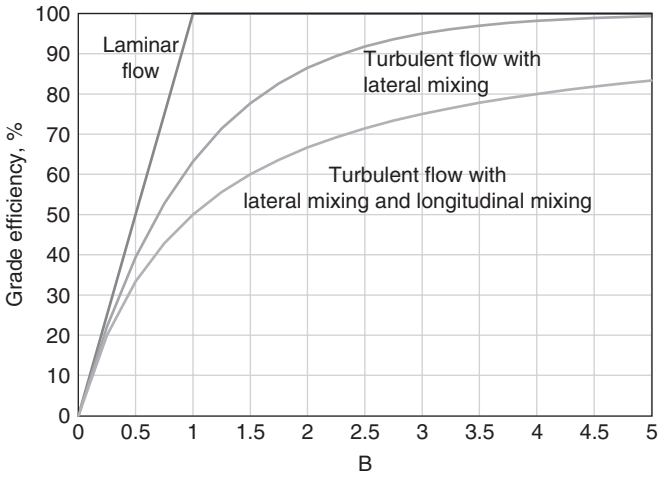

**FIG. 17-47** Comparison of grade efficiency curves of settling chamber models.

**Louver and Baffle Collectors** With these devices (Fig. 17-48), particles are separated from a dust-laden stream when the direction of gas flow is abruptly changed. Due to inertia, the particles do not follow the gas streamlines but continue to be concentrated in the dust stream. A typical cut size of 10 to 20 μm can be achieved by these collectors. The pressure drop is slightly higher than with gravity settlers, but comparatively higher efficiency and lower space requirements make them a viable alternative. They are used as precleaners (e.g., for an engine intake) or concentrators (e.g., fly ash removal). The inside surface can be irrigated with water to reduce reentrainment and further increase the performance.

**Cyclone Separators** Cyclones have been widely used in process industries as primary separators or as precleaners to reduce dust loading on primary separators. The lack of moving parts, simplicity of construction, ability to operate at high temperature and pressure, separation of dust in dry state, and low capital cost make them an attractive option for gas cleaning. Successful applications of cyclones can be found in many industries involved with fluid–particle processing, including

- Petroleum (e.g., FCC cracking and fluid coking processes)
- Chemical (e.g., pneumatic conveying, drying, grinding)

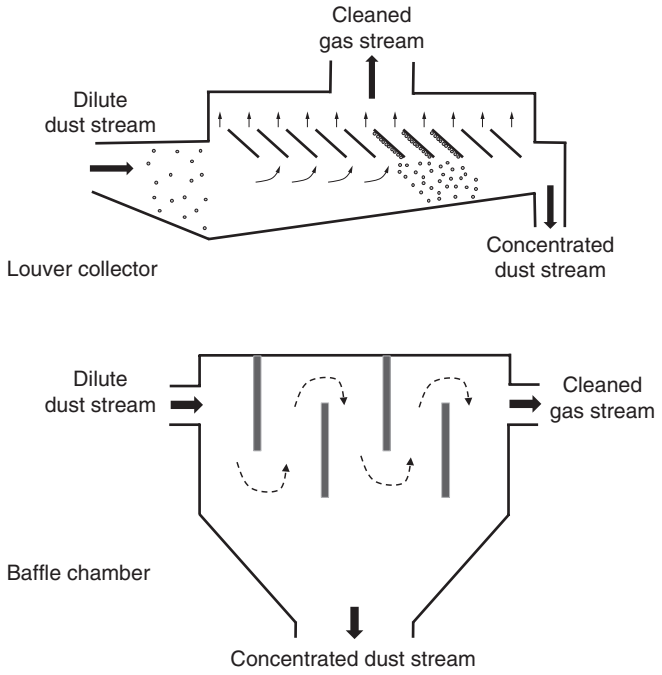

**FIG. 17-48** Louver and baffle collectors.

- Agricultural (e.g., grain processing and conveying)
- Food (e.g., conveying, classification, grinding)
- Power (e.g., precleaners, emission control)
- Mineral (e.g., smelting, ore refining, dust control)

Within the range of their performance capabilities, cyclone collectors offer one of the least expensive means of dust collection from the standpoint of both investment and operation. Their major limitation is that their efficiency is low for the collection of particles smaller than 5 to 10 microns. However, third-stage separators (TSS) in fluid catalytic cracking (FCC) units can achieve very high efficiencies for particles as small as 2 μm. Typically, the TSS units collect everything larger than 5 μm, and approximately 90 percent of the particles in the loss stream will be smaller than 2 μm. If the loading is low to a TSS, (typically less than about 200 mg/Nm$^3$), the TSS in conjuction with a fourth-stage separator (FSS) can meet the emission requirements from a plant. If the loading is higher than about 200 mg/Nm$^3$, a hot gas filter is required after the TSS to meet the emission requirements. For emission control applications, especially for PM2.5 or PM1 (particulate matter with size less than 2.5 μm and 1 μm, respectively), cyclones must be followed by a secondary separator (e.g., fabric filter or electrostatic precipitator). However, highly efficient cyclones have been successfully designed for lower flow rates. Dyson's innovative (U.S. Patent 4593429, 1986) bagless vacuum cleaners based on cyclone technology have proven to be commercially successful. Small cyclones are also used for stack sampling and particle-size analysis of fines.

Although cyclones may be used to collect particles larger than 200 μm, gravity settling chambers or simple inertial separators (such as gas-reversal chambers) are usually satisfactory for this size of particle and are less subject to abrasion. In special cases in which the dust is highly agglomerated or where concentrations over 230 g/m$^3$ (100 gr/ft$^3$) are encountered, cyclones will remove dusts having small particle sizes. In certain instances, efficiencies as high as 98 percent have been attained with dusts having ultimate particle sizes of 0.1 to 2.0 μm because of the predominant effect of particle agglomeration due to large interparticle forces. Cyclones are used to remove both solids and liquids from gases, and they have been operated at temperatures as high as 1200°C and pressures as high as 50,700 kPa (500 atm).

Cyclones can be very small or very large. The smallest cyclones range from approximately 1 to 2 cm in diameter and the largest up to about 10 m in diameter. The number of cyclones used for a single fluidized bed can vary from 1 to up to 22 sets of first-stage and second-stage cyclones (44 cyclones total). Cyclones in process duty can be installed internally or externally to a reactor, horizontally or vertically, in series and in parallel, and in pressure/vacuum operation. Their adaptability to suit various applications has resulted in innumerable designs, but the underlying mechanisms of gas–solid separation are similar.

***Mechanism of Separation*** In a conventional reverse-flow cyclone, the dust-laden gas usually enters a cylindrical or conical chamber tangentially at one or more entrances (usually rectangular in cross section) and leaves through a central opening (Fig. 17-49). The tangential entry of gas creates a swirling flow within the cyclone body that imparts a substantial centrifugal separating force on the particles. The force exerted in the particles relative to the gravitational force is proportional to $(U_i)^2/gr_o$, where $g$ is the gravitational acceleration, $U_i$ is the inlet velocity in the cyclone inlet, and $r_o$ is the radius of the cyclone. For a cyclone with an inlet width that is 20 percent of the diameter of the cyclone (40 percent of the radius), the number of $g$'s that the particles experience (assuming the particles are all at the centerline of the cyclone inlet) is

$$\frac{U_i^2}{g\ 0.8r_o} = \frac{U_i^2}{9.81(0.4D_b)} \tag{17-16}$$

For a cyclone with a barrel diameter of 1 m and operating with an inlet gas velocity of 20 m/s, over 100 $g$'s will be exerted on the entering particles. As a result, the particles move outward toward the cyclone wall, and aided by the outer vortex they migrate toward the dust outlet. The centrifugal force is opposed by the drag force that is directed inward. The cleaned gas stream leaves from the gas exit at the top of the cyclone.

Uniflow cyclones, also known as straight-though cyclones or swirl tubes, generate the swirling action with inlet vanes instead of a tangential inlet. The classified stream near the wall with higher dust concentration is discharged from the cyclone along with 1 to 3 percent of the incoming gas.

***Flow Pattern*** In a reverse flow cyclone, the gas moves in a double vortex, with the gas initially spiraling downward at the outside after it enters the inlet, then flowing upward in the center of the cyclone before it exits. It should be noted that there is an inward flux of gas from outer vortex to inner vortex, which is not necessarily uniform in the axial direction. Due to the swirling nature of the flow, a high static pressure region is created near the wall in the entrance region. The resulting pressure gradient causes inward leakage, called "lip-leakage," along the roof and outer wall of the vortex finder

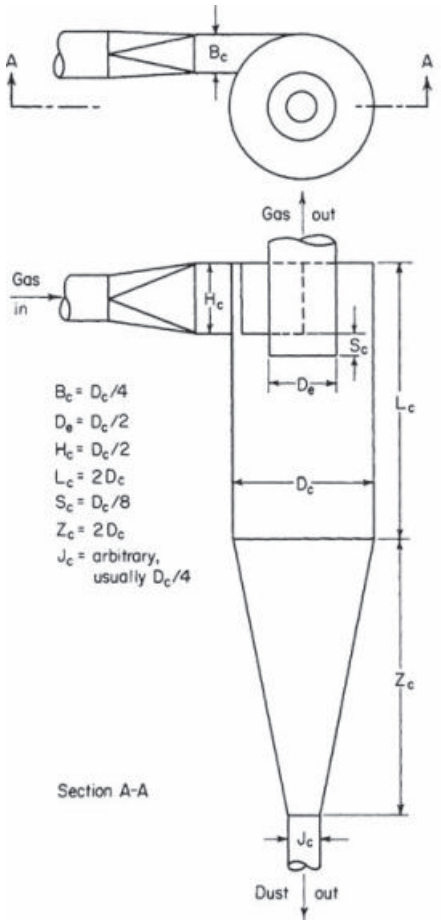

**FIG. 17-49** Cyclone separator proportions.

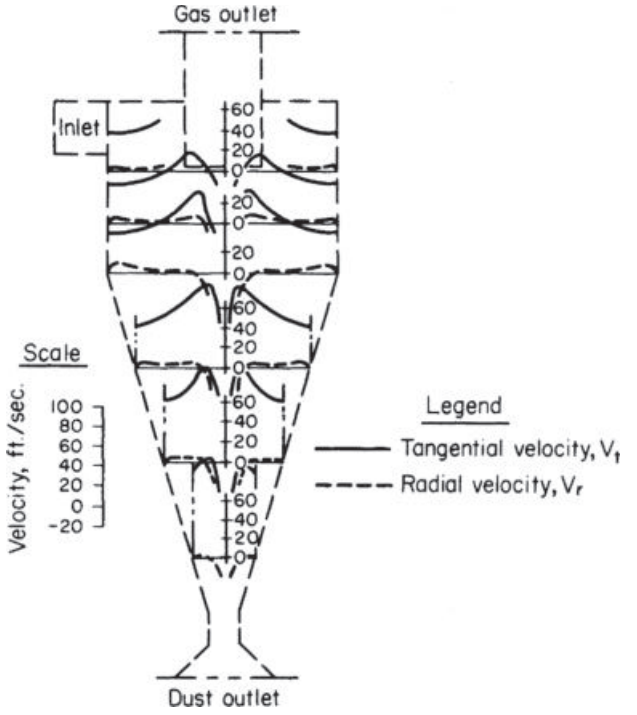

**FIG. 17-50** Variation of tangential velocity and radial velocity at different points in a cyclone. [Ter Linden, *Inst. Mech. Eng. J.* **160:** 235 (1949).]

[Hoffman and Stein, *Gas Cyclones and Swirl Tubes—Principles, Design and Operation*, Springer, Berlin, 2002]. For practical purposes, it can be assumed that approximately 10 percent of incoming gas will bypass the cyclone due to this leakage [Muschelknautz, in *VDI Heat Atlas*, 2d ed. (English), Springer, Berlin, 2010]. The negative impact of this circulation pattern on collection efficiency can be significant for high-pressure cyclones [Heumann, *Chemical Engineering* (June): 118–123 (1991)] with a dished top (as compared to a flat top). This issue can be resolved by installing an internal false roof so the cyclone effectively operates with a flat roof.

When the gas enters the cyclone, its velocity undergoes a redistribution so that the tangential component of velocity increases with decreasing radius. The tangential velocity in a cyclone typically may reach a value approximately two to three times the average inlet gas velocity. Although the gas velocity approaches zero at the wall, the boundary layer is sufficiently thin that pitot-tube measurements show relatively high tangential velocities there, as shown in Fig. 17-50. The radial velocity, $V_r$, is directed toward the center throughout most of the cyclone, except at the center, where it is directed outward. Superimposed on the "double spiral," there may be a "double eddy" [Van Tongran, *Mech. Eng.* **57:** 753 (1935); and Wellmann, *Feuerungstechnik* **26:** 137 (1938)] similar to that encountered in pipe coils. Measurements on cyclones of the type shown in Fig. 17-49 indicate, however, that such double-eddy velocities are small compared with the tangential velocity [Shepherd and Lapple, *Ind. Eng. Chem.* **31:** 972 (1939); **32:** 1246 (1940)]. Recent analyses of flow patterns can be found in Hoffman et al., *Powder Technol.* **70:** 83 (1992); and Trefz and Muschelknautz, *Chem. Eng. Technol.* **16:** 153 (1993).

The preceding observations were made on smooth-wall cyclones. In practice, there are nonuniformities on the wall surface due to scaling, fouling, corrosion, weld seams, refractory, thermocouples, sampling probes, access ports, sight glasses, and sometimes due to hammer dents caused during unplugging operations [Hoffman and Stein, *Gas Cyclones and Swirl Tubes—Principles, Design and Operation*, Springer, Berlin, 2002]. Any such nonidealities can result in disruption of the boundary layer and cause reentrainment of collected solids, thereby reducing the collection efficiency. The effect of the roughness applies to low loading (i.e., second-stage) cyclones. High-loading cyclones (with loadings above about 1 kg of solids/kg of gas) are not as sensitive to wall roughness.

The inner vortex (often called the core of the vortex) rotates at a higher velocity than the outer vortex. In the absence of solids, the diameter of this inner vortex has been measured to be 0.8 to 0.85 times the diameter of the gas outlet tube. With axial inlet cyclones, the inner core vortex is aligned with the axis of the gas outlet tube. With tangential or volute cyclone inlets, however, the vortex is not exactly aligned with the axis. The asymmetric entry of the tangential or volute inlet causes the axis of the vortex to be slightly off center from the axis of the cyclone. This means that the bottom of the vortex is displaced some distance from the axis and can "pluck off" and reentrain dust from the solids sliding down the cyclone cone if the vortex gets too close to the wall of the cyclone cone.

At the bottom of the vortex, there is substantial turbulence as the gas flow reverses and flows up the middle of the cyclone into the gas outlet tube. As indicated previously, if this region is too close to the wall of the cone, substantial reentrainment of the separated solids can occur. If the cyclone is located above a solids collection hopper, even if the inner vortex does not touch the cone but extends beyond the dust outlet, it can entrain the collected dust from the hopper in a manner similar to a tornado. Just as important is an inner vortex that reverses within the body of the cylinder, which creates a secondary recirculation pattern below the vortex that can lead to reentrainment near the dust exit (Hoffman and Stein, *Gas Cyclones and Swirl Tubes—Principles, Design and Operation*, Springer, Berlin, 2002). Therefore, the relationship between the cyclone dimensions and vortex length must be taken into account during design.

If the cyclone is part of a recirculating system with a dipleg below the cyclone, then this reentrainment does not occur in the same manner because the solids are moving downward in the dipleg.

The vortex of a cyclone will precess (or wobble) about the center axis of the cyclone. This motion can bring the vortex into close proximity of the wall of the cone of the cyclone and "pluck" off and reentrain the collected solids flowing down along the wall of the cone. The vortex may also cause erosion of the cone if it touches the cone wall. Sometimes an inverted cone or a similar device called a vortex stabilizer is added to the bottom of the cyclone in the vicinity of the cone and dipleg to stabilize and "fix" the vortex. If it is placed correctly, the vortex will attach to the vortex stabilizer and the vortex movement will be stabilized, thus minimizing the efficiency loss due to plucking the solids off the wall and also minimizing the erosion of the cyclone cone.

Hugi and Reh [*Chem. Eng. Technol.* **21**(9): 716–719 (1998)] have reported that (at high solids loadings) enhanced cyclone efficiency occurs when the solids form a coherent, stable strand at the entrance to a cyclone. The formation of such a strand is dependent on several factors. They reported a higher cyclone efficiency for smaller ($d_{p50} < 40$ micron) solids than for larger solids ($d_{p50} = 125$ μm). This is not what theory would predict. However, they also found that the smaller particles formed coherent, stable strands more readily than the larger particles, which explained the reason for the apparent discrepancy.

***Cyclone Efficiency*** The overall efficiency of any gas–solid separation device is given by the ratio of mass of solids collected to the mass of solids in the inlet stream. The overall collection efficiency of a cyclone is affected by the particle-size distribution of the feed stream even if all the operating conditions remain the same (see Fig. 17-45). The collection efficiency of each size fraction, known as the fractional or grade efficiency, must be determined when evaluating the performance of a cyclone. It is also important to specify the definition of the particle size along with its measurement technique. The aerodynamic particle size or a similar sedimentation-based method is recommended for cyclone applications. However, in many processes, the Sauter mean diameter is used to evaluate cyclones.

A reliable prediction of collection efficiency or emission rate is critical for manufacturers of pollution control equipment where performance warranties are required. Despite all the scientific progress made in the past 100 years, no generalized theory or calculation method from first principles is available that can calculate the performance (efficiency and pressure drop) with certifiable certainty. In practice, manufacturers conduct extensive experimental studies on a family of cyclone designs at various scales to generate the necessary scale-up information or fit parameters in the existing models for better predictive capability.

The cyclone efficiency can be estimated by theoretical models, scaling approach, or computational fluid dynamics (CFD). Each approach has its own merits and limitations. The theoretical models can be classified as (1) equilibrium orbit models [Barth, *Brennstoff-Warme-Kraft 8*, Heft 1 (1956); Muschelknautz, *Chemie-Ing.-Techn.* **44:** 63–71 (1972); Licht, *Air Pollution Control Engineering*, Marcel Dekker, New York (1980)] and (2) residence time or time-of-flight models [Rosin et al., *Zeit Ver. Deutscher Ing.* **76:** 433 (1932); Reitema, *De Ingenieur 71 jaargang No. 39*, ch 59–ch 65 (1959); Zenz, "Cyclone Design," in W. C. Yang, ed., *Fluidization Solids Handling and Processing Industrial Applications*, Noyes, Devon, UK (1999)]. Dietz [*AIChE Journal* **27:** 888–892 (1981)] and Mothes and Loffler [*Int. Chem. Eng.* **28:** 231–240 (1988)], among others, have proposed models that combine both approaches.

In this section, the approach outlined by Zenz and the so-called Stokesian scaling approach are presented.

***Zenz Method*** The methods described here for calculation of pressure drop and efficiency were given by Zenz in *Manual on Disposal of Refinery Wastes—Atmospheric Emissions,* chap. 11 (1975), American Petroleum Institute Publ. 931 and improved by Particulate Solid Research Inc. (PSRI), Chicago. Cyclones work by using centrifugal force to increase the gravity field experienced by the solids. The solids then move to the wall under the influence of their effectively increased weight. Movement to the wall is improved as the path the solids traverse under centrifugal flow is increased. This path is equated with the number of spirals the solids make in the cyclone barrel. Figure 17-51 gives the number of spirals $N_s$ as a function of the maximum velocity in the cyclone. The maximum velocity may be either the inlet or the outlet velocity, depending on the design. The equation for $d_{\text{pth}}$, the theoretical size of a particle collected by the cyclone at 50 percent collection efficiency, is

$$d_{\text{pth}} = \sqrt{\frac{9\mu_g B_c}{\pi N_s v_{\max}(\rho_p - \rho_g)}} \tag{17-17}$$

This equation is a result of the residence time theory of particle collection. In this theory, the time that it takes for a particle to reach the wall is balanced by the time that a particle spends in the cyclone. The particle size that makes it to the wall by the time that it exits the cyclone is the particle size collected at 50 percent collection efficiency, $d_{\text{pth}}$.

When consistent units are used, the particle size calculated by Eq. (17-17) will be in either meters or feet. The equation contains the effects of cyclone size, gas velocity, gas viscosity, gas density, and particle density of the solids. In practice, a design curve such as that given in Fig. 17-52 uses $d_{\text{pth}}$ as the size at which 50 percent of solids of a given size are collected by the cyclone. The material entering the cyclone is divided into fractional sizes, and the collection efficiency for each size is determined. The total low loading efficiency of collection is the sum of the product of the individual collection efficiencies of the cuts, $E_{oi}$, and the weight fraction of the cuts.

Equation (17-17) for $d_{\text{pth}}$ applies for very dilute systems, usually on the order of 1 gr/ft$^3$, or 2.3 g/m$^3$ where 1 gr = (1/7000) lb. When denser flows of solids are present in the inlet gas, cyclone efficiency increases dramatically. This is thought to be due to the coarse particles carrying a large percentage of the finer particles along with them in their interstices as they flow to the wall of the cyclone. Other explanations are that the solids have a lower drag coefficient or tend to agglomerate in multiparticle environments, thus effectively becoming larger particles. At very high inlet solids loadings, it is believed the gas simply cannot hold that much solid material in suspension at high centrifugal forces, and the bulk of the solids simply "condenses" out of the gas stream.

The phenomenon of increasing efficiency with increasing loading is represented by Fig. 17-53. The initial efficiency of a cyclone operating at low loading ($E_0$) is found on the left, $y$-axis of the chart, and the parametric line is followed to the proper overall solids loading. The efficiency for that cut size is then read from the graph.

A single cyclone can sometimes give sufficient gas–solids separation for a particular process or application. However, solids collection efficiency can usually be enhanced by placing cyclones in series. Cyclones in series are typically necessary for most processes to minimize particulate emissions or to minimize the loss of expensive solid reactant or catalyst. Two cyclones in series are most common, but very often three cyclones in series are used. Some processes even have four stages of cyclones. Cyclones placed

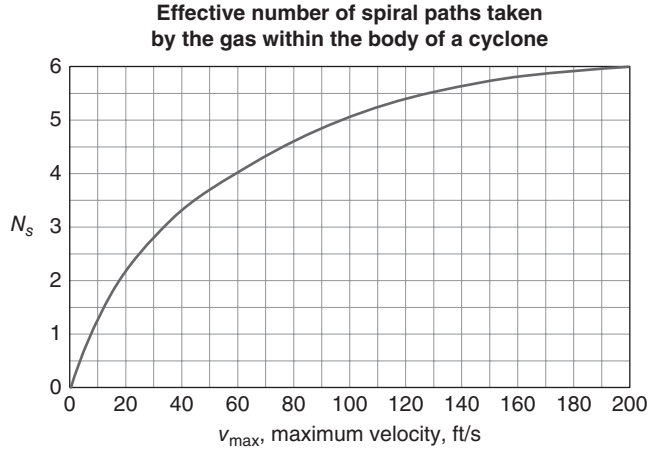

**FIG. 17-51** $N_s$ versus gas velocity, where the larger of either the inlet or outlet gas velocity is used.

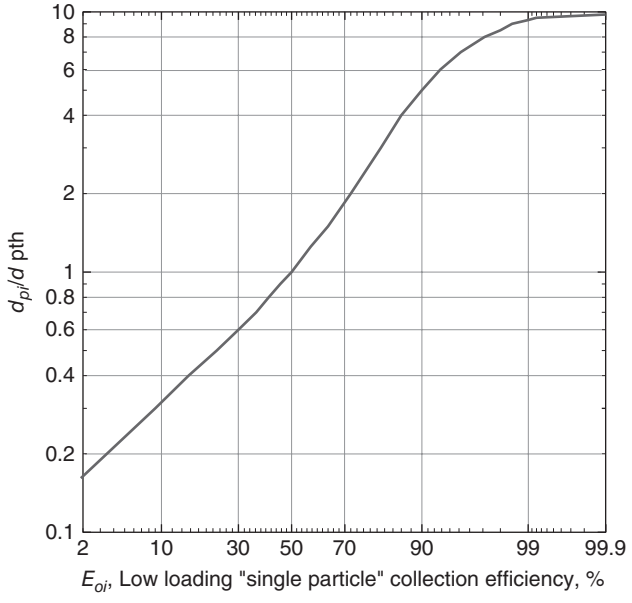

**FIG. 17-52** Low loading ("single particle") cyclone collection efficiency curve. (*Courtesy of PSRI, Chicago.*)

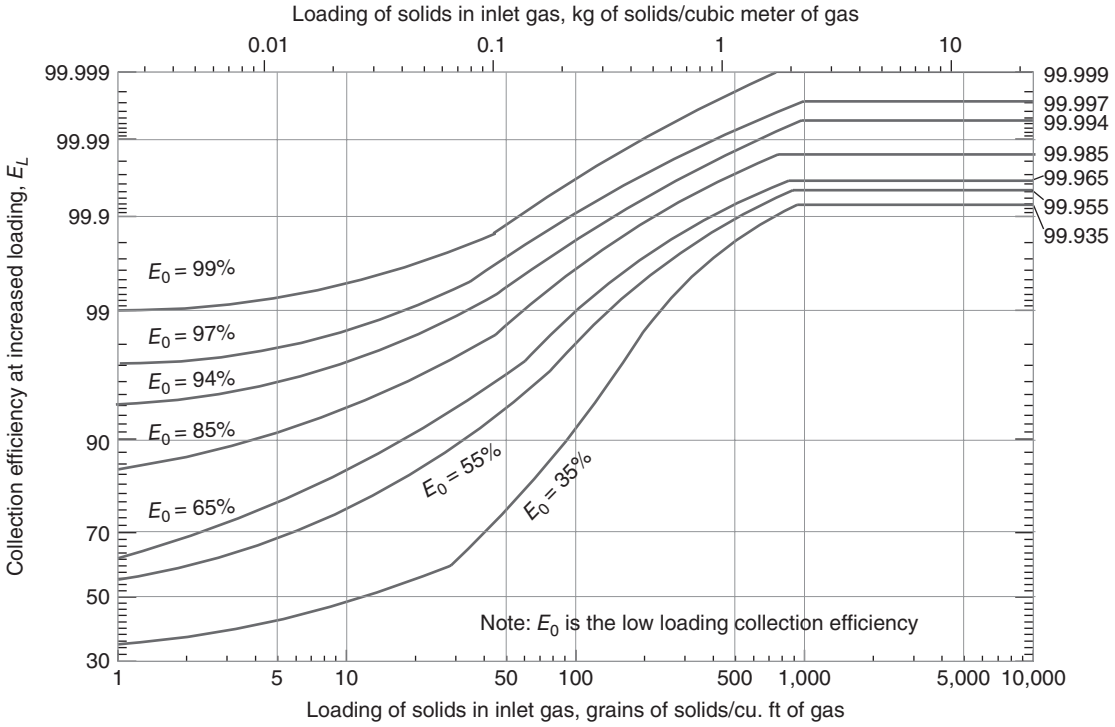

**FIG. 17-53** Effect of inlet solids loading on cyclone collection efficiency. (*Courtesy of PSRI, Chicago.*)

in series can be very efficient. In fluidized catalytic cracking regenerators, two stages of cyclones can give efficiencies of up to and even greater than 99.999 percent.

Typically, first-stage cyclones will have an inlet gas velocity less than that of second-stage cyclones. The lower inlet velocity of first-stage cyclones results in lower particle attrition rates and lower wall erosion rates. After most of the solids are collected in the first stage, a higher velocity is generally used in second-stage cyclones to increase the centrifugal force on the solids and increase collection efficiency. Inlet erosion rates are generally low in the second stage because of the vastly reduced flux of solids into the second-stage cyclone. However, cone erosion rates in second-stage cyclones are much greater than in first-stage cyclones. Cone erosion rates can be most effectively reduced or eliminated by adding a vortex stabilizer to the cyclone cone.

***Pressure Drop*** Cyclone pressure drop can be determined by summing five pressure drop components associated with a cyclone.

1. *Inlet contraction*

$$\Delta p = 0.5\rho_g \left(v_{\text{in}}^2 - v_{\text{vessel}}^2 + K v_{\text{in}}^2\right) \tag{17-18}$$

where $K$ is taken from Table 17-4, and $v_{\text{in}}$ and $v_{\text{vessel}}$ are the velocities in the cyclone inlet duct and the velocity in the freeboard of the reactor vessel, respectively. The area ratios in Table 17-4 are either: (1) the area of the inlet duct to the area of the reactor freeboard, or (2) the cross-sectional area of the gas outlet tube to the cross-sectional area of the cyclone barrel. Using SI units gives the pressure drop in Pa. In U.S. conventional units, the factor of 32.2 for $g$ must be included. This pressure loss is primarily associated with cyclones located in the freeboard of a fluidized bed. If the cyclone is located externally to a vessel and the high-pressure tap used to measure the cyclone pressure drop is in the inlet pipe before the cyclone, the measured pressure drop will generally not include this pressure loss, and this term should not be used to calculate total cyclone pressure drop. However, if the high-pressure tap to measure the cyclone pressure drop is located in the freeboard of the bed, this component will be included in the measured pressure drop, and it should be included in the calculation of the total cyclone pressure drop.

**TABLE 17-4 *K* versus Area Ratio**

| Area ratio | *K* |
|---|---|
| 0 | 0.50 |
| 0.1 | 0.47 |
| 0.2 | 0.43 |
| 0.3 | 0.395 |
| 0.4 | 0.35 |

2. *Particle acceleration*

$$\Delta P = L v_{\text{in}} (v_{p\text{in}} - v_{p\text{vessel}}) \tag{17-19}$$

For small particles, the particle velocity of the solids in the cyclone inlet is taken to be equal to the gas velocity, and $L$ is the solids loading, kg/m$^3$.

3. *Barrel friction* The inlet diameter, $d_{\text{in}}$, is taken to be the hydraulic diameter, which is 4 × (inlet area)/inlet perimeter. Then

$$\Delta P = \frac{2 f \rho_g v_{\text{in}}^2 \pi D_c N_s}{d_{\text{in}}} \tag{17-20}$$

where the Reynolds number for determining the Fanning friction factor, $f$, is based on the cyclone inlet area. Values of $f$ are typically between 0.003 and 0.008.

4. *Gas flow reversal*

$$\Delta P = \frac{\rho_g v_{\text{in}}^2}{2} \tag{17-21}$$

5. *Exit contraction*

$$\Delta p = 0.5\rho_g \left(v_{\text{exit}}^2 - v_c^2 + K v_{\text{exit}}^2\right) \tag{17-22}$$

where $K$ is again determined from Table 17-4 based on the area ratio of the area of the gas outlet tube to the area of the barrel of the cyclone. The total pressure drop is the sum of the five individual pressure drops.

However, the actual pressure drop observed turns out to be a function of the solids loading. The cyclone pressure drop is high when the inlet gas is free of solids and then *decreases* as the solids loading increases up to about 3 kg/m$^3$ (0.2 lb/ft$^3$). This is unusual because adding solids to most flowing gas streams results in an increase of the pressure drop. The cause of the initial decline is that the presence of solids decreases the tangential velocity of the gas [Yuu, *Chem. Eng. Sci.* **33:** 1573 (1978)]. Figure 17-54 gives the actual pressure drop based on the cyclone loading. When solids are absent, the observed pressure drop can be 2.5 times the calculated pressure drop with solids present.

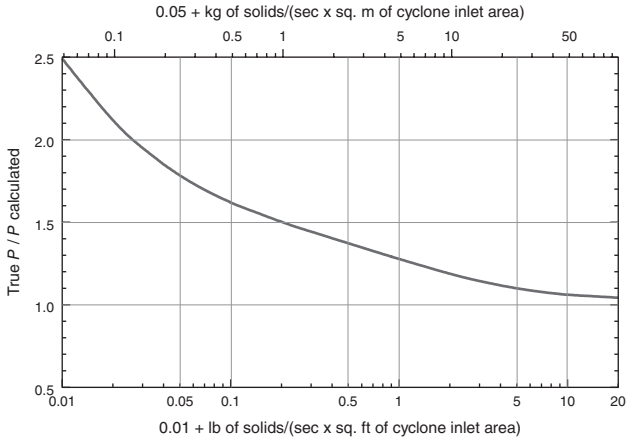

**FIG. 17-54** Effect of cyclone inlet loading on pressure drop. (*Courtesy of PSRI, Chicago.*)

The sum of the pressure drops calculated above is assumed to be at a loading greater than 20 lb/s/ft$^2$ of cyclone inlet area (on the *x*-axis). If the loading is greater than this value, then the pressure drop calculation from adding the five different terms above is correct. However, if the loading is significantly lower (and the pressure drop is higher), then the calculated pressure drop must be multiplied by the value on the *x*-axis in Fig. 17-54 to give the corrected pressure drop. For example, if the inlet solids flux is approximately 1, then the calculated pressure drop should be multiplied by approximately 1.3.

***Scaling Approach*** Theoretically, performance characteristics of a new large cyclone can be estimated using lab test data on a geometrically similar smaller cyclone of the same family. Dimensional analysis has been used to derive relationships for separation efficiency and pressure drop [Hoffman and Stein, *Gas Cyclones and Swirl Tubes—Principles, Design and Operation*, Springer, Berlin, 2002; Svarovsky, *Solid–Gas Separation, Handbook of Powder Technology*, vol. 3, Elsevier, Amsterdam, 1981]. From dimensional analysis, it can be shown that separation efficiency is a function of Reynolds number and Stokes number.

$$\eta(d_p) = f(\mathrm{Re}, \mathrm{Stk}) \tag{17-23}$$

For cut size ($d_{p50}$), the efficiency is 0.5, and Eq. (17-23) can be rewritten as

$$\mathrm{Stk}(d_{p50}) = \frac{(\rho_p - \rho_g) d_{p50}^2 v_{\mathrm{in}}}{18 \mu D_c} = f(\mathrm{Re}) \tag{17-24}$$

Comparison of cyclones of various geometries [Overcamp and Scarlett, *Aerosol Science and Technology* **19:** 362–370 (1993)] suggests that the Stokes number [Stk($d_{p50}$)] is largely independent of Reynolds number $> 2 \times 10^4$, and each design can be assigned a unique value of Stk($d_{p50}$). It implies

$$[\mathrm{Stk}(d_{p50})]_{\text{lab-cyclone}} = [\mathrm{Stk}(d_{p50})]_{\text{field-cyclone}} \tag{17-25}$$

This analysis suggests that the cut size of a larger cyclone in a process can be estimated from a reasonably smaller scale lab unit. This relationship was derived for conventional cyclones with smooth walls and low dust concentrations (<1 g /m$^3$). The effect of loading can be estimated from Smolik's empirical equation (Svarovksy, *Solid–Gas Separation Handbook of Powder Technology*, vol. 3, Elsevier, Amsterdam, 1981):

$$\eta(c_1) = 1 - (1 - \eta(c_1)) \left( \frac{c_1}{c_2} \right)^{0.182} \tag{17-26}$$

The Euler number is used to relate pressure losses in a process unit to characteristic velocity.

***Qualitative Trends*** The separation efficiency has been found to:

- Increase with an increase in inlet velocity
- Increase with an increase in particle specific gravity
- Increase with an increase in solids loading
- Increase with a decrease in gas temperature
- Increase with a decrease in cyclone diameter
- Increase with an decrease in gas outlet diameter (vortex finder)
- Increase with an increase in particle residence time in cyclone

***Cyclone Design Factors*** Cyclones are sometimes designed to meet specified pressure drop limitations. For ordinary installations, operating at approximately atmospheric pressure, fan limitations generally dictate a maximum allowable pressure drop corresponding to a cyclone inlet velocity in the range of 8 to 30 m/s (25 to 100 ft/s). Consequently, cyclones are usually designed for an inlet gas velocity of 15 to 20 m/s (50 to 65 ft/s), although there are exceptions where the inlet gas velocity would be required to be lower and higher than indicated in this range.

Because of the relatively high gas velocities at the inlet of cyclones, particle attrition in fluidized-bed systems is generally dominated by the attrition produced in the cyclone. In some catalytic systems with very expensive catalysts, the economics of the process can be dependent on low attrition losses. In such cases, reducing the inlet velocity of the cyclone will significantly reduce the attrition losses in the process. To compensate for the reduction in inlet velocity, the exit gas velocity will generally be increased (by reducing the diameter of the outlet tube) in order to maintain high cyclone efficiencies. Reducing the outlet tube diameter increases the outlet gas velocity and increases the velocity in the vortex of the cyclone (and the centrifugal force in the vortex), increasing collection efficiency. However, as the vortex velocity is increased, its length is also increased. Therefore, care must be taken to ensure that the cyclone is long enough to contain the increased vortex length. If it is not, the vortex can extend far into the cone and can entrain solids flowing on the sides of the cone as it comes near them.

***Cyclone Roughness*** Large weld beads and other factors can also reduce cyclone efficiency. If the solids flow along the wall of a cyclone encounters a large protuberance such as a weld bead, the weld bead acts as a type of "ski jump" and causes the solids to be deflected farther into the center of the cyclone, where they can be thrown into the vortex and carried out of the cyclone. In small pilot or research cyclones, this is especially common, because the distance between the wall of the cyclone and the vortex tube is very small. Because of their detrimental effect on cyclone efficiency, weld beads should be ground off to make the cyclone inner wall smooth.

In high-temperature processes, cyclones are often lined with refractory to both minimize heat loss and protect the metal surfaces from abrasion. These refractory surfaces are not as smooth as metal, but after a few days of operation, the refractory becomes smoother because of the abrasive action of the solids.

With very small laboratory or pilot cyclones, some solids (large polymer beads, spherical particles, etc.) can sometimes bounce off the cyclone wall immediately across from the cyclone inlet and be deflected into the vortex. Very large particles can be found in the gas outlet stream of the cyclone with these very small cyclones and with particles that bounce. To increase cyclone efficiency with these types of solids, the cyclone barrel diameter can be increased. This increases the distance between the cyclone vortex and the wall and prevents most of the solids from bouncing back into the vortex.

Theoretically, a primary design factor that can be used to control collection efficiency is the cyclone diameter. A smaller-diameter unit operating at a fixed pressure drop generally has a higher efficiency than a larger-diameter cyclone [Anderson, *Chem. Metall.* **40:** 525 (1933); Drijver, *Wärme* **60:** 333 (1937); and Whiton, *Power* **75:** 344 (1932); *Chem. Metall.* **39:** 150 (1932)]. In addition, smaller-diameter cyclones have a much smaller overall length. Small-diameter cyclones, however, will require multiple units in parallel to give the same capacity as a large cyclone. In such cases, the smaller cyclones generally discharge the dust into a common receiving hopper [Whiton, *Trans. Am. Soc. Mech. Eng.* **63:** 213 (1941)]. However, when cyclones discharge into a common hopper, there is a tendency of the gas to produce "cross-talk." This occurs when the gas exiting from one small cyclone passes up the exit of an adjoining cyclone, thus reducing efficiency. Various types of mechanical devices are generally added to the bottom of these small cyclones in parallel to reduce the cross-talk. The final cyclone design involves a compromise between collection efficiency and the complexity of the equipment. It is customary to design systems for a single cyclone for a given capacity, resorting to multiple parallel units only if the predicted collection efficiency is inadequate for a single unit or single units in series.

Reducing the gas outlet diameter should increase both collection efficiency and pressure drop. To exit the cyclone, gas must enter the cyclonic flow associated with the outlet tube. If the outlet diameter is reduced, the outlet vortex increases in length to compensate. Therefore, when the outlet area is less than the inlet area, the length of the cyclone must increase. Too short a cyclone is associated with erosion of the cone and reentrainment of solids into the exit flow. Table 17-5 gives the required increase in cyclone length as a function of outlet-to-inlet area. The cyclone length is measured centrally along an "extended vortex," a cylinder 10 cm larger in diameter than the inner diameter of the outlet tube, to prevent interference with the cone. If the cone interferes with this extended vortex, the cyclone must be lengthened.

As previously discussed, theoretically a smaller-diameter cyclone should be able to collect smaller particles because it can develop a higher centrifugal force. However, using smaller cyclones generally means that many have

**TABLE 17-5 Required Cyclone Length as a Function of Area Ratio**

| $A_{out}/A_{in}$ | Length below outlet tube/$D_c$ |
|---|---|
| >1.0 | 2.0 |
| 0.8 | 2.2 |
| 0.6 | 2.6 |
| 0.4 | 3.2 |

to be used in parallel to accommodate large gas flows. The problem with parallel cyclones (as indicated above) is that it is difficult to get even distribution of solids into all the cyclones. If maldistribution occurs, this can cause inefficiencies that can negate the natural advantage of the smaller cyclones.

Cyclone diameters can be very large. Perhaps the largest cyclones are those used in circulating fluidized-bed combustors, where cyclone diameters approach or exceed 10 m. Large-diameter cyclones also result in very long cyclones, and so these large-diameter, long-length cyclones are really not feasible as internal cyclones in fluidized beds (they make the vessel too tall).

The minimum cone angle of the cyclone should be 60°. It is generally much greater (usually 70° to 75°), with steeper cone angles appropriate to materials that are more cohesive. The cyclone inlet is almost always rectangular (more efficient at getting material to the wall). In any case, the projection of the inlet flow path should never strike the wall of the outlet tube. This means that the inlet width of a cyclone should always be less than the distance between the wall and the outside diameter of the outlet tube. If a very heavy solids loading is anticipated, the barrel diameter should be increased slightly to minimize solids interference with the outlet gas tube.

Collection efficiency is normally increased by increasing the gas throughput [Drijver, *Wärme* **60:** 333 (1937)]. However, if the entering dust is agglomerated, high gas velocities may cause breakup of the agglomerated solids in the cyclone, so efficiency remains the same or actually decreases. Also, variations in design proportions that result in increased collection efficiency with dispersed dusts may be detrimental with agglomerated dusts. Kalen and Zenz [*Am. Inst. Chem. Eng. Symp. Ser.* **70**(137): 388 (1974)] report that collection efficiency increases with increasing gas inlet velocity up to a minimum tangential velocity at which dust is either reentrained or not deposited because of saltation. Koch and Licht [*Chem. Eng.* **84**(24): 80 (1977)] estimate that for typical cyclones the saltation velocity is consistent with cyclone inlet velocities in the range of 15 to 27 m/s (50 to 90 ft/s). Lapple (private communication) reports that in cyclone tests with talc dust, collection efficiency increased steadily as the inlet velocity was increased up to a maximum of 52 m/s (170 ft/s). With ilmenite dust, which was much more strongly flocculated, efficiency decreased over the same inlet velocity range. In later experiments with well-dispersed talc dust, collection efficiency continued to increase at inlet velocities up to the maximum used, 82 m/s (270 ft/s).

Another effect of increasing the cyclone inlet gas velocity is that friable materials may disintegrate (or attrit) as they hit the cyclone wall at high velocity. Thus, the increase in efficiency associated with increased velocity may be more than lost due to the generation of fine attrited material that the cyclone cannot collect. High inlet gas velocities in a primary cyclone can also lead to erosion of the cyclone where the solids in the inlet stream hit the wall.

Cyclones can be either placed in the freeboard above the fluidized bed or located outside of the fluidized-bed vessel. There are advantages and disadvantages to each type of placement, and the optimum type of placement depends on what is best for a particular process.

Internal cyclones have the advantages that they require no inlet piping (their inlets can be open to the freeboard), they require no high-pressure shell, and they normally have straight cyclone diplegs. Internal cyclones are generally smaller in diameter than external cyclones because their size is limited by the headspace available in the freeboard above the fluidized bed. These size limitations generally result in using several smaller cyclones in parallel instead of one large cyclone. However, it is difficult to aerate second-stage cyclone diplegs (generally an advantageous technique) when internal cyclones are used. Aerating secondary cyclone diplegs can improve the operation of the diplegs significantly.

The advantages of external cyclones are that (1) they can be much larger than internal cyclones, (2) they are more accessible than internal cyclones, and (3) their diplegs can be aerated more easily. The primary disadvantage of external cyclones is that they require a pressure shell.

***Cyclone Inlets*** The design of the cyclone inlet can greatly affect cyclone performance. It is generally desired to have the width of the inlet, $B_c$, be narrow so that the entering solids will be as close as possible to the cyclone wall where they can be collected. However, narrow inlet widths require that the height of the inlet $H$ be very long in order to give an inlet area required for the desired inlet gas velocities. Therefore, a balance between narrow inlet widths and the length of the inlet height has to be struck. Typically, low-loading cyclones (cyclones with inlet loadings less than approximately 2 to 5 kg/m$^3$) have height/width ratios, $H/B_c$, of between 2.5 and 3.0. For high-loading cyclones, this inlet aspect ratio can be increased to as high as 7 or so with the correct design. Such high inlet aspect ratios require that the cyclone barrel length increase.

A common cyclone inlet is a rectangular tangential inlet with a constant area along its length. This type of inlet is satisfactory for many cyclones, especially those operating at low solids loadings. However, a better type of inlet is one in which the inner wall of the inlet is angled toward the outer cyclone wall at the cyclone inlet. This induces solids momentum toward the outer wall of the cyclone. The bottom wall of this inlet is angled downward so that the area decrease along the inlet flow path is not too rapid and acceleration is controlled. In addition, the entire inlet can be angled slightly downward to give enhanced efficiencies. This type of inlet is superior to the constant-area tangential inlet, especially for higher solids loadings (greater than 2 to 5 kg/m$^3$).

Hugi and Reh [*Chem. Eng. Technol.* **21**(9): 716–719 (1998)] report that continuous acceleration of the solids throughout the inlet is desired for improved efficiency, and that the angled inlet previously described achieves this. If the momentum of the solids is sufficient and the solids are continuously accelerating along the length of the inlet, the stable, coherent strand important for high collection efficiencies is produced.

The best type of inlet for high solids loadings is the volute cyclone inlet. At high inlet loadings (above approximately 2 to 3 kg/m$^3$) in a *tangential* cyclone inlet, the gas–solids stream expands rapidly from its minimum width at the point of contact. This rapid expansion disturbs the laminar gas flow around the gas outlet tube and causes flow separation around the tube. At some loadings, the inlet stream can expand to such an extent that the solids can hit the gas outlet tube. Both effects result in lowered cyclone efficiency. However, when a volute inlet is used, the expanding solids stream is farther from the gas outlet tube and enters at an angle so that the solids do not induce as much flow separation or asymmetric flow around the gas outlet tube. Therefore, cyclone efficiency is not affected to as great a degree. If a tangential cyclone is used at high solids loadings, an extra distance between the gas outlet tube and the cyclone wall should be designed into the cyclone to prevent the solids from striking the gas outlet tube. At low solid loadings, the solids do not hit the gas outlet tube. Because tangential cyclone inlets are less expensive than volute inlets, the tangential cyclone is often typically used for low loadings, and the volute inlet cyclone is used for high loadings.

The nature of the gas solids flow in the inlet ducting to the cyclone can affect cyclone efficiency significantly. If the solids in the inlet salt out on the bottom and result in dune formation and the resulting unsteady or pulsing flow, cyclone efficiency is adversely affected. To minimize the possibility of this occurring, it is recommended that the inlet line to the cyclone operate above the saltation velocity (Gauthier et al., in *Circulating Fluidized Bed Technology III,* ed. Basu, Horio, and Hasatani, Pergamon Press, Oxford, 1990, pp. 639–644), which will prevent the solids from operating in the dune or pulsing flow regime. If this is not possible, then the inlet line can be angled downward (approximately 15° to 20°) to let gravity assist in the flow of the solids. Keeping the inlet line as short as possible can also minimize any pulsing of the solids flow.

The presence of bends before and in close proximity to the cyclone inlet can be beneficial or detrimental, depending on the orientation of the bend. A bend that turns in the opposite direction from the gas entering the cyclone will decrease the collection efficiency since it concentrates the solids away from the cyclone wall at the inlet.

***Discharge Outlet*** A cyclone will operate equally well on the suction or pressure side of a fan. One of the greatest causes of poor cyclone performance is the leakage of air into the dust outlet of the cyclone. A slight air leak at this point can result in a tremendous drop in collection efficiency, particularly with fine dusts. For batch operation, an airtight hopper or receiver may be used. For continuous withdrawal of collected dust from a hopper, a rotary star valve, a double-lock valve, or a screw conveyor may be used. The size of the outlet at the bottom of the hopper or receiver should be large enough to prevent flow impediment due to upward air leakage.

For continuous solids flow operation, mechanical trickle and flapper valves at the end of cyclone diplegs can also be used for continuous withdrawal into fluidized beds or into the freeboard of fluidized beds. Open-ended diplegs simply immersed into a fluidized bed can be used in cases where start-up losses are not excessive, and they are the simplest type of discharge system for returning solids into a fluidized bed (see Solids Discharge in the subsection Fluidized-Bed Systems).

***Solids Loading Range*** Cyclones can collect solids over a wide range of loadings. Traditionally, solids loadings have been reported as either kilograms of solids per cubic meter of gas (kg/m$^3$), or as kilograms of solids per kilogram of gas (kg$_s$/kg$_g$). However, loading based on mass is probably not

the best way to report solids loadings for cyclones. This is so because the volume of solids processed by a cyclone at the same mass loading can vary greatly, depending on the density of the solids. For example, many polymers have a bulk density of approximately 400 kg/m$^3$, and iron ore has a bulk density of approximately 2400 kg/m$^3$. This difference is a factor of 6. Therefore, a cyclone operating with polymer would have to process six times the volume of solids that a cyclone operating with iron ore would process at the same mass loading. If the cyclone operating with the polymer were designed to operate at high loadings on a mass basis, it could plug. In addition, the diplegs below the cyclone operating with the polymer may experience operational problems because of the high volumetric loading.

At ambient conditions, cyclones have been operated at solids loadings as low as 0.002 kg/m$^3$ (0.00125 kg/kg) and as high as 64 kg/m$^3$ (50 $kg_s/kg_g$). This is a factor of 32,000. In general, cyclone efficiency increases with increasing solids loading. This is so because at higher loadings, very fine particles are trapped in the interstices of the larger particles, and this entrapment increases the collection efficiency of the small particles. Even though collection efficiencies are increased with increased loading, cyclone loss rates are also increased as loading is increased. This is so because the cyclone efficiency increase is almost always less than the efficiency due to the increase in the solids loading.

A heavy chain suspended from the gas outlet duct has been found to be beneficial to minimize dust buildup on the cyclone walls in certain circumstances. Such a chain should be suspended from a swivel so that it can rotate without twisting. Substantially all devices that have been reported to reduce pressure drop do so by reducing spiral velocities in the cyclone chamber and consequently result in reduced collection efficiency.

A cyclone will operate as well in a horizontal position as in a vertical position. However, departure from the normal vertical position results in an increasing tendency to plug the dust outlet line. If the dust outlet becomes plugged, collection efficiency will, of course, be low. If the cyclone exit duct must be reduced to tie in with proposed duct sizes, the transition should be made at least three pipe diameters downstream from the cyclone outlet and preferably after a bend. In the event that the transition must be made closer to the cyclone, a Greek cross can be installed in the transition piece to avoid excessive pressure drop.

***Cyclone Length*** As described previously, the cyclone length should be great enough to contain the vortex below the gas outlet tube. It is generally advisable to have the cyclone somewhat longer than required so that modifications to the gas outlet tube can be made in the future if required. Either the barrel or the cone can be increased in length to contain the vortex. However, cyclone barrels can be made too long. If the barrel is too long, the rotating spiral of solids along the wall can lose its momentum. When this happens, the solids along the wall can be reentrained into the rotating gas in the barrel, and cyclone efficiency will be reduced.

Hoffman et al. [*AIChE J.* **47**(11): 2452–2460 (2001)] studied the effect of cyclone length on cyclone efficiency and showed that the efficiency of a cyclone increases with length. However, they also found that after a certain length, cyclone efficiency decreased. They reported that cyclone efficiency suddenly decreased after a certain cyclone length, which in their cyclone was at a length-to-diameter ratio of 5.65, although recent tests at PSRI with larger cyclones have shown no reduction in cyclone efficiency at length-to-diameter ratios of 7. Hoffman et al. also reported that cyclone pressure drop decreased with increasing cyclone length. This probably occurs for the same reason that cyclone pressure drop decreases with increasing cyclone loading. For long cyclones, the increased length of the cyclone wall results in a longer path for the gas to travel. This creates greater resistance to the flow of the gas in the cyclone (much as a longer pipe produces greater resistance to gas flow than a shorter pipe) that results in reducing the tangential velocity in the cyclone and, therefore, the cyclone pressure drop.

***Commercial Equipment and Operation*** Simple cyclones are available in a wide variety of shapes ranging from long, slender units to short, large-diameter units. The body may be conical or cylindrical, and entrances may be involute or tangential and round or rectangular.

Some of the special types of commercial cyclones are shown in Fig. 17-55. In the multiclone, a spiral motion is imparted to the gas by annular vanes, and it is furnished in multiple units of 15.2- and 22.9-cm (6- and 9-in) diameter. Its largest field of application has been in the collection of fly ash from steam boilers.

In some cyclones, the roof is helically shaped. This is done to ensure that the rotating solids stream does not collide with the inlet solids stream. Axial cyclones make use of the annular inlet vanes as discussed for multiclones. The spiral, or volute, inlet adds solids more gradually to the cyclone. This type of inlet is a better inlet for high-loading cyclones because it minimizes any interaction of the solids with the inlet solids stream.

In addition to the conventional reverse-flow cyclones, some use is made of uniflow, or straight-through, cyclones, in which the gas and solids discharge at the same end (Fig. 17-56 in a vertical position and in Fig. 17-55

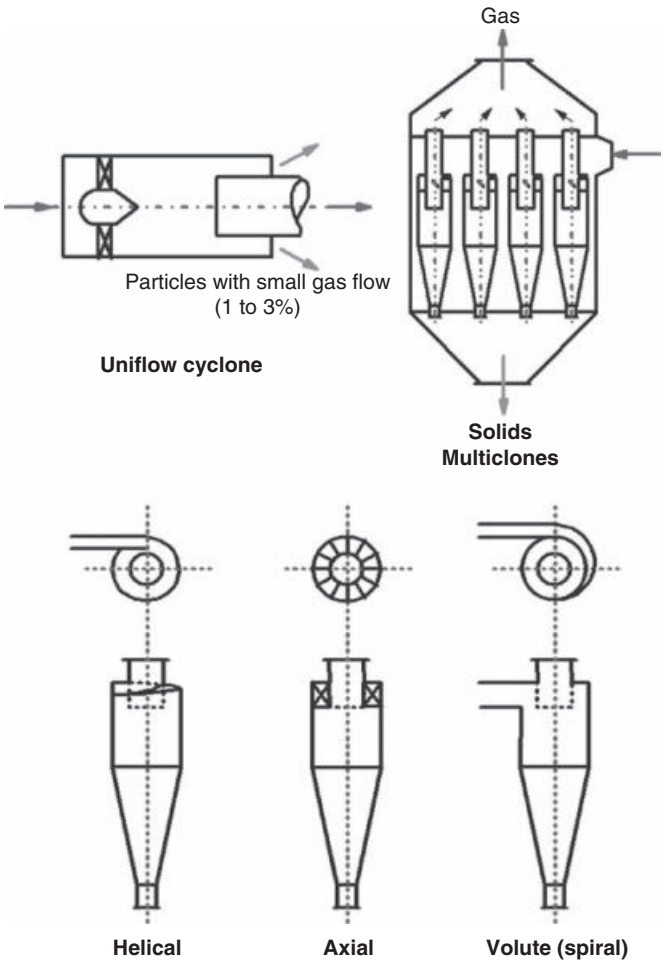

**FIG. 17-55** Different types of cyclone designs. (*Courtesy of PSRI, Chicago.*)

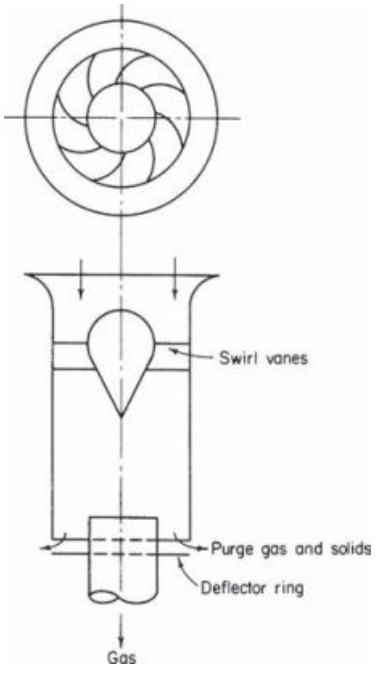

**FIG. 17-56** Uniflow cyclone. [*Ter Linden,* Inst. Mech. Eng. J., ***160,*** *233* (*1949*).]

in a horizontal position). These devices generally act as concentrators; the concentrated dust, together with the inlet gas, is discharged at the periphery, while the clean gas passes out through the center tube. The straight-through cyclones are usually designed into multiple-tube units. They are also used to try to minimize the residence time of gas and solids to limit unwanted reactions.

Most processes operate at high temperatures and/or high pressures. Therefore, it is important to know how cyclones operate at these conditions. Efficient cyclones can collect very small particles sizes. Therefore, cyclone efficiency is proportional to $1/d_{pth}$.

$$E_0 \propto \frac{1}{d_{pth}} = \sqrt{\frac{\pi N_s U(\rho_p - \rho_g)}{9\mu B_c}} \tag{17-27}$$

The effects of temperature and pressure manifest themselves in how they affect the gas density and gas viscosity. From Eq. (17-27), it can be seen that cyclone efficiency is theoretically related to gas density and gas viscosity as

$$E_0 \propto \sqrt{\frac{\rho_p - \rho_g}{\mu}} \tag{17-28}$$

As pressure is increased, gas density will increase. However, the term $(\rho_p - \rho_g)$ does not change with increases in gas density because particle density is so much greater than the gas density (typically about 2000 kg/m$^3$ versus approximately 20 kg/m$^3$ at high pressure) that it dominates this term. Therefore, it is expected that gas density would have a small effect on cyclone efficiency. Conversely, cyclone efficiency would be expected to decrease with system temperature because gas viscosity increases with increasing pressure.

Knowlton and Bachovchin [*Coal Processing Technol.* **4:** 122–127 (1978)] studied the effect of pressure on cyclone performance and found little change in overall cyclone efficiency with pressure over a pressure range from 0 to 55 barg. However, fractional efficiency curves from the same study showed that cyclone efficiency decreased with pressure for particle sizes less than about 20 μm. For particle sizes greater than about 20 μm there was no effect of pressure on cyclone efficiency.

The effect of temperature on cyclone efficiency was studied by both Parker et al. [*J. Environ. Sci. and Technol.* **15**(4): 451 (1981)] and Patterson and Munz [*Canadian J. Chem. Eng.* **67:** 321 (1989)]. Both studies showed that cyclone efficiency decreased with increasing gas viscosity. Similar to the studies at high pressure, Patterson and Munz (1989) reported that only the collection efficiency of particles less than about 10 μm was reduced because of operation at high temperature.

***Troubleshooting*** Key operational issues for cyclones are related to efficiency, pressure drop, and erosive wear. Table 17-6 provides basic guidance on troubleshooting.

**Mechanical Centrifugal Separators** A number of collectors in which the centrifugal field is supplied by a rotating member are commercially available. In the typical unit shown in Fig. 17-57, the exhauster or fan and dust collector are combined as a single unit. The blades are specially shaped to direct the separated dust into an annular slot leading to the collection hopper, while the cleaned gas continues to the scroll. The performance characteristics of the impeller blades are similar to a forward-curve blade fan with a medium pressure range. The concentrated dust suspension in the secondary air circuit enters a sealed collection hopper which serves as a gravity settling chamber. The returning air from the hopper is fed back into the separators. The hopper operates under a slight positive pressure; therefore, an airlock at the hopper outlet is required for continuous discharge of collected dust.

These separators offer a unitized approach for dust separation in exhaust systems for ceramics, chemicals, food products, rubber, plastics, woodworking, grains, and metalworking. They have a compact construction, low pressure drop, low power consumption, minimal maintenance, and can maintain constant airflow regardless of dust loading. For dust streams with large particles or for heavy loading, additional precleaners may be installed to improve efficiency and reduce wear.

Although no comparative data are available, the collection efficiency of units of this type is probably comparable with that of the single-unit, high-pressure-drop-cyclone installation. The clearances are smaller and the centrifugal fields higher than in a cyclone, but these advantages are probably compensated for by the shorter gas path and the greater degree of turbulence with its inherent reentrainment tendency. The chief advantage of these units lies in their compactness, which may be a prime consideration for large installations or plants requiring a large number of individual collectors. Caution should be exercised when trying to apply this type of unit to a dust that shows a marked tendency to build up on solid surfaces because of the high maintenance costs that may be encountered from plugging and rotor unbalancing.

**Particulate Scrubbers** Wet collectors, or scrubbers, form a class of devices in which a liquid (usually water) is used to assist or accomplish the separation of dusts, mist, or fumes from a gas stream. Such devices have been in use for well over 100 years, and innumerable designs have been or are offered commercially or constructed by users. Remarkably, most of the designs are based on the similar fundamental mechanisms of particle capture and removal, and associated energy losses. They collect particulates on droplets, liquid film, or liquid-coated surfaces.

The primary advantages of particle scrubbers (wet collectors) include:

- Both gaseous and particulate contaminants can be removed.
- Suitable for sticky, hygroscopic, combustible, and explosive dust particles.
- Able to process gaseous streams with high humidity or condensable components.
- Suitable for high-temperature gas streams that can be quenched and scrubbed.
- Smaller footprint as compared to dry collectors.
- Constant pressure drop during operation.
- Generally, less expensive than electrostatic precipitators and filter collectors unless a wastewater treatment facility is needed.

Some of the disadvantages are:

- A new process stream (slurry) is generated that must be treated for product recovery or waste treatment. This will adversely affect the process economics.
- Higher energy consumption (operating cost) for fine particle removal.
- Submicron particles are difficult to remove without significant energy expenditure.
- Operational problems, such as fouling, scaling, and corrosion, must be dealt with.
- The scrubbing liquid (water) requires freeze protection in cold climates.

For more detailed discussion, refer to *ASHRAE Handbook 2016*; Cooper, in *Handbook of Powder Science & Technology*, ed. Fayed and Otten, Chapman and Hall, London, 1997; Cooper and Alley, *Air Pollution Control—A Design Approach*, 4th ed., Waveland Press, Long Grove, Ill., 2011; Schifftner and Hesketh, *Wet Scrubbers*, 2d ed., Technomic Pub., Lancaster, Pa., 1996.

***Separation Mechanism*** In particulate scrubbers, the liquid is dispersed into the gas as a spray, and the liquid droplets are the principal collectors for the dust particles. Depending on their design and operating conditions, particulate scrubbers can be adapted to collecting fine as well as coarse particles. Collection of particles by the drops follows the same principles illustrated in Fig. 17-42. Many investigations of the relative contributions of the various mechanisms have led to the conclusion that the predominant mechanism is inertial impaction. Flow-line interception is only a minor mechanism in the collection of the finer dust particles by liquid droplets of the sizes encountered in scrubbers. Diffusion is indicated to be a relatively minor mechanism for the particles larger than 0.1 μm that are of principal concern. Thermal deposition is negligible. Gravitational settling is ineffective because of the high gas velocities and short residence times used in scrubbers. Electrostatic deposition is unlikely to be important except in cases in which the dust particles or the water, or both, are being deliberately charged from an external power source to enhance collection. Deposition produced by Stefan flow can be significant when water vapor is condensing in a scrubber. A similar mechanism is in play when the particles are captured on a liquid film or liquid-coated surfaces in fluidized beds, mobile beds, fibrous beds, and packed-bed scrubbers.

Despite many claims or speculations that wetting of dust particles by the scrubbing liquid plays a major role in the collection process, there is no unequivocal evidence that this is the case. The issue is whether wetting is an important factor in the adherence of a particle to a collecting droplet upon impact. From the body of general experience, it can be inferred that wettable particles probably are not collected much, if any, more readily than nonwettable particles of the same size. However, the available experimental techniques have not been adequate to permit any direct test to resolve the question. Changing from a wettable to a nonwettable test aerosol or from one scrubbing liquid to another is virtually certain to introduce other (and possibly unknown) factors into the scrubbing process. The most informative experimental studies appear to be some by Weber [*Staub,* English trans. **28:** 37 (November 1968); **29:** 12 (July 1969)], who bombarded single drops of various liquids with dust particles at different velocities and studied the behavior at impact by means of high-speed photography. Dust particles hitting the drops were invariably retained by the latter, regardless of their wettability by the liquid used. The use of wetting agents in scrubbing water is equally controversial, and there has been no clear demonstration that it is beneficial. The hypothesis is that wettable particles are ensconced inside the droplet, whereas the nonwettable particles are attached to the surface.

A particulate scrubber may be considered to consist of two stages: (1) a contactor stage, in which a spray is generated and the dust-laden gas stream is brought into contact with it; and (2) an entrainment separation stage, in which the spray and deposited dust particles are separated from

**TABLE 17-6 Troubleshooting Guide for Cyclone Separators**

| Symptom | Possible cause | Solution |
|---|---|---|
| Collection efficiency is lower than expected. | Design basis is wrong. | Verify that the specified design conditions and vendor performance predictions are correct.<br>If higher $\Delta P$ can be provided by the system air mover, and the collection efficiency is close to the desired level, and the dipleg seals can accommodate the higher pressure drops, and erosion and attrition are not a concern, modify cyclone inlet and/or outlet to increase the velocity.<br>Replace the cyclone with a better cyclone. |
| | Gas leakage into the cyclone. | Check and repair any leaks or holes.<br>Check to make sure flange connections are properly gasketed and tight.<br>In pneumatic conveying systems, check and repair feeder valves for proper operation and gas tightness.<br>For a low-loaded cyclone, with a trickle valve at the end of the dipleg, the gas flow up the dipleg may be too high. In this case, immerse the dipleg end into the fluidized bed. |
| | Inlet or outlet ductwork is improperly designed. | Check and repair inlet and/or outlet ductwork if any flow disturbance is induced into the cyclone. |
| | There is an internal obstruction. | Ensure that any access doors are flush and smooth.<br>Ensure that there are no instruments or probes sticking into the cyclone flow stream.<br>If the cyclone is lined, check for and repair any major erosion that causes a sharp edge disturbance to the flow stream.<br>If plugging is occurring, see below. |
| Plugging | Feeder valve is sized improperly for the particulate loading and density. | Resize and replace the feeder valve. |
| | Cyclone discharge diameter or dipleg is too small for the particulate loading and apparent density. | Redesign and replace lower sections. |
| | Dipleg plugs. | Add dipleg purges (although the introduction of purge gas itself can reduce collection efficiency, this is preferable to 0% collection resulting from a plug).<br>Check and repair dipleg discharge valve. |
| | Particulate build up on surfaces. | If caused by condensation, insulate and/or heat trace.<br>Consider non-stick coatings or polished surfaces. If caused by condensation, insulate and/or heat trace.<br>Periodic vibration and/or air cannon. Consider non-stick coatings or polished surfaces.<br>Replace with a cyclone with greater internal clearances, periodic vibration, and/or air cannon.<br>Provide easy access for cleaning and maintenance. Replace with a cyclone with greater internal clearances.<br>If buildup is on the backside of the outlet tube, consider using an eccentric gas outlet to minimize eddy formation. Provide easy access for cleaning and maintenance. |
| Erosion | Cyclone inlet velocity is too high. | Replace the cyclone or modify the inlet so that the inlet velocity is as low as possible. If buildup is on the backside of the outlet tube, consider using an eccentric gas outlet to minimize eddy formation.<br>Reduce the gas flow rate, if possible. Replace the cyclone or modify the inlet so that the inlet velocity is as low as possible.<br>Use a vortex stabilizer to reduce erosion of the cone in low-loading cyclones. Reduce the gas flow rate if possible. |
| | Particulate is abrasive. | Use the lowest possible inlet velocity. Use a vortex stabilizer to reduce erosion of the cone in low-loading cyclones. |
| | Particulate is abrasive. | Add an inside lining to the cyclone made out of an abrasion-resistant material. If a combination of corrosion is occurring with erosion, then the materials of construction must first be corrosion resistant since virtually all materials will abrade away rapidly when in an oxidized state. Use the lowest possible inlet gas velocity.<br>Design the installation and cyclone itself so that worn parts can be replaced and/or repaired as economically as possible. |
| $\Delta P$ is too high | Design basis is wrong. | Verify that specified design conditions and vendor performance predictions are correct. Design the installation and cyclone itself so that worn parts can be replaced and/or repaired as economically as possible.<br>If the high $\Delta P$ is not causing any real problem, leave it alone. The cyclone should be providing higher collection efficiency than specified. Verify that specified design conditions and vendor performance predictions are correct.<br>Modify the air-moving portion of the system to accommodate higher $\Delta P$. If the high $\Delta P$ is not causing any real problem, leave it alone. The cyclone should be providing higher collection efficiency than specified.<br>Enlarge the cyclone inlet or outlet pipe to reduce velocity (note this will reduce the cyclone collection efficiency). Modify the air-moving portion of the system to accommodate higher $\Delta P$.<br>Replace the cyclone. Enlarge the cyclone inlet or outlet pipe to reduce velocity (note this will reduce the cyclone collection efficiency).<br>Check $\Delta P$ instrumentation. Replace the cyclone. |
| | Excess air leaking into upstream ductwork. | Repair ductwork. Check $\Delta P$ instrumentation. |
| $\Delta P$ is too low. | Design basis is wrong. Excess air leaking into upstream ductwork. | Verify that specified design conditions and vendor performance predictions are correct. Repair ductwork. |
| | Design basis is wrong. | If the low $\Delta P$ is not causing any real problem, leave it alone. Verify that specified design conditions and vendor performance predictions are correct.<br>If the cyclone efficiency is too low by a small margin, modify the inlet and/or outlet to increase velocity. If the low $\Delta P$ is not causing any real problem, leave it alone.<br>Increase the gas flow rate to the cyclone. If the cyclone efficiency is too low by a small margin, modify the inlet and/or outlet to increase velocity. |
| | Leaks into the cyclone. | Repair. Increase the gas flow rate to the cyclone.<br>Check $\Delta P$ instrumentation. Repair. |
| | Internal obstruction. | Inspect and clear or repair. Check $\Delta P$ instrumentation. |
| Particle attrition | Inlet gas velocity is too high. Internal obstruction. | Reduce the inlet gas velocity by increasing the inlet area. sInspect and clear or repair. |
| | Inlet gas velocity is too high. | Reduce the inlet gas velocity by increasing the inlet area. |

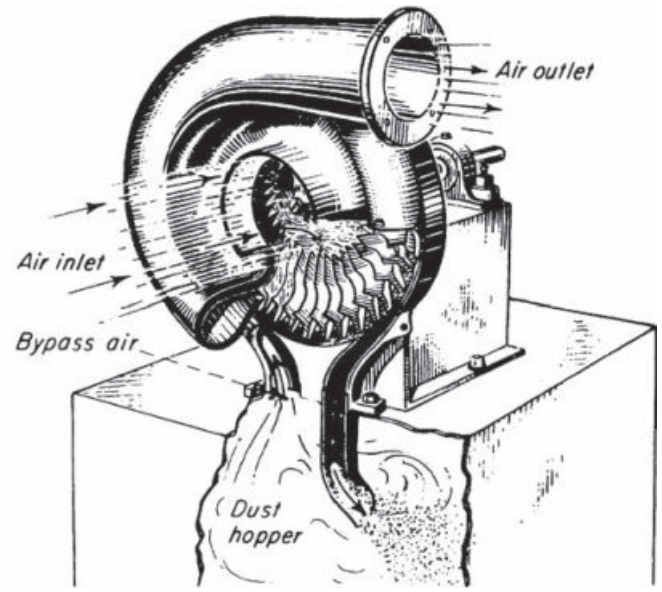

**FIG. 17-57** Typical mechanical centrifugal separator. Type D Rotoclone (cutaway view). (*American Air Filter Co., Inc.*)

the cleaned gas. These two stages may be separate or physically combined. The contactor stage may be of any form intended to bring about effective contacting of the gas and spray. The spray may be generated by the flow of the gas itself in contact with the liquid, by spray nozzles (pressure-atomizing or pneumatic-atomizing), by a motor-driven mechanical spray generator, or by a motor-driven rotor through which both gas and liquid pass. The droplet size is typically between 50 and 500 microns.

***Contactor Stage*** In this zone, the particulates in the dust-laden gas are brought into contact with the liquid (water or slurry) droplets. The velocity difference between the two phases facilitates the impact and capture of particles on the droplets, thereby increasing their effective size. Higher liquid-to-gas ratios increase the probability of impact and capture. There is an optimal size of the droplets as well. While fine droplets will have a higher surface-area-to-volume ratio for better capture, they will have a lower slip velocity, which reduces the probability of impaction. The transition from the dry to the wet zone must be carefully designed to avoid fouling, scaling, and build-up problems. Proper distribution of liquid is critical for low- and medium-pressure scrubber designs.

***Entrainment Separation Stage*** The entrainment separator is a critical element of a scrubber, since the collection efficiency of the scrubber depends on essentially total removal of the spray from the gas stream. The sprays generated in scrubbers are generally large enough in droplet size that they can be readily removed by properly designed inertial separators, which are usually cyclones or impingement separators of various forms. If properly designed, these devices can remove virtually all droplets of the sizes produced in scrubbers.

Primary collection of the spray is seldom the critical limitation on separator performance, but reentrainment is a common problem. Reentrainment of the liquid can take place in poorly designed or overloaded separators. Although the most common cause of reentrainment is simply the use of excessive gas velocities, few data are available on the gas-handling capacities of separators. In the absence of good data, there is a frequent tendency to underdesign separators in an effort to reduce costs.

In dust scrubbers, it is essential that the entrainment separator not be of a form readily subject to blockage by solids deposits, and that it be readily cleared of deposits if they should occur. Cyclone separators are advantageous in this respect and are widely used with venturi contactors. However, they cannot readily be made integral with scrubbers of some other configurations, which can be more conveniently fitted with various forms of impingement separators.

Wet-film collectors logically form a separate subcategory of devices. They comprise inertial collectors in which a film of liquid flows over the interior surfaces, preventing reentrainment of dust particles and flushing away the deposited dust. Wetted-wall cyclones are an example [Stairmand, *Trans. Inst. Chem. Eng.* **29:** 356 (1951)]. Wet-film collectors have not been studied systematically, but they can probably be expected to perform much as do equivalent dry inertial collectors, except for the benefit of reduced reentrainment.

***Scrubber Types and Performance*** The diversity of particulate scrubber designs is so great as to defy any detailed and consistent system of classification based on configuration or principle of operation. However, it is convenient to characterize scrubbers loosely according to prominent constructional features, even though the modes of operation of different devices in a group may vary widely.

The relationship of power consumption to collection efficiency is characteristic of all particulate scrubbers. Attaining increased efficiency requires increased power consumption, and the power consumption required to attain a given efficiency increases as the particle size of the dust decreases. Experience generally indicates that the power consumption required to provide a specific efficiency on a given dust does not vary widely even with markedly different devices. The extent to which this generalization holds true has not been fully explored, but the known extent is sufficient to suggest that the underlying collection mechanism may be essentially the same in all types of particulate scrubbers.

Since some relationship of power consumption to performance appears to be a universal characteristic of particulate scrubbers, it is useful to characterize such devices broadly according to the source from which the energy is supplied to the gas–liquid contacting process. The energy may be drawn from (1) the gas stream itself, (2) the liquid stream, or (3) a motor driving a rotor. For convenience, devices in these classes may be termed, respectively, (1) gas-atomized spray scrubbers, (2) spray, or preformed-spray, scrubbers, and (3) mechanically aided or disintegrator scrubbers. The gas-atomized spray scrubbers include venturi, orifice, impingement-plate, tray (plate), self-induced spray, packed-bed, and mobile-bed scrubbers. Examples of scrubbers with preformed spray are spray, cyclone, ejector venturi, and some baffle-type scrubbers.

Particulate scrubbers may also be classed broadly into low-energy, medium-energy, and high-energy scrubbers (see Table 17-7). The distinction between the classes is arbitrary, since the devices are not basically different and the same device may fall into either class, depending on the amount of power it consumes. However, some differences in configuration are sometimes necessary to adapt a device for high-energy service. Typically, high-energy scrubbers may be regarded as those using sufficient power to give substantial efficiencies on submicrometer particles.

Calvert (*Scrubber Handbook*, 1977) has organized scrubbers into generic categories according to the particle collection mechanisms: plate, packed bed, fiber bed, preformed spray, gas-atomized spray, centrifugal, baffle, impingement-and-entrainment, mechanically aided, moving bed, and combinations. A brief discussion of salient design features and range of operating variables for select scrubbers is included here (see Table 17-8). More details can be found in Calvert [*Chem. Eng.*, (August 29): 54–68 (1977); *Scrubber Selection Guide, Calvert Environmental Equipment* (1988)], Schifftner and Hesketh (*Wet Scrubbers*, 2d ed., Technomic Pub., Lancaster, Pa., 1996); Cooper and Alley (*Air Pollution Control*, 4th ed., Waveland Press, Long Grove, Ill., 2011); L. Theodore (*Air Pollution Control Equipment Calculations*, Wiley, New York, 2008).

***Venturi Scrubbers*** The venturi scrubber is one of the most widely used types of particulate scrubbers. The designs have become generally standardized, and units are manufactured by many companies. Venturi scrubbers may be used as either high- or low-energy devices, but they are most commonly employed as high-energy units. The units originally studied and used were designed to the proportions of the classical venturis used for metering, but since it was discovered that these proportions have no special merits, simpler and more practical designs have been adopted. Most "venturi" contactors in current use are in fact not venturis but variable orifices of one form or another. Any of a wide range of devices can be used, including a simple pipe-line contactor. Although the venturi scrubber is not inherently more efficient at a given contacting power than other types of devices, its simplicity and flexibility favor its use. It is also useful as a gas absorber for relatively soluble gases, but because it is a cocurrent contactor, it is not well suited to absorption of gases having low solubilities.

Current designs for venturi scrubbers generally use the vertical downflow of gas through the venturi contactor and incorporate three features:

**TABLE 17-7 Classification of Scrubbers Based on Energy Consumption and Pressure Drop**

| Class | Energy consumption | Range of pressure drop |
|---|---|---|
| Low energy | <2 kJ/m$^3$ (<1 W/cfm) | 0.25–1.5 kPa (1–6 in WC) |
| Medium energy | 2–6 kJ/m$^3$ (1–3 W/cfm) | 1.5–4.5 kPa (6–18 in WC) |
| High energy | >6 kJ/m$^3$ (>3 W/cfm) | > 4.5 kPa (>18 in WC) |

*ASHRAE Handbook—HVAC Systems and Equipment*, 2016, Chapter 30, "Industrial Gas Cleaning and Air Pollution Control," p. 30.15.

**TABLE 17-8 Comparison of Performance Characteristics of Various Scrubbers**

| Scrubber type | Particle diameter,* μm | Typical collection efficiency, % | Comparative energy requirement† | Gas pressure loss, Pa | Liquid pressure loss, Pa |
|---|---|---|---|---|---|
| Gravity spray | 10 | 70 | 5 | 25–250 | 140–690 |
| Centrifugal | 5 | 90 | 12–26 | 500–2000 | 140–690 |
| Impingement | 5 | 95 | 9–31 | 500–2000 | 140–690 |
| Packed bed | 5 | 90 | 4–34 | 125–2500 | 35–210 |
| Dynamic (mechanically aided) | 2 | 95 | 30–200 | Provides pressure | 35–210 |
| Self-inducted spray | 2 | 90 | 9–21 | 500–1500 | None |
| Jet | 2 | 90 | 15–30 | Provides pressure | 345–610 |
| Venturi | 0.1 | 95–99 | 30–300 | 2500–15000 | 70–210 |

*Adapted from ASHRAE Handbook—HVAC Systems and Equipment, Ch. 30, 2016.*

(1) a "wet-approach" or "flooded-wall" entry section, to avoid dust buildup at a wet/dry junction; (2) an adjustable throat for the venturi (or orifice), to provide for adjustment of the pressure drop; and (3) a "flooded elbow" located below the venturi and ahead of the entrainment separator, to collect large droplets and coarse particles via the impingement mechanism and to reduce wear by abrasive particles. The venturi throat is sometimes fitted with a refractory lining to resist abrasion by dust particles. The entrainment separator is commonly, but not invariably, of the cyclone type. An example of the "standard form" of venturi scrubber is shown in Fig. 17-58.

The scrubbing liquid, which is injected directly at the entrance of the throat or distributed as a liquid film before the entrance, is atomized into droplets by the gas turbulence in the throat region. The wet-approach entry section has made practical the recirculation of slurries. In some designs, supplementary nozzles are used, but they are prone to plugging or wear unless clean liquid is used. Various forms of adjustable throats, which may be under manual or automatic control, permit maintaining a constant pressure drop and constant efficiency under conditions of varying gas flow.

The grade (or fractional) efficiency of venturi scrubbers is affected primarily by throat velocity and liquid-to-gas ratio, and to a much lesser extent by the mode of liquid distribution and the shape of the converging and diverging sections. Calvert [*Chem. Eng.*, (August 29): 54–68 (1977)] suggested that it is a good practice to use high liquid-to-gas ratios rather than high gas velocities to achieve a given cut diameter.

The orifice plate scrubbers can be considered a special case of venturi scrubbers where the throat length is zero. The orifice plate with multiple orifices is irrigated with scrubbing liquid, and the droplets are formed at the edge of an orifice due to shear induced by the gas flow. They can be designed for high- or medium-energy operation.

Venturi scrubbers are used to control particulate emissions from boilers and incinerators and from chemical, mineral products, wood, pulp and paper, rock products, asphalt, lead, aluminum, iron and steel, and grey iron manufacturing industries (*Air Pollution Control Technology Fact Sheet*, EPA-452/F-03-017).

***Ejector-Venturi Scrubbers*** In the ejector-venturi scrubber (Fig. 17-59) the cocurrent water jet from a spray nozzle serves both to scrub the gas and to provide the draft for moving the gas. No fan is required, but the equivalent

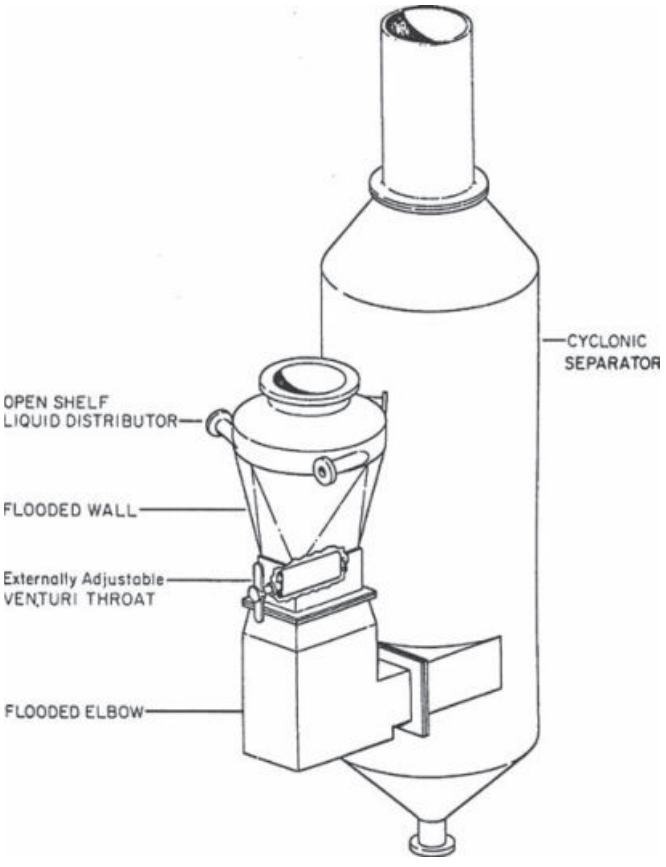

**FIG. 17-58** Venturi scrubber. (*Nepture AirPol.*)

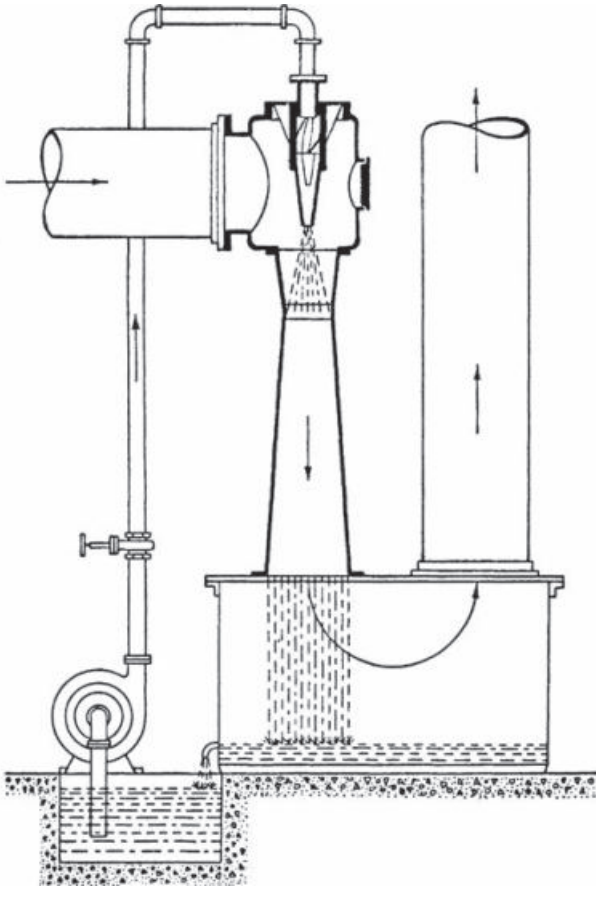

**FIG. 17-59** Ejector-venturi scrubber. (*Schutte & Koerting Division, Amtek, Inc.*)

power must be supplied to the pump that delivers water to the ejector nozzle. The water must be supplied in sufficient volume and at high enough pressure to provide both adequate draft and enough contacting power for the required scrubbing operation. Considered as a gas pump, the ejector is not a very efficient device, but the dissipated energy that is not effective in pumping does serve in gas–liquid contacting. The energy equivalent to any gas pressure rise across the scrubber is not part of the contacting power (Semrau et al., EPA-600/2-77-234, 1974).

The ejector-venturi scrubber is widely used as a gas absorber, but the combinations of water pressure and flow rate that are sufficient to provide the required draft usually do not also yield enough contacting power to give high collection efficiencies on submicrometer particles. Other types of ejectors have been employed to provide higher contacting-power levels. In one, superheated water is discharged through the nozzle, and part flashes to steam, increasing the mechanical energy available for scrubbing [Gardenier, *J. Air Pollut. Control Assoc.* **24:** 954 (1974)]. Some units use two-fluid nozzles, with either compressed air or steam as the compressible fluid [Sparks, *J. Air Pollut. Control Assoc.* **24:** 958 (1974)]. Most of the energy for gas movement and for atomizing the liquid and scrubbing the gas is derived from the compressed air or steam. In some ejector-venturi scrubber installations, part of the draft is supplied by a fan [Williams and Fuller, *TAPPI* **60**(1): 108 (1977)].

***Self-Induced Spray Scrubbers*** Self-induced spray scrubbers form a category of gas-atomized spray scrubbers in which a tube or a duct of some other shape forms the gas–liquid contacting zone. An inverted cone may be placed at the bottom to provide an annular opening that can be adjusted. The gas stream flowing at high velocity through the contactor atomizes the liquid in essentially the same manner as in a venturi scrubber. The dust-laden gas makes a turn through the liquid surface into the central tube or duct. However, the liquid is fed into the contactor and later recirculated from the entrainment separator section by gravity instead of being circulated by a pump as in venturi scrubbers. The scheme is well illustrated in Fig. 17-60*a*. The pressure drop, hence the efficiency, is controlled by the level of the liquid and the annular space between the inverted cone and the tube. A static pool of liquid must be continuously maintained during operation.

A great many such devices using contactor ducts of various shapes, as in Fig. 17-60*b*, are offered commercially. Oftentimes, they are also referred to as orifice scrubbers, gas-induced spray scrubbers, or entrainment scrubbers. Although self-induced spray scrubbers can be built as high-energy units and sometimes are, most such devices are designed for medium to low-energy service.

The principal advantage of self-induced spray scrubbers is the elimination of a pump for recirculation of the scrubbing liquid. However, the designs for high-energy service are somewhat more complex and less flexible than those for venturi scrubbers. The design and maintenance of the sludge removal system is a significant challenge. The industrial applications include food and pharmaceutical processing and packing, and the manufacture of chemicals, rubber, plastics, ceramics, and fertilizers.

***Spray Scrubbers*** Spray scrubbers consist of empty chambers of some simple form in which the gas stream is contacted with liquid droplets generated by spray nozzles. A common form is a spray tower, in which the gas flows upward through a bank or successive banks of spray nozzles. Similar arrangements are sometimes used in spray chambers with horizontal gas flow. Such devices have very low gas pressure drops, and all but a small part of the contacting power is derived from the liquid stream. The required contacting power is obtained from an appropriate combination of liquid pressure and flow rate. All the energy may be supplied from the liquid, using a pressure nozzle, but some or all may also be provided by compressed air or steam in a two-fluid nozzle or by a motor driving a spray generator.

Most spray scrubbers are low-energy units. Collection of fine particles is possible but may require very high liquid-to-gas ratios, liquid feed pressures, or both. Removal efficiencies up to 90 percent for particles larger than 5 μm, 60 to 80 percent for particle size between 3 and 5 μm, and less than 50 percent for particles smaller than 3 μm are typically observed (*EPA Report*, EPA/452/B-02-001-Section 6 Particulate Matter Controls).

Plugging of small nozzles can be a persistent maintenance problem. Plugging on the gas side is rare, so these scrubbers are suitable for streams with high dust loadings. Entrainment separators are necessary to prevent carryover of spray into the exit gas, especially when the superficial velocity exceeds 1 m/s (3.3 ft/s).

***Cyclone Scrubbers*** The vessels of cyclone scrubbers are all in the form of cyclones, which provide for compact integral entrainment separation. The gas–liquid contacting section normally uses some sort of spray generator to disperse liquid throughout the gas. These devices have higher relative velocities between the droplets and the particles compared to simple tray towers, and the efficient capture of droplets due to cyclonic action can improve collection efficiency in certain applications (Calvert, S., and R. Parker, EPA-600/8-78-005c, U.S. EPA, June 1978). Collection efficiencies as high as 95 percent for particles larger than 5 μm and 60 to 75 percent for submicron particles have been reported (EPA Report, EPA/452/B-02-001).

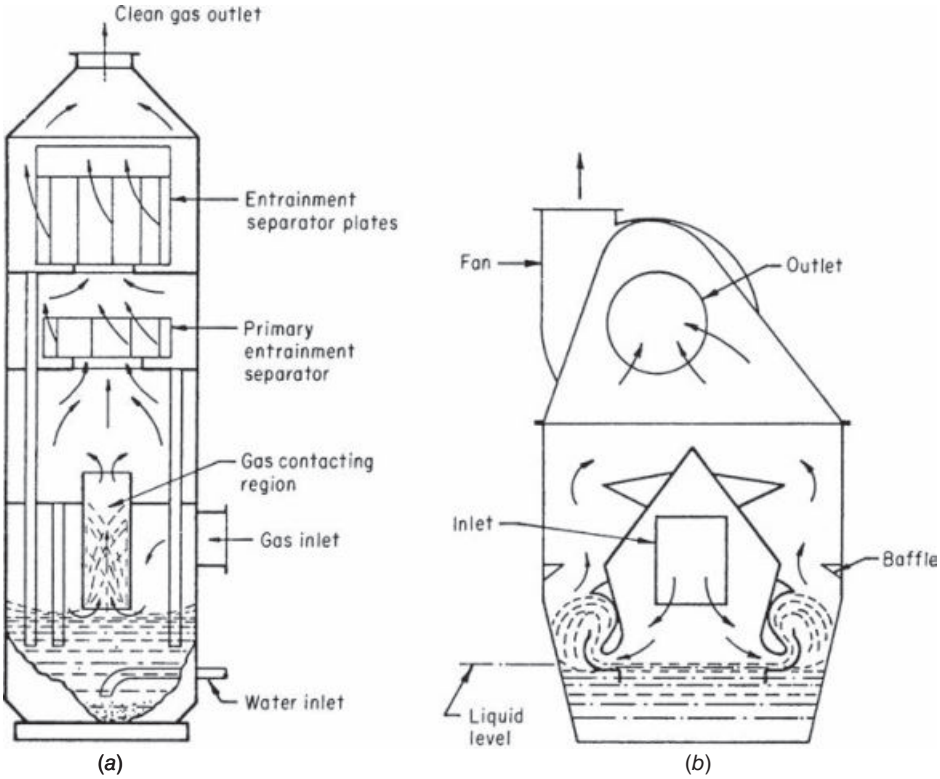

**FIG. 17-60** Self-induced spray scrubbers. (*a*) Blaw-Knox Food & Chemical Equipment, Inc. (*b*) American Air Filter Co., Inc.

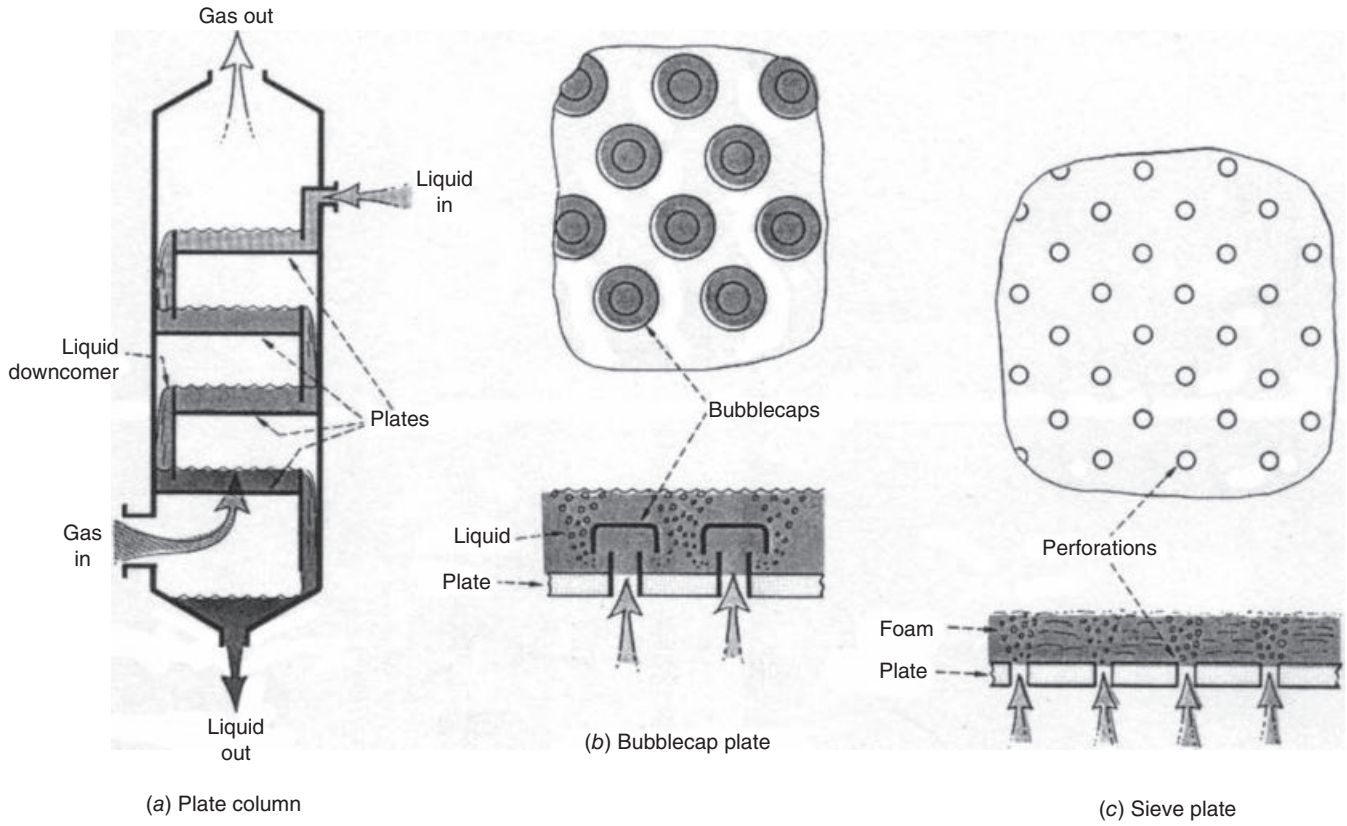

**FIG. 17-61** Plate (tray) scrubber. (Calvert, S., *Chemical Engineering*, p. 54, August 29, 1977.)

***Plate Scrubbers*** Plate (tray) scrubbers are countercurrent gas-atomized spray scrubbers using one or more plates for gas–liquid contacting. They are essentially the same as, if not identical to, the devices used for gas absorption, and are often employed in applications in which gases are to be absorbed simultaneously with the removal of dust. Except possibly in cases in which condensation effects are involved, countercurrent operation is not significantly beneficial in dust collection.

The plates may be any of several types, including sieve, bubble-cap, and valve trays (Fig. 17-61). For sieve trays, the liquid flow into the holes is prevented by the upward flow of dust-laden gas. The gas flow rate must be maintained in a certain range to prevent weeping on the low side and flooding on the high side. The bubble-caps provide an impingement surface that enhances the collection. The impingement surfaces are continuously washed by the liquid. Valve trays constitute multiple self-adjusting orifices that provide a nearly constant gas pressure drop over considerable ranges of variation in gas flow. The gas pressure drop that can be taken across a single plate is necessarily limited, so units designed for high contacting power must use multiple plates. The efficiency of plate scrubbers for particles larger than 5 mm can be as high as 97 percent (Cooper, C.D., and F.C. Alley, *Air Pollution Control: A Design Approach*, Waveland Press, Long Grove, Ill., 2011).

Plate towers are more subject to plugging and fouling than venturi-type scrubbers that have large passages for gas and liquid.

***Packed-Bed Scrubbers*** Packed-bed scrubbers using gas-absorption-type tower packings may also be used for collecting soluble solids, but they are not irrigated intensively enough to avoid plugging by deposits of insoluble solids. Mobile-bed and fiber-bed scrubbers can be self-cleaning if they are adequately flushed.

***Mobile-Bed Scrubbers*** Mobile-bed scrubbers (Fig. 17-62) are constructed with one or more beds of low-density spheres that are free to move between upper and lower retaining grids. The spheres are commonly 1.0 in (2.5 cm) or more in diameter and made from rubber or a plastic such as polypropylene. The plastic spheres may be solid or hollow. Gas and liquid flows are countercurrent, and the spherical packings are fluidized by the upward-flowing gas. The movement of the packings is intended to minimize fouling and plugging of the bed. Mobile-bed scrubbers were first developed for absorbing gases from gas streams that also carry solid or semisolid particles.

The spherical packings are too large to serve as effective targets for the deposition of fine dust particles. In dust-collection service, the packings actually serve as turbulence promoters, while the dust particles are collected primarily by the liquid droplets.

The gas pressure drop through the scrubber may be increased by increasing the gas velocity, the liquid-to-gas ratio, the depth of the bed, the density of the packings, and the number of beds in series. In an experimental study,

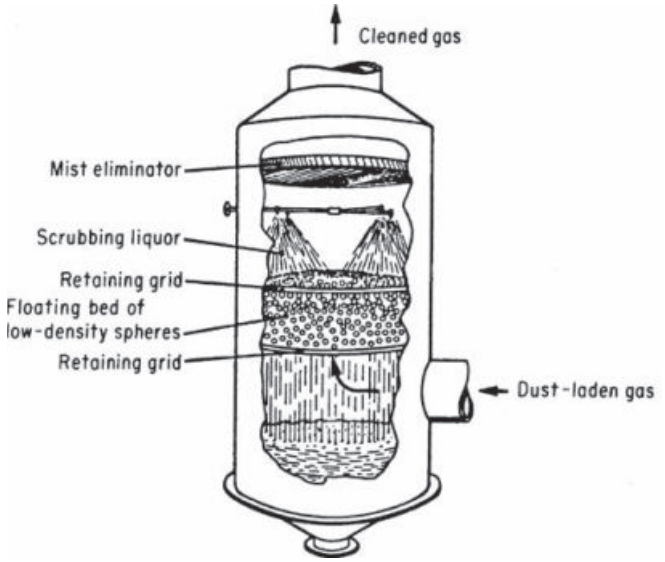

**FIG. 17-62** Mobile-bed scrubber. (*Air Correction Division, UOP.*)

Yung et al. (EPA-600/7-79-071, 1979) determined that the collection efficiency of a mobile-bed scrubber was dependent only on the gas pressure drop and was not influenced independently by the gas velocity, the liquid-to-gas ratio, or the number of beds except as these factors affected the pressure drop. Yung et al. also reported that the mobile-bed scrubber was less efficient at a given pressure drop than scrubbers of the venturi type, but without offering comparable experimental supporting evidence.

***Fiber-Bed Scrubbers*** Fibrous-bed structures are sometimes used as gas–liquid contactors, with cocurrent flow of the gas and liquid streams. In such contactors, both scrubbing (particle deposition on droplets) and filtration (particle deposition on fibers) may take place. If only mists are to be collected, small fibers may be used, but if solid particles are present, the use of fiber beds is limited by the tendency of the beds to plug. For dust-collection service, the fiber bed must be composed of coarse fibers and have a high void fraction, so as to minimize the tendency to plug. The fiber bed may be made from metal or plastic fibers in the form of knitted structures, multiple layers of screens, or random-packed fibers. However, the bed must have sufficient dimensional stability so that it will not be compacted during operation. Fiber-bed scrubbers are not suitable for applications where the dust loading of insoluble solids is high.

Lucas and Porter (U.S. Patent 3,370,401, 1967) developed a fiber-bed scrubber in which the gas and scrubbing liquid flow vertically upward through the fiber bed (Fig. 17-63). The beds tested were composed of knitted structures made from fibers with diameters ranging from 89 to 406 μm. Lucas and Porter reported that the fiber-bed scrubber gave substantially higher efficiencies than venturi-type scrubbers tested with the same dust at the same gas pressure drop. In similar experiments, Semrau et al. (Semrau and Lunn, "Performance of Particulate Scrubbers as Influenced by Gas–liquid Contactor Design and by Dust Flocculation," EPA-600/9-82-005c, 1982, p. 43) also found that a fiber-bed contactor made with random-packed steel wool fibers gave higher efficiencies than an orifice contactor. However, there were indications that the fiber bed would have little advantage in the collection of submicron particles, presumably because of the large fiber size feasible for dust-collection service.

Alliger (U.S. Patents 3,659,402, 1972, and 3,905,788, 1975) describes fiber-bed structures that are not random, but are rather built up from flat mesh sheets offset angularly from one layer to the next and then compressed and bonded. Such bonded beds of relatively coarse hydrophobic fibers both are remarkably flushable, to prevent fouling by insoluble solids, and have surprisingly high collection efficiency per unit pressure drop for submicron particles, approaching that of irrigated fine hydrophobic fiber filters such as those described by Fair (U.S. Patent 3,135,592, 1964) and Vosseller (U.S. Patent 3,250,059, 1966).

***Electrically Augmented Scrubbers*** In some types of wet collectors, attempts are made to apply the electrostatic-deposition mechanism by charging the dust particles, the water droplets, or both. The objective is to combine in one scrubber both the high efficiency for collecting fine particles and the moderate power consumption characteristic of an electrical precipitator. Successful devices of this type have been essentially wet electrical precipitators and should properly be discussed in that category (see the subsection Electrical Precipitators). So far, there has been no clear demonstration of a device that combines the small size, compactness, and high efficiency of a high-energy scrubber with the relatively low power consumption of an electrical precipitator.

***Mechanical Scrubbers*** Mechanical scrubbers or dynamic scrubbers comprise those devices in which a power-driven rotor produces the fine spray and the contacting of gas and liquid. The liquid is injected at the hub of the fan where it is drawn into the rotating blades. In the disintegrator concept, a partially submerged impeller is used to generate the droplets. As in other types of scrubbers, it is the droplets that are the principal collecting bodies for the dust particles. The rotor acts as a turbulence producer. An entrainment separator, such as a cyclonic separator, must be used to prevent carryover of spray. Among potential maintenance problems are unbalancing of the rotor by buildup of dust deposits and abrasion by coarse particles. A precleaner is often used to remove the coarse particles and to reduce the dust loading. These devices are not preferred for high-temperature applications.

The simplest commercial devices of this type are essentially fans upon which water is sprayed. The unit shown in Fig. 17-64 is adapted to light duty, and heavy dust loads are avoided to minimize buildup on the rotor.

***Scrubber Performance Models*** A number of investigators have made theoretical studies of the performance of venturi scrubbers and have sought to produce performance models, based on first principles, that can be used to design a unit for a given duty without recourse to experimental data other than the particle size and size distribution of the dust. Among these workers are Calvert [*Am. Inst. Chem. Eng. J.* **16:** 392 (1970); *J. Air Pollut. Control Assoc.* **24:** 929 (1974)], Boll [*Ind. Eng. Chem. Fundam.* **12:** 40 (1973)], Goel and Hollands [*Atmos. Environ.* **11:** 837 (1977)], Yung et al. [*Environ. Sci. Technol.* **12:** 456 (1978)], Azzopardi et al. [*Filtr. Sep.* **21:** 196 (1984); *Trans. IChemE* **69B:** 237 (1991)], and Hesketh [*Journal of Air Pollution Control Association* **24:** 10 (1974)]. Comparatively few efforts have been made to model the performance of scrubbers of types other than the venturi, but a number of such models are summarized by Yung and Calvert (U.S. EPA-600/8-78-005b, 1978).

The various venturi-scrubber models embody a variety of assumptions and approximations. The solutions of the equations for particulate collection must in general be determined numerically, although Calvert et al. [*J. Air Pollut. Control Assoc.* **22:** 529 (1972)] obtained an explicit equation by making some simplifying assumptions and incorporating an empirical constant that must be evaluated experimentally; the constant may absorb some of the deficiencies in the model. Although other models avoid direct incorporation of empirical constants, the use of empirical relationships is necessary to obtain specific estimates of scrubber collection efficiency. One of the areas of greatest uncertainty is the estimation of droplet size.

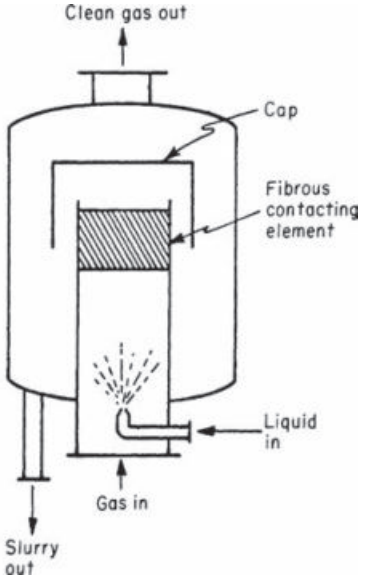

**FIG. 17-63** Fibrous-bed scrubber. (*Lucas and Porter, U.S. Patent 3,370,401, 1967.*)

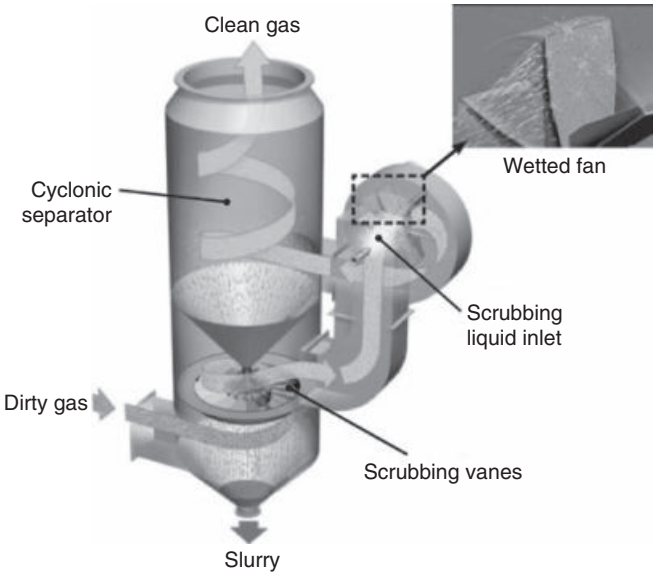

**FIG. 17-64** Mechanical scrubber. (*Courtesy of Nederman Mikropul.*)

Most of the investigators have assumed the effective drop size of the spray to be the Sauter (surface-mean) diameter, and they have used the empirical equation of Nukiyama and Tanasawa [*Trans. Soc. Mech. Eng., Japan,* **5:** 63 (1939)] to estimate the Sauter diameter:

$$D_o = \frac{1920\sqrt{\sigma_L}}{V_o\sqrt{\rho_L/62.3}} + 75.4\left(\frac{\mu_L}{\sqrt{\sigma_L\rho_L/62.3}}\right)^{0.45}\left(\frac{1000Q_L}{Q_G}\right)^{1.5} \qquad (17\text{-}29)$$

where $D_o$ = drop diameter, μm; $V_o$ = gas velocity, ft/s; $\sigma_L$ = liquid surface tension, dyn/cm; $\rho_L$ = liquid density, lb/ft$^3$; $\mu_L$ = liquid viscosity, cP; $Q_L$ = liquid flow rate, ft$^3$/s; and $Q_G$ = gas flow rate, ft$^3$/s.

The Nukiyama-Tanasawa equation, which is not dimensionally homogeneous, was derived from experiments with small, internal-mix pneumatic atomizing nozzles with a concentric feed of air and liquid (Lapple et al., "Atomization: A Survey and Critique of the Literature," Stanford Res. Inst. Tech. Rep. No. 6, AD 821-314, 1967; Lapple, "Atomization," in *McGraw-Hill Encyclopedia of Science and Technology,* 5th ed., vol. 1, McGraw-Hill, New York, 1982, p. 858). The effect of nozzle size on the drop size is undefined. Even within the range of parameters for which the relationship was derived, the drop sizes reported by various investigators have varied by twofold to threefold from those predicted by the equation [Boll, *Ind. Eng. Chem. Fundam.* **12:** 40 (1973)]. The Nukiyama-Tanasawa equation has, nevertheless, been applied to large venturi and orifice scrubbers with configurations radically different from those of the atomizing nozzles for which the equation was originally developed.

Primarily because of the lack of adequate experimental techniques (particularly, the production of appropriate monodisperse aerosols), there has been no comprehensive experimental test of any of the venturi-scrubber models over wide ranges of design and operating variables. The models for other types of scrubbers appear to be essentially untested.

The pressure drop across venturi scrubbers is generally expressed as:

$$\Delta P = KV_t^2\rho_g\left(\frac{Q_L}{Q_G}\right) \qquad (17\text{-}30)$$

where $V_t$ = throat velocity and $K$ is design specific.

***Contacting Power Correlation*** A scrubber design method that has achieved wide acceptance and use is based on correlation of the collection efficiency with the power dissipated in the gas–liquid contacting process, which is termed "contacting power." The method originated from an investigation by Lapple and Kamack [*Chem. Eng. Prog.* **51:** 110 (1955)] and has been extended and refined in a series of papers by Semrau and coworkers [*Ind. Eng. Chem.* **50:** 1615 (1958); *J. Air Pollut. Control Assoc.* **10:** 200 (1960); **13:** 587 (1963); U.S. EPA-650/2-74-108, 1974; U.S. EPA-600/2-77-234, 1977; *Chem. Eng.* **84**(20): 87 (1977); and "Performance of Particulate Scrubbers as Influenced by Gas–Liquid Contactor Design and by Dust Flocculation," EPA-600/9-82-005c, 1982, p. 43]. Other workers have made extensive independent studies of the correlation method [Walker and Hall, *J. Air Pollut. Control Assoc.* **18:** 319 (1968)], and numerous studies of narrower scope have been made. The major conclusion from these studies is that the collection efficiency of a scrubber on a given dust is essentially dependent only on the contacting power and is affected to only a minor degree by the size or geometry of the scrubber or by the way in which the contacting power is applied. This contacting-power rule is strictly empirical, and the full extent of its validity has still not been explored. It has been best verified for the class of gas-atomized spray scrubbers, in which the contacting power is derived from the gas stream and takes the form of gas pressure drop. Tests of the equivalence of contacting power supplied from the liquid stream in pressure spray nozzles have been far less extensive and are strongly indicative but not yet conclusive. Evidence for the equivalence of contacting power from mechanically driven devices is also indicative, but extremely limited in quantity.

Contacting power is defined as the power per unit of volumetric gas flow rate that is dissipated in gas–liquid contacting and is ultimately converted to heat. In the simplest case, in which all the energy is obtained from the gas stream in the form of pressure drop, the contacting power is equivalent to the friction loss across the wetted equipment, which is termed *effective friction loss*, $F_E$. The pressure drop may reflect kinetic-energy changes rather than energy dissipation, and pressure drops that result solely from kinetic-energy changes in the gas stream do not correlate with performance. Likewise, any friction losses taking place across equipment that is operating dry do not contribute to gas–liquid contacting and do not correlate with performance. The gross power input to a scrubber includes losses in motors, drive shafts, fans, and pumps that obviously should be unrelated to scrubber performance.

The effective friction loss, or "gas-phase contacting power," is easily determined by direct measurements. However, the "liquid-phase contacting power," supplied from the stream of scrubbing liquid, and the "mechanical contacting power," supplied by a mechanically driven rotor, are not directly measurable; the theoretical power inputs can be estimated, but the portions of these quantities effectively converted to contacting power can only be inferred from comparison with gas-phase contacting power. Such data as are available indicate that the contributions of contacting power from different sources are directly additive in their relation to scrubber performance.

Contacting power is variously expressed in units of MJ/1000 m$^3$ (SI), kWh/1000 m$^3$ (meter-kilogram-second system), and hp/(1000 ft$^3$/min) (U.S. customary). Relationships for conversion to SI units are

$$1.0\ \text{kWh}/1000\ \text{m}^3 = 3.60\ \text{MJ}/1000\ \text{m}^3$$

$$1.0\ \text{hp}/(1000\ \text{ft}^3/\text{min}) = 1.58\ \text{MJ}/1000\ \text{m}^3$$

The gas-phase contacting power, $P_G$, may be calculated from the effective friction loss by the following relationships:

SI units:

$$P_G = 1.0F_E \qquad (17\text{-}31)$$

where $F_E$ = kPa.

U.S. customary units:

$$P_G = 0.1575F_E \qquad (17\text{-}32)$$

where $F_E$ = in of water.

The power input from a liquid stream injected with a hydraulic spray nozzle may usually be taken as approximately equal to the product of the nozzle feed pressure, $p_F$, and the volumetric liquid rate. The liquid-phase contacting power, $P_L$, may then be calculated from the following formulas:

SI units:

$$P_L = 1.0p_F(Q_L/Q_G) \qquad (17\text{-}33)$$

where $p_F$ = kPa gauge, and $Q_L$ and $Q_G$ = m$^3$/s.

U.S. customary units:

$$P_L = 0.583p_F(Q_L/Q_G) \qquad (17\text{-}34)$$

where $p_F$ = lb$_f$/in$^2$ gauge, $Q_L$ = gal/min, and $Q_G$ = ft$^3$/min.

The correlation of efficiency data is based on the total contacting power, $P_T$, which is the sum of $P_G$, $P_L$, and any power $P_M$ that may be supplied mechanically by a power-driven rotor.

In general, the liquid-to-gas ratio does not have an influence independent of contacting power on the collection efficiency of scrubbers of the venturi type. This is true at least of operation with liquid-to-gas ratios above some critical lower value. However, several investigations [Semrau and Lunn, "Performance of Particulate Scrubbers as Influenced by Gas–Liquid Contactor Design and by Dust Flocculation," EPA-600/9-82-005c, 1982, p. 43; and Muir et al., *Filtr. Sep.* **15:** 332 (1978)] have shown that at low liquid-to-gas ratios, relatively poor efficiencies may be obtained at a given contacting power. Such regions of operation are obviously to be avoided.

It has sometimes been asserted that multiple gas–liquid contactors in series will give higher efficiencies at a given contacting power than will a single contacting stage. However, there is little experimental evidence to support this contention. Lapple and Kamack [*Chem. Eng. Prog.* **51:** 110 (1955)] obtained slightly higher efficiencies with a venturi and an orifice in series than they did with a venturi alone. Muir and Mihisei [*Atmos. Environ.* **13:** 1187 (1979)] obtained somewhat higher efficiencies on two redispersed dusts when using two venturis in series rather than one. The improvement obtained with two-stage scrubbing was greatest with the coarser of the two dusts and was relatively small with the finer dust. Flocculation or deflocculation of the dusts may have been responsible for some of the behavior encountered. Semrau et al. (EPA-600/2-77-234, 1977) compared the performance of a four-stage, multiple-orifice contactor with that of a single-orifice contactor, using well-dispersed aerosols generated from ammonium fluorescein. The multiple-orifice contactor gave about the same efficiency as the single-orifice in the upper range of contacting power, but lower efficiencies in the lower range. The deviations in performance in this case were probably characteristic of the particular multiple-orifice contactor rather than of multistage contacting as such.

Most scrubbers actually incorporate more than one stage of gas–liquid contacting even though these may not be identical (e.g., the contactor and the entrainment separator). The preponderance of evidence indicates that multiple-stage contacting is not inherently either more or less efficient than single-stage contacting. However, two-stage contacting may have practical benefits in dealing with abrasive or flocculated dusts.

Some investigators have proposed, mostly on the basis of mathematical modeling, to optimize the design of scrubbers to obtain a given efficiency with a minimum power consumption [e.g., Goel and Hollands, *Atmos. Environ.* **11:** 837 (1977)]. In fact, no optimum in performance appears to exist; so long as increased entrainment is prevented, increased contacting power yields increased efficiency.

***Scrubber Performance Curves*** The scrubber performance curve, which shows the relationship of scrubber efficiency to the contacting power, has been found to take the form

$$N_t = \alpha P_T^{\gamma} \tag{17-35}$$

where $\alpha$ and $\gamma$ are empirical constants that depend primarily on the aerosol (dust or mist) collected. In a log-log plot of $N_t$ versus $P_T$, $\gamma$ is the slope of the performance curve and $\alpha$ is the intercept at $P_T = 1$. Figure 17-65 shows such a performance curve for the collection of coal fly ash by a pilot-plant venturi scrubber (Raben "Use of Scrubbers for Control of Emissions from Power Boilers," United States–U.S.S.R. Symposium on Control of Fine-Particulate Emissions from Industrial Sources, San Francisco, 1974). The scatter in the data reflects not merely experimental errors but actual variations in the particle-size characteristics of the dust. Because the characteristics of an industrial dust vary with time, the scrubber performance curve necessarily must represent an average material, and the scatter in the data is often greater than is shown in Fig. 17-65. For best definition, the curve should cover as wide a range of contacting power as possible. Obtaining the data thus requires pilot-plant equipment with the flexibility to operate over a wide range of conditions. Because scrubber performance is not greatly affected by the size of the unit, it is feasible to conduct the tests with a unit handling no more than 170 $m^3$/h (100 $ft^3$/min) of gas. Davis (*Air Pollution Engineering Manual*, 2d ed., Wiley, 2000) has summarized values of empirical constants $\alpha$ and $\gamma$ for various scrubbing applications.

A clear interpretation of $\gamma$, the slope of the curve, is still lacking. Presumably, it should be related to the particle-size distribution of the dust. Because scrubbing preferentially removes the coarser particles, the fraction of the dust removed (or the increment of $N_t$) per unit of contacting power should decrease as the contacting power and efficiency increase, so that the value of $\gamma$ should be less than unity. In fact, the value of $\gamma$ has been less than unity for most dusts. Nevertheless, some data in the literature have displayed values of $\gamma$ greater than unity when plotted on the transfer-unit basis, indicating that the residual fraction of dust became more readily collectible as contacting power and efficiency increased. More recent studies by Semrau et al. (EPA-650/2-74-108 and EPA-600/2-77-237) have revealed performance curves having two branches (typified by Fig. 17-66), the lower having a slope greater than unity and the upper a slope less than unity. This suggests that had the earlier tests been extended into higher contacting-power ranges, performance curves with flatter slopes might have appeared in those ranges.

Among the aerosols that gave performance curves with $\gamma > 1$, the only obvious common characteristic was that a large fraction of each was composed of submicron particles.

The manufacturers can provide performance curves for their scrubber designs based on lab and operational data (see Figs. 17-67 and 17-68). These are essentially grade efficiency curves, as discussed previously. The overall collection efficiency can be calculated by integrating it with the particle-size distribution of the incoming dust.

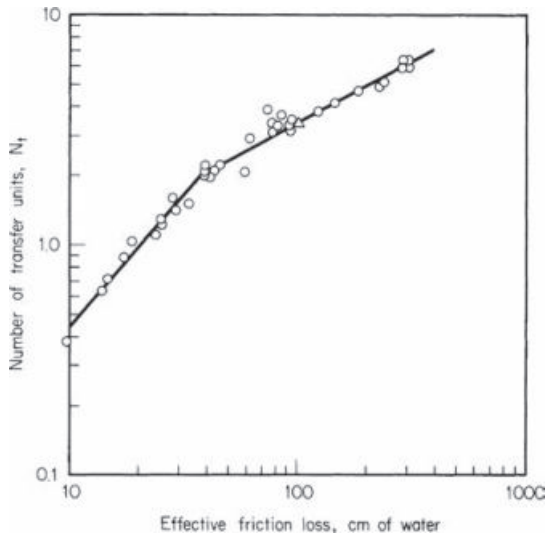

**FIG. 17-66** Performance curve for orifice scrubber collecting ammonium fluorescin aerosol. (*Semrau et al. EPA 600/2-77-237, 1977.*)

***Cut-Power Correlation*** Another design method, also based on scrubber power consumption, is the cut-power method of Calvert [*J. Air Pollut. Control Assoc.* **24:** 929 (1974); *Chem. Eng.* **84**(18): 54 (1977)]. Since most scrubbers collect particles by inertial impaction, the relationship between penetration $(1 - \eta)$ and the aerodynamic size can be modeled by

$$Pt_i = e(-Ad_a^B) = \frac{c_o}{c_i} \tag{17-36}$$

where $Pt_i$ = particle penetration for $i$th fraction, $d_a$ = aerodynamic particle size, $c_o$ = outlet particle concentration, and $c_i$ = inlet particle concentration (g/$m^3$). $A$ and $B$ are empirical constants. The overall efficiency can be calculated by integrating the penetration of individual size fractions with the size distribution. Calvert suggests that the value of $B$ for gas-atomizing, packed-bed and plate-type scrubbers is 2.0, whereas it is 0.7 for centrifugal cyclonic scrubbers. A value of 2.0 can be assumed for all practical purposes. Calvert further proposed fitting the aerodynamic particle-size distribution data to a log-normal distribution, which can be functionally represented by the mass median diameter ($d_{pg}$) and geometric standard deviation ($\sigma_g$). Integrated values of penetration are plotted in Fig. 17-69 as a function of cut-ratio ($d_{RC}/d_{pg}$); where $d_{RC}$ is the required cut diameter. The required cut diameter can be estimated based on the desired overall collection efficiency and inlet particle-size distribution.

The cut diameter (the particle diameter for which the collection efficiency is 50 percent) as a function of the gas pressure drop or of the power input per unit of volumetric gas flow rate for various scrubbers is shown in Fig. 17-70. The functional relationship is presented as a log-log plot of the cut diameter versus the pressure drop (or power input). In principle, the function could be constructed by experimentally determining scrubber performance curves for discrete particle sizes and then plotting the particle sizes against the corresponding pressure drops necessary to give efficiencies of 50 percent. In practice, Calvert and coworkers have in most cases constructed the cut-power functions for various scrubbers by modeling (Yung and Calvert, U.S. EPA-600/8-78-005b, 1978). They show a variety of curves, whereas empirical studies have indicated that different types of scrubbers generally have about the same performance at a given level of power consumption.

***Condensation Scrubbing*** The collection efficiency of scrubbing can be increased by the simultaneous condensation of water vapor from the gas stream. Water-vapor condensation assists in particle removal by two entirely different mechanisms. One is the deposition of particles on cold-water droplets or other surfaces as the result of Stefan flow. The other is the condensation of water vapor on particles as nuclei, which enlarges the particles and makes them more readily collected by inertial deposition on droplets. Both mechanisms can operate simultaneously. However, for the buildup of particles by condensation to be effective, there must be adequate time for the particles to grow substantially before the principal gas–liquid contacting operation takes place. Hence, if particle buildup is to be sought, the scrubber should be preceded by an appropriate gas-conditioning section. On the other hand, particle collection by Stefan flow can be induced

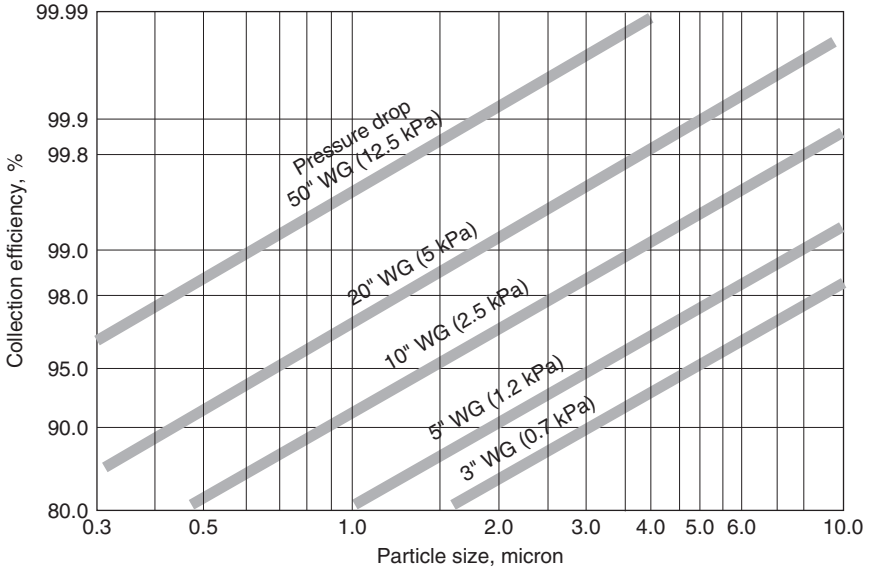

**FIG. 17-67** Typical scrubber performance curve provided by manufacturer.

simply by scrubbing the hot, humid gas with sufficient cold water to bring the gas below its initial dew point. Any practical method of inducing condensation on the dust particles will incidentally afford opportunities for the operation of the Stefan-flow mechanism. The hot gas stream must, of course, have a high initial moisture content, since the magnitude of the effects obtained is related to the quantity of water vapor condensed.

Although there is a considerable body of literature on particle collection by condensation mechanisms, most of it is either theoretical or, if experimental, treats basic phenomena in simplified cases. Few studies have been made to determine what performance may be expected from condensation scrubbing under practical conditions in industrial applications. In a series of studies, Calvert and coworkers investigated several types of equipment for condensation scrubbing, generally emphasizing the use of the condensation center effect to build up the particles for collection by inertial deposition (Calvert and Parker, EPA-600/8-78-005c, 1978). From early estimates, they predicted that a condensation scrubber would require only about one-third or less of the power required by a conventional high-energy scrubber. A subsequent demonstration-plant scrubber system consisted of a direct-contact condensing tower fed with cold water followed by a venturi scrubber fed with recirculated water (Chmielewski and Calvert, EPA-600/7-81-148, 1981). The condensation and particle buildup took place in the cooling tower. In operation on humidified iron-foundry-cupola gas, this system still required about 65 percent as much power as for conventional high-energy scrubbing.

Semrau and coworkers [*Ind. Eng. Chem.* **50:** 1615 (1958); *J. Air Pollut. Control Assoc.* **13:** 587 (1963); EPA-650/2-74-108, 1974] investigated condensation scrubbing in pilot-plant studies in the field and, later, under laboratory conditions. Hot, humid gases were scrubbed directly with cold water under conditions that were favorable for the Stefan-flow mechanism but offered little or no opportunity for particle buildup. Some of the field studies indicated a contacting-power saving of as much as 50 percent for condensation scrubbing of Kraft-recovery-furnace fume. Laboratory tests on a predominantly submicrometer synthetic aerosol showed contacting-power savings of up to 40 percent with condensation scrubbing.

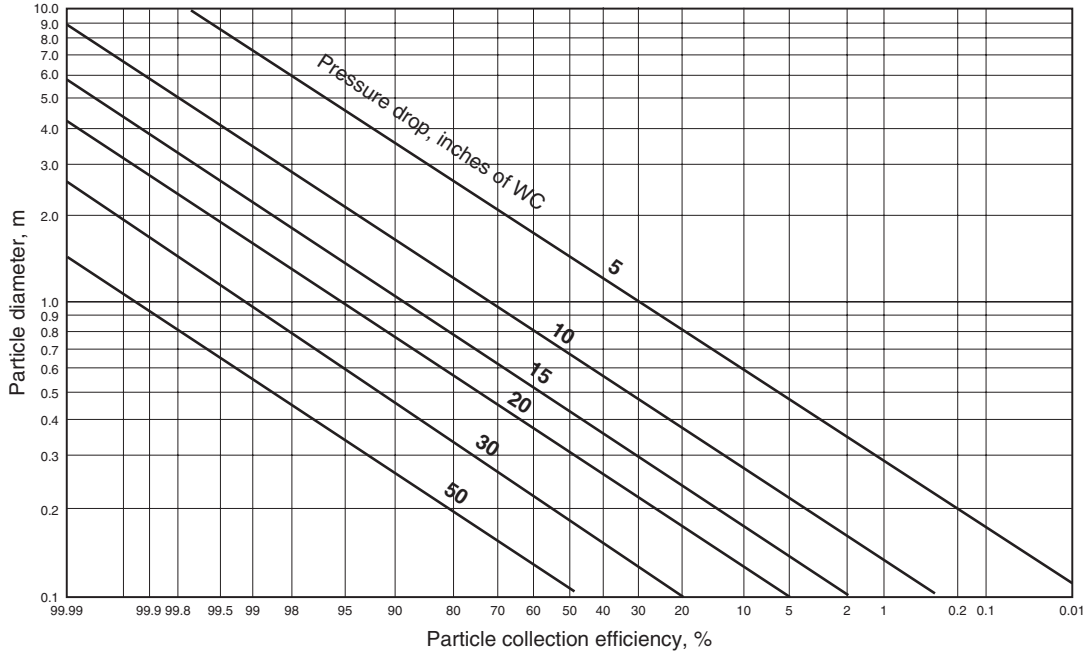

**FIG. 17-68** Performance characteristics of a venturi scrubber.

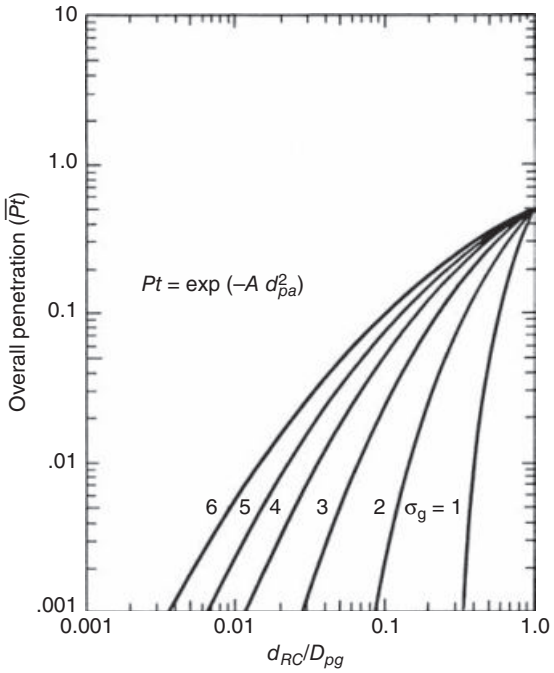

**FIG. 17-69** Performance characteristic for scrubbers ($B = 2.0$). [*Calvert, Chem. Eng., 84* (*18*), *54* (*1977*).]

In the scrubbing of hot gases with high water content, condensation reduces contacting power and affords a direct power saving through the reduction of the gas volume by cooling and water-vapor condensation, but it incurs other costs for power and equipment for heat transfer and water cooling. However, condensation scrubbing may offer a net economic advantage if recovery of low-level heat is practical. It should also be advantageous when a hot gas must not only be cleaned but cooled and dehumidified as well; examples are the cleaning of blast-furnace gas for use as fuel and of $SO_2$-bearing waste gases for feed to a sulfuric acid plant.

**Fabric Filters** Fabric filters, commonly termed "bag filters" or "baghouses," are collectors in which dry particles are removed from the gas stream by passing the dust-laden gas through a filter medium of some type (e.g., woven cloth, felt, paper or porous membrane). The filter media can be flexible (bags or envelops), semirigid (cartridges), or rigid (ceramic/metal cartridges).

Fabric filters are chosen as gas–solid separation equipment when used as:

1. Pollution control devices where health and safety are concerned
2. In-process applications to separate solids from a gas (e.g., pneumatic conveying systems)

The performance requirements for these two applications are very different. The inlet dust loading for pollution control devices is typically low (<80 g/m$^3$), and the operation can be intermittent. In-process applications may require continuous operation where operational reliability and product recovery are of prime concern. Fabric filters can be used as standalone units or in conjunction with precleaners (e.g., cyclones) to reduce dust loading.

Because of their inherently high efficiency with dusts in all particle-size ranges, fabric filters have been used as primary gas cleaning equipment for the collection of fine dusts and fumes for over 100 years. Some of the key advantages over alternate technologies, such as wet scrubbers or electrostatic precipitators, are:

*a.* Infinite turndown ratio.
*b.* Almost complete collection for particles larger than 2 μm.
*c.* Solids are collected in a dry state.
*d.* Works with a wide range of particle sizes.
*e.* Collection efficiency is insensitive to particle properties or process upsets.

Limitations:

*a.* High-temperature applications: The greatest limitation on filter application has been imposed by the temperature limits of available fabric materials. The upper limit for natural fibers is about 90°C (200°F). The major new developments in filter technology that have been made since 1945 have followed the development of fabrics made from glass and synthetic fibers, which has extended the temperature limits to about 230°C to 260°C (450°F to 500°F). The capabilities of available fibers to resist high temperatures are still among the most severe limitations on the possible applications of fabric filters.

*b.* Presence of liquid droplets, moist and sticky particles will blind the pores of the media and result in an irrecoverable increase in the pressure drop. Fabric filters are not suitable for such applications. To prevent the condensation of vapors in the filter body, the temperature of the gas and all surfaces in contact with the filter media must be kept above the dew point.

*c.* The presence of very fine particles may blind the filter media due to penetration. Special fabrics, such as PTFE membranes, must be used. This will limit the operability window.

*d.* The life of filter media can be severely affected by the abrasive nature of dust, the presence of alkaline or acidic components in gas, or high operating temperatures. The long-term operability must be taken into consideration with the factors we have described.

***Mechanism of Separation*** These devices are "surface" filters in that dust collects in a layer on the surface of the filter medium, and the dust layer itself becomes the effective filter medium. The pores in the medium (particularly in woven cloth) are usually many times the size of the dust particles, so collection efficiency is low until enough particles have been collected to build up a "precoat" in the fabric pores (Billings and Wilder, *Handbook of Fabric Filter Technology,* vol. I, EPA No. APTD-0690, NTIS No. PB-200648, 1979). During this initial period, particle deposition takes place mainly by inertial and flow-line interception, inertial deposition, diffusion, and electrostatic attrition. The agglomerates of fine particles can bridge over openings as large as 10 times the particle diameter, thereby creating a layer of dust upon which subsequent particles deposit. Some of the fine particles penetrate into the fabric during the initial phase (clean media) of cake deposition, and they continue to increase in amount over the life of the filter. Once the dust layer (or dust cake) has been fully established, sieving or depth filtration becomes the dominant mechanism. The pressure drop is largely incurred by gas flow through the dust cake, which acts as a compressible packed bed. The thickness of the dust cake continues to build until the cleaning cycle is initiated.

The process of dust removal on a fabric filter is inherently a batch process. The dust cake is attached to the filter media by adhesive forces, and it is held together with cohesive forces. These forces must be overcome to break the cake and dislodge it from the filter media. All cleaning mechanisms are functionally designed to overcome the adhesion and cohesion. The nature of the cake upon detachment and the extent of cleanliness of the filter after a cleaning cycle will depend on the forces generated during the cleaning cycle. Starting from a clean medium, the removal of particles after each cycle is not 100 percent—the cleaning leaves a small amount of fines adhered to the filter medium. The residual fines amount eventually reaches an equilibrium, and the filter is assumed to be conditioned with a stable pressure drop after the cleaning cycle. Since the filtration mechanism changes with time of operation, the concept of grade efficiency is not suitable for fabric filters. The overall collection efficiency is usually very high after the initial dust layer has been deposited. The lowest efficiencies during operation are observed during start-up, during and immediately after the cleaning cycle, and with problems with media integrity or leakage due to improper installation.

***Classification of Fabric Filters (or Baghouses)*** Fabric filters can be broadly classified as static or fixed filters and regenerative or cleanable filters. The static filters are usually discarded after one-time use and are not expected to be cleanable. An inlet cartridge filter for a blower is a typical example. The majority of fabric filters in process industries are the cleanable type, where the dust burden on the filter is maintained at an equilibrium by periodic cleaning. Fabric filters or baghouses must be evaluated as a *unit operation* where the gas flow patterns, dust distribution, gas–solid separation at the filter interface, cake filtration, cake adhesion/cohesion, and reentrainment of dust are key factors influencing the performance. The performance metrics include pressure drop, collection efficiency, life of filter media, capital cost, and operating cost. A wide array of designs has evolved over the past 100 years as the range of applications has grown. The key differentiating features for various design categories are as follows:

*Location of deposited dust:* Interior or exterior surface of the filter bag (see Fig. 17-71)

*Cleaning mechanisms:* Shaker, reverse air, pulse (reverse air pulse, pulse jet) and acoustic

*Direction of gas flow:* Upflow (countercurrent to the separated dust), downflow, and cross-flow (see Fig. 17-71)

*Mode of operation:* Batch, intermittent, continuous

*Filter media type:* Bags/envelopes, cartridges (paper, felt, ceramic, sintered metal), rigid media made with sintered polymer

The most common approach is to categorize by the method of cleaning. Certain design features are feasible only in select combinations of other features, which allow the narrowing down of design choices.

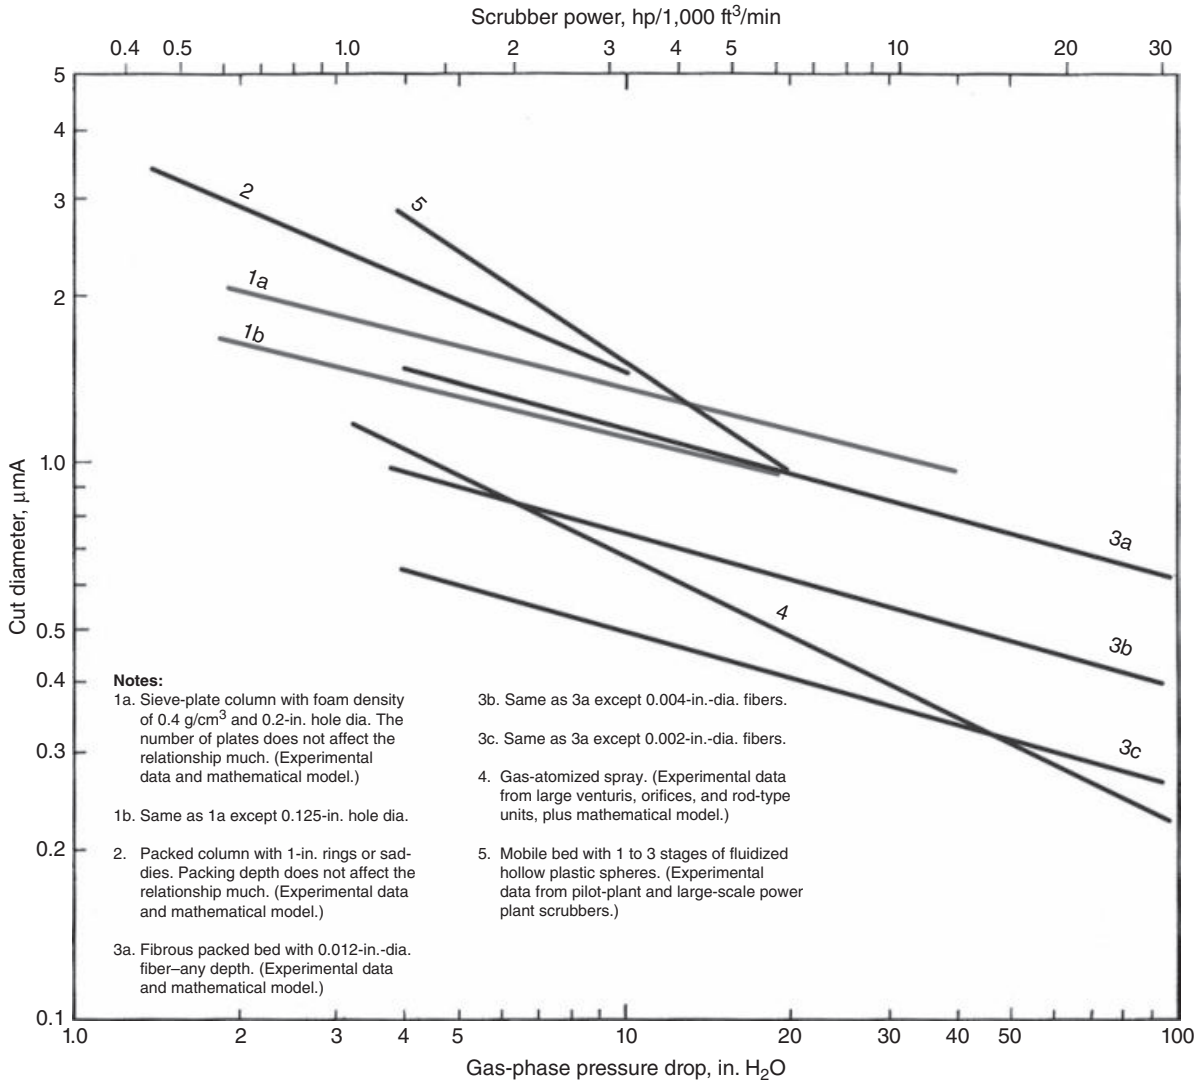

**FIG. 17-70** Cut diameter as a function of power consumption or pressure drop. [*Calvert, Chem. Eng., 84* (*18*), *54* (*1977*).]

***Location of Deposited Dust/Mode of Filtration*** As shown in Fig. 17-71, the filtered dust can be deposited either on the inside surface or on the outside surface of the bag. Inside collection was prevalent in the earlier designs with shaker cleaning mechanisms. The pulse-jet collectors are exclusively used with outside collection, whereas reverse air collectors can be operated either way.

***Cleaning Mechanisms*** As the separated dust deposits on the surface of a filter medium, it increases the resistance to gas flow (pressure drop), thereby increasing the energy consumption. All cleaning mechanisms rely on imparting sufficient force to break the adhesive bond between filter media and dust layer (cake), and the cohesive bonds between progressive layers of the deposited dust. The detached material falls under the force of gravity toward the discharge hopper, where it is removed. During each cleaning cycle, the entire layer of dust on the filter medium may not be detached. However, over the long term, an equilibrium dust burden, which is unique for a given set of conditions, is established.

There are three major designs for cleaning mechanisms in common practice: (1) shaker (includes oscillation, vibration, and tapping), (2) reverse air cleaning, and (3) reverse pulse cleaning (high-volume, low-pressure and low-volume, high-pressure). Shaking may be combined with reverse air cleaning or with acoustic energy cleaning to enhance its effectiveness.

The shaker mechanism, which was commercially introduced in late 1800s, was the earliest attempt at cleaning filter media. The most common design entails a shaking mechanism at the top where the bags are attached directedly or to a common frame connected to a shaking mechanism (see Fig. 17-72). The oscillations can be horizontal, vertical, or a combination of the two. The amplitude (half-stroke) of the oscillations is usually between 10 mm (0.4 in) and 64 mm (2.5 in), and frequencies between 4 Hz and 8 Hz are common. Various modes of shaking have been summarized in an EPA report (*Fabric Filter Cleaning Studies*, p. 37, EPA-650/2-75-009, January 1975). Numerous patents related to shaking techniques have been issued for improving dust removal. The effective duration of cleaning depends on particle properties and filter media, and in the absence of specific experience, 200 to 300 cycles can be a good starting point.

The acceleration imparted to the media by the shaker mechanism causes the pores to open momentarily. This allows the fines to penetrate more deeply into the media and increases abrasive wear. Proper bag tension is critical to prevent the dampening of oscillatory motion. Excessive tension, on the other hand, will reduce the life of bags and increase emissions due to opening of the pores.

The filtration airflow must be stopped during a shaking cycle. If the filter is to be operated continuously, it must be constructed with multiple compartments so that the individual compartments can be sequentially taken off line for cleaning while the other compartments continue in operation. The section undergoing cleaning will not participate in filtration, and the design calculations must account for it. The relative magnitude of cleaning time and filtration time dictates the number of compartments a shaker-type filter must be designed for.

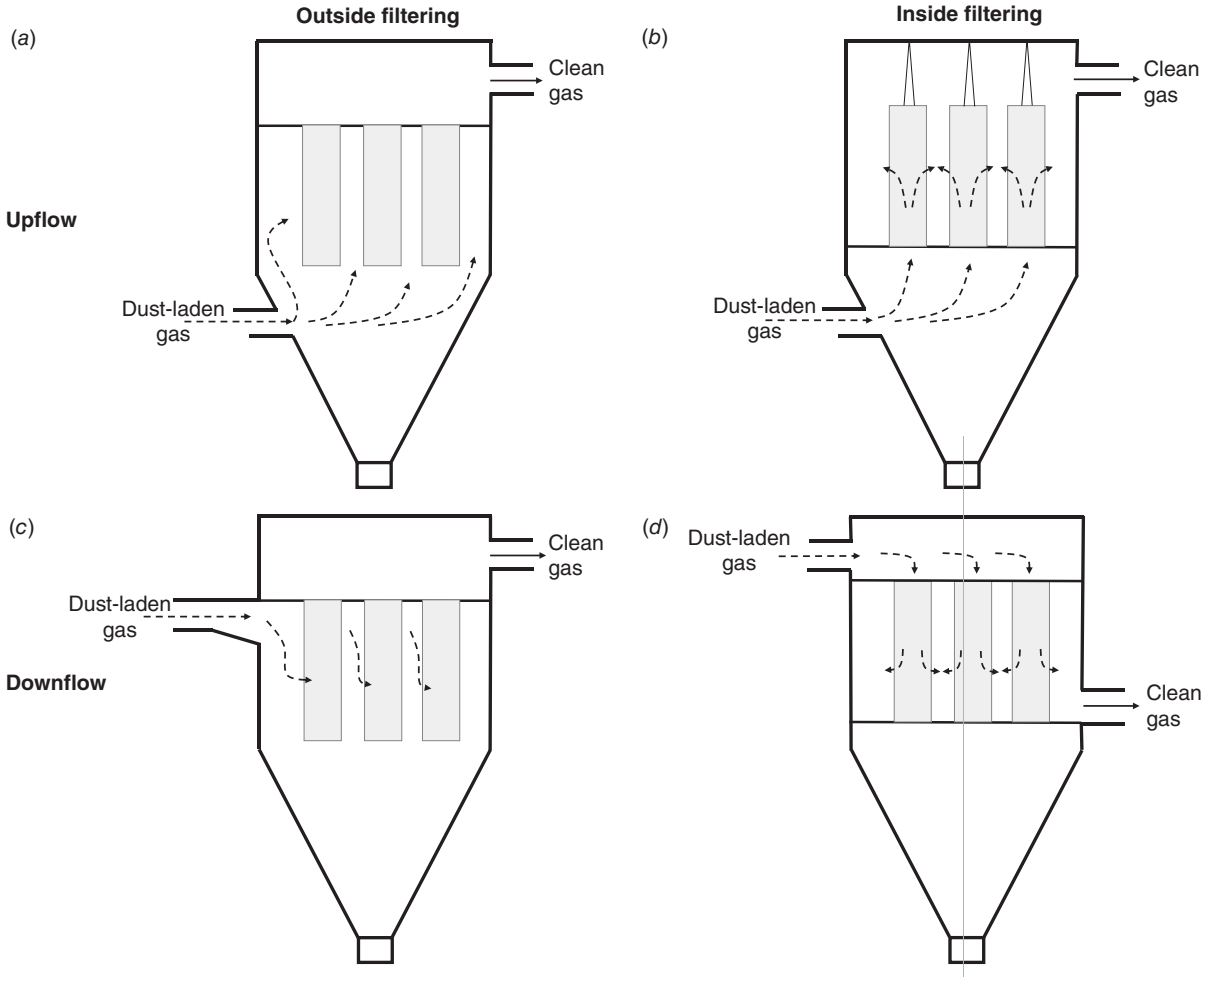

**FIG. 17-71** Flow modes and directions of filtration in dust collectors.

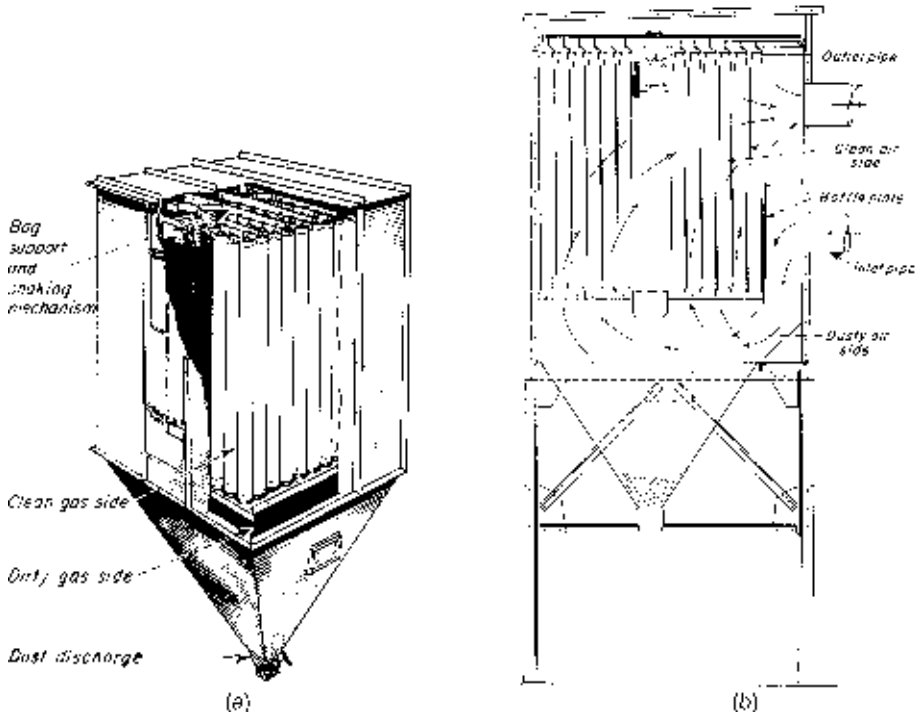

**FIG. 17-72** Typical shaker-type fabric filters. (*a*) *Buell Norblo* (cutaway view). (*b*) *Wheelabrator-Frye, Inc.* (sectional view).

Shaker-cleaned filters are available as standard commercial units, although large baghouses for heavy-duty service are commonly custom-designed and fabricated. The oval or round bags used in the standard units are usually 12 to 20 cm (5 to 8 in) in diameter and 2.5 to 5 m (8 to 17 ft) long. The large, heavy-duty baghouses may use bags up to 30 cm (12 in) in diameter and 9 m (30 ft) long. The bags must be made of woven fabrics to withstand the flexing and stretching involved in shaking. The fabrics may be made from natural fibers (cotton or wool) or synthetic fibers. Fabrics of glass or mineral fibers are generally too fragile to be cleaned by shaking and are usually used in reverse-flow-cleaned filters. Felted fabrics operate at higher face velocities than woven fabrics.

Large units (other than custom units) are usually built up of standardized rectangular sections in parallel. Each section contains on the order of 1000 to 2000 $ft^2$ of cloth, and the sections are assembled in the field to form a single filter housing. In this manner, the filter can be partitioned so that one or more sections at a time can be cut out of service for shaking or general maintenance.

Ordinary shaker-cleaned filters may be shaken every one-quarter to 8 h, depending on the service. A fixed time cycle requires one to estimate the rate of pressure rise based on inlet loading. Excessive cleaning will result in premature failure of bags, whereas insufficient cleaning can result in higher energy consumption and blinding. On-demand cleaning based on measurement of pressure drop is the recommended approach.

It is essential that the gas flow through the filter be stopped when shaking in order to permit the dust to fall off. With very fine dust, it may even be necessary to equalize the pressure across the cloth [Mumford, Markson, and Ravese, *Trans. Am. Soc. Mech. Eng.* **62:** 271 (1940)]. In practice this can be accomplished without interrupting the operation by cutting one section out of service at a time, as shown in Fig. 17-73. In automatic filters this operation involves closing the dampers, shaking the filter units either pneumatically or mechanically, sometimes with the addition of a reverse flow of cleaned gas through the filter, and lastly reopening the dampers. For compressed-air-operated automatic filters, this entire operation may take only 2 to 10 s. For ordinary mechanical filters equipped for automatic control, the operation may take as long as 3 min.

Shaker-cleaned filters are generally operated at filtration velocities of 0.3 to 2.5 m/min (1 to 8 ft/min) and at pressure drops of 0.5 to 1.5 kPa (2 to 6 inches water). For very fine dusts or high dust concentrations, filtration velocities should not exceed 1 m/min (3.3 ft/min). For fine fumes and dusts in heavy-duty installations, filtration velocities of 0.3 to 0.6 m/min (1 to 2 ft/min) have long been accepted on the basis of operating experience. The concept of filtration velocity is discussed in greater depth later.

Where the dust is collected on the inside surface of the filter, the gas velocity at the inlet of the filter bag is the highest because the cross-sectional area of the bag is substantially smaller than the overall filter area. Excessive inlet velocity can lead to abrasive wear on the bag.

Cyclone precleaners are sometimes used to reduce the dust load on the filter or to remove large, hot cinders or other materials that might damage the bags. However, reducing the dust load on the filter by this means may not reduce the pressure drop, since the fines exiting the cyclone can create a dust layer with lower permeability and hence negate the advantage of reduction in the fabric dust loading.

Reverse-flow-cleaned filters are generally similar to the shaker-cleaned filters except for the elimination of the shaker. It was developed as a gentler option for cleaning fragile bags (e.g., glass-fiber fabric). After the flow of dirty gas has stopped, a fan is used to force clean gas through the bags from the clean-gas side. This flow of gas flexes the bags and dislodges the collected dust, which falls into the dust hopper. The reverse airflow also reduces the cohesion within the dust layer, which enhances removal efficiency.

Reverse air cleaning can be implemented for (1) inside-out (dust deposition inside the bag; see Fig. 17-71*b* or *d*) or (2) outside-in (dust deposition outside the bag, see Fig. 17-71*a* or *c*) operation. For the former mode, rings are usually sewn into the bags at intervals along the length to prevent complete collapse, which would obstruct the fall of the dislodged dust. In the latter case, the collector is designed with filter elements laid out radially in the tube sheet (see Fig. 17-74). As the rotating manifold aligns itself with a row of bags, the airflow through the bags is momentarily reversed for cleaning. The filter bag forms a sleeve that is drawn over a wire cage or perforated tube, which is usually cylindrical. The cage supports the fabric on the clean-gas side, and the dust is collected on the outside of the bag. During the filtration cycle, the bag clings to the wire cage (or support tube) which prevents it from collapsing. The shape of the bag becomes convex outward during the reverse flow cleaning cycle, thereby dislodging the accumulated dust.

Medium-sized collectors can be cleaned on-line continuously using this approach. However, large collectors must be compartmentalized into modules for off-line cleaning (see Fig. 17-73). As with shaker-cleaned filters, compartments of the baghouse are taken off line sequentially for bag cleaning. The use of butterfly valves or poppet valves is common for the isolation of various modules and automatic cleaning sequences (Heumann, *Industrial Air Pollution Control System*, McGraw-Hill, New York, 1997).

The principal applications of reverse-flow cleaning are in units using fiberglass fabric bags for dust collection at temperatures above 150°C (300°F). Collapsing and reinflation of the bags can be made sufficiently gentle to avoid putting excessive stresses on the fiberglass fabrics [Perkins and Imbalzano,

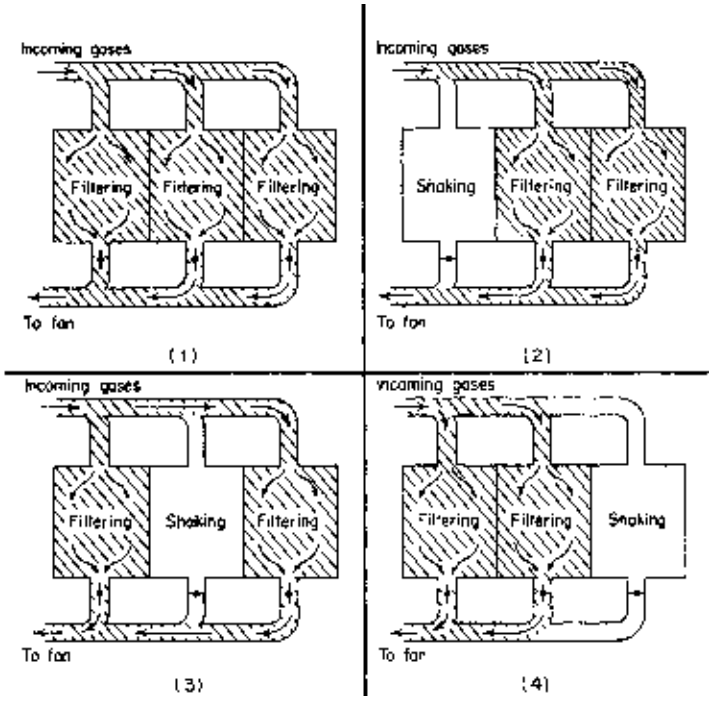

**FIG. 17-73** Three-compartment bag filter at various stages in the cleaning cycle. (*Wheelabrator-Frye, Inc.*)

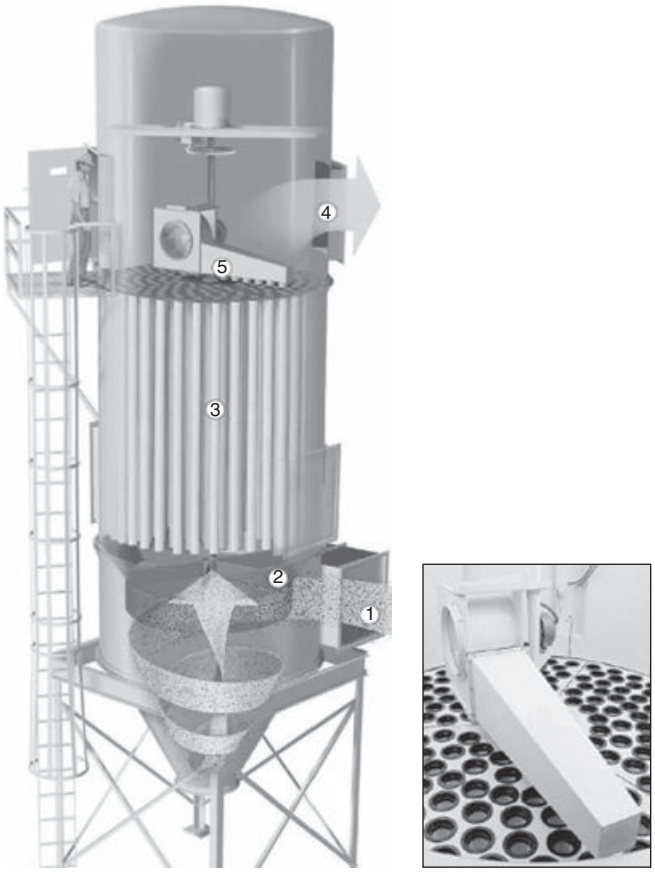

**FIG. 17-74** Reverse air dust collector: (1) air inlet; (2) plenum; (3) filter bags; (4) rotating manifold; (5) air outlet. (*Courtesy of Nederland Mikropul.*)

"Factors Affecting the Bag Life Performance in Coal-Fired Boilers," 3d APCA Specialty Conference on the User and Fabric Filtration Equipment, Niagara Falls, N.Y., 1978; and Miller, *Power* **125**(8): 78 (1981)].

The gas for reverse-flow cleaning is commonly supplied in an amount necessary to give a superficial velocity through the bags that is the same or higher than the filtration velocities for a given application (EPA Report, EPA/452/B-02-001, December 1998). A separate blower provides sufficient cleaning air for one or two compartments. Typical pressures are between 14 and 28 kPa (2 to 4 psi). The operational filtration face velocities (air-to-cloth ratio) for reverse air filters are similar to shaker filters.

Reverse-pulse filters (often termed reverse-jet filters) were developed in the 1950s and have become popular due to their lower capital cost and ability to operate continuously (Fig. 17-75). They combine the two previously discussed mechanisms, flexing of filter media and reverse airflow through the dust cake, to disrupt adhesive and cohesive forces. Two distinct pulse cleaning methods have evolved in practice: low-pressure/high-volume and high-pressure/low-volume cleaning modes (Heumann, *Industrial Air Pollution Control System*, McGraw-Hill, New York, 1997). This cleaning mechanism is used for filters where the dust is collected on the outer surface of the bag or filter element.

The low-pressure/high-volume approach is similar to reverse air cleaning (see Fig. 17-74) for outside-in flow except that a reservoir is used to accumulate the air from the blower at typical pressures of 41 to 55 kPa (6 to 8 psi). A large diaphragm valve is used to discharge the air in a few milliseconds. The high-volume pressure pulse momentarily stops the gas flowing through the bank of filters and inflates the bags, causing the separated dust to fall into the hopper. The cleaning efficacy is better than conventional reverse air cleaning.

The high-pressure/low-volume cleaning approach is the most common approach practiced today. It requires a source of clean (oil-free) and dry compressed air (60 psig to 120 psig) to create the reverse pulse. A venturi nozzle is located in the clean-gas outlet from the bag. For cleaning, a jet of high-velocity air is directed through the venturi nozzle and into the bag, inducing a flow of cleaned gas to enter the bag and flow through the fabric to the dirty-gas side. The high-velocity jet is released in a sudden, short pulse

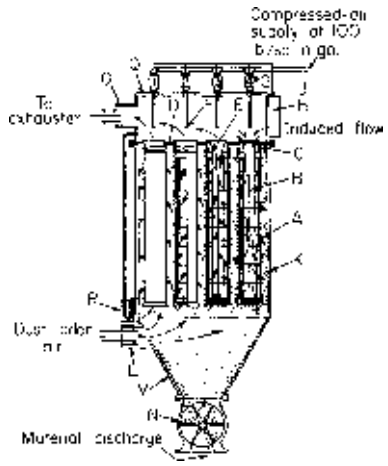

**FIG. 17-75** Reverse-pulse fabric filter: (A) filter cylinders; (B) wire retainers; (C) collars; (D) tube sheet; (E) venturi nozzle; (F) nozzle or orifice; (G) solenoid valve; (H) timer; (J) air manifold; (K) collector housing; (L) inlet; (M) hopper; (N) air lock; (O) upper plenum; (P) manometer; (Q) top of filter housing. (*Mikropul Division, U.S. Filter Corp.*)

(typical duration 100 ms or less) from a compressed-air line by a solenoid valve. The propagating pulse of air expands the bag as it travels downward and dislodges the collected dust. The pulse intensity naturally decays as it travels downward, which reduces the cleaning efficiency toward the bottom of the bag. A perforated tube, instead of the cage, may be used to maintain the uniformity of pulse intensity where appropriate.

Rows of bags are cleaned in a timed sequence by programmed operation of the solenoid valves. The pressure of the pulse is sufficient to dislodge the dust without cessation of the gas flow through the filter unit.

Some manufacturers are using relatively low-pressure air (100 kPa, or 15 lbf/in$^2$, instead of 690 kPa, or 100 lbf/in$^2$) and are eliminating the venturi tubes for clean-gas induction. Others have eliminated the separate jet nozzles located at the individual bags and use a single jet to inject a pulse into the outlet-gas plenum.

Reverse-pulse filters are typically operated at higher filtration velocity, also called air-to-cloth ratio, than shaker or reverse-flow filters designed for the same duty (Table 17-9). Recommended values of filtration velocities

**TABLE 17-9 Examples of Recommended Filtration and Can Velocity**

| Material | Filtration velocity shaker/reverse air cleaning, ft/min | Filtration velocity pulse cleaning, ft/min | Maximum recommended can velocity, ft/min |
|---|---|---|---|
| Activated carbon | 2 | 6 | 175 |
| Aluminum oxide | 2 | 9 | 200 |
| Baking powder | 2.5 | 9 | 175 |
| Bauxite | 2.5 | 8 | 200 |
| Cement | 2.5 | 8 | 225 |
| Feeds, grain | 3.5 | 14 | 200 |
| Fertilizer | 3 | 8 | 200 |
| Fly ash | 2.5 | 7 | 200 |
| Graphite | 2 | 5 | 200 |
| Iron oxide | 2.5 | 7.5 | 200 |

Adapted from Croom, M., Filter Dust Collectors, McGraw Hill, 1995.

for various products have been tabulated in Croom, *Filter Dust Collectors,* McGraw-Hill, New York, 1995; Heumann, *Industrial Air Pollution Control System*, McGraw-Hill, New York, 1997; and EPA Report, EPA/452/B-02-001, December 1998. Filtration velocities may range from 1 to 4.5 m/min (3 to 15 ft/min), depending on the dust being collected, but for most dusts the commonly used range is about 1.2 to 2.5 m/min (4 to 8 ft/min). The frequency of cleaning is also dependent on the nature and concentration of the dust, with the intervals between pulses varying from about 2 to 15 min.

The cleaning action of the pulse is so effective that the dust layer may be completely removed from the surface of the fabric. Consequently, the fabric itself must serve as the principal filter medium for at least a substantial part of the filtration cycle. Woven fabrics are unsuitable for such service, and felts of various types must be used. The bulk of the dust is still removed from the surface layer, but the felt ensures that an adequate collection efficiency is maintained until the dust layer has formed. This cleaning mechanism is applicable to various types of filter elements, such as bags, envelopes, nonwoven cartridges, ceramic, and metal cartridges.

It has been a common practice to clean the bags on-line (i.e., without stopping the flow of dirty gas into the filter), and reverse-pulse bag filters have been built without division into multiple compartments. However, investigations [Leith et al., *J. Air Pollut. Control Assoc.* **27:** 636 (1977)] and experience have shown that, with on-line cleaning of reverse-pulse filters, a large fraction of the dust dislodged from the bag being cleaned may redeposit on neighboring bags rather than fall into the dust hopper. The gas flow through a bag (or row of bags) is substantially higher after it has been cleaned. When the adjacent row is cleaned, all the dislodged dust simply migrates to the previously cleaned row. To mitigate this problem, the reverse-pulse cleaning sequence is randomized so that adjacent rows are not sequentially cleaned.

**Acoustic Cleaning** Acoustic or sonic energy can be used to dislodge dust cake from filter media. It is used either as a supplement to the shaker to enhance cleaning efficiency or as a standalone method of cleaning. The acoustic energy is generated by a diaphragm using compressed air, which is then channeled through a horn. A typical frequency range is 60 Hz to 250 Hz, with lower frequencies being more effective but tending to diffuse more rapidly. Higher frequencies are directional and tend to be an irritant for operational personnel in the process area. The power of sound energy is expressed in decibels, which is a logarithmic scale. The output of sonic horns is generally between 120 and 150 decibels. It is also possible to clean the accumulation in dead zones or initiate flow in the hopper using sonic horns.

***Direction of Gas Flow*** The relative locations of the dust-laden gas inlet and the clean air outlet will result in different flow regimes within the body of the collector, namely upflow, downflow, and cross-flow. Since the dust is always removed by gravity settling, the bulk airflow in the filter can be cocurrent or countercurrent to the separated dust. Downflow or cross-flow configurations are advantageous when collecting fine, light, or fluffy dust (e.g., fumes, wood dust, polymer dust) because the dust removed from the filter elements is swept by the flowing gas toward the collection hopper. For an upflow configuration, it is necessary to keep the approach velocity of dust-laden air, called the *can velocity*, below a critical value to prevent reentrainment of dust. The allowable can velocity is higher than the single-particle terminal velocity because it is assumed that the cake falls as chunks or large agglomerates. The guidance provided in Table 17-9 is based on operational experience.

The *can velocity* is based on the actual flow area, which is calculated by subtracting the total area occupied by the filter elements (bags/cartridges) from the overall cross section of the filter housing (ASHRAE Handbook—2016, Chapter 30).

$$V_c = \frac{q}{A_h - NA_f} \tag{17-37}$$

where $V_c$ = can velocity, m/s ( ft/min)
$q$ = gas flow being cleaned, $m^3/s$ ( $ft^3/min$)
$A_h$ = cross-sectional area of housing, $m^2$ ( $ft^2$)
$N$ = number of filter bags ( filter elements) in the collector
$A_f$ = cross-sectional area, perpendicular to gas flow, of each filter bag (or filter element), $m^2$ ( $ft^2$)

For the upflow configuration, the can velocity will be maximum in the plane below the bottom of the filter elements. The can velocity is not relevant for downflow configuration.

Optimal design of a collector must balance can velocity, filtration velocity, pressure drop, footprint, and capital cost.

***Mode of Operation*** Certain process applications, such as collection of nuisance dust, allow intermittent stoppage for the filter to undergo a cleaning cycle. On the other hand, filters for pneumatic conveying systems in a production process must operate continuously without the possibility of a shutdown for cleaning. Shaker and reverse collectors operate in batch or intermittent mode, while pulse-jet collectors are most suited for operation in continuous mode.

***Type of Fabric Filter Elements*** There are three major types of fabric filter elements in common practice: bags, envelopes, and cartridges. Bag, sock, or tube filters are the most common filter elements in use today. They can be sewn from woven or felted media with a seam along the length. The design of the open end is adapted for ease of installation (e.g., snap bands). Grounding wires are incorporated in the design for combustible dust applications.

Envelope-type elements are usually found in smaller unit collectors where multiple banks of elements can be closely packed horizontally or vertically to achieve high filtration area (see Fig. 17-76). The cartridge type collectors are limited to outside-in flow and reverse air or pulse-jet cleaning mechanisms. They have gained greater market share in the past 20 years due to their compactness and ability to function at high efficiencies. Cartridges

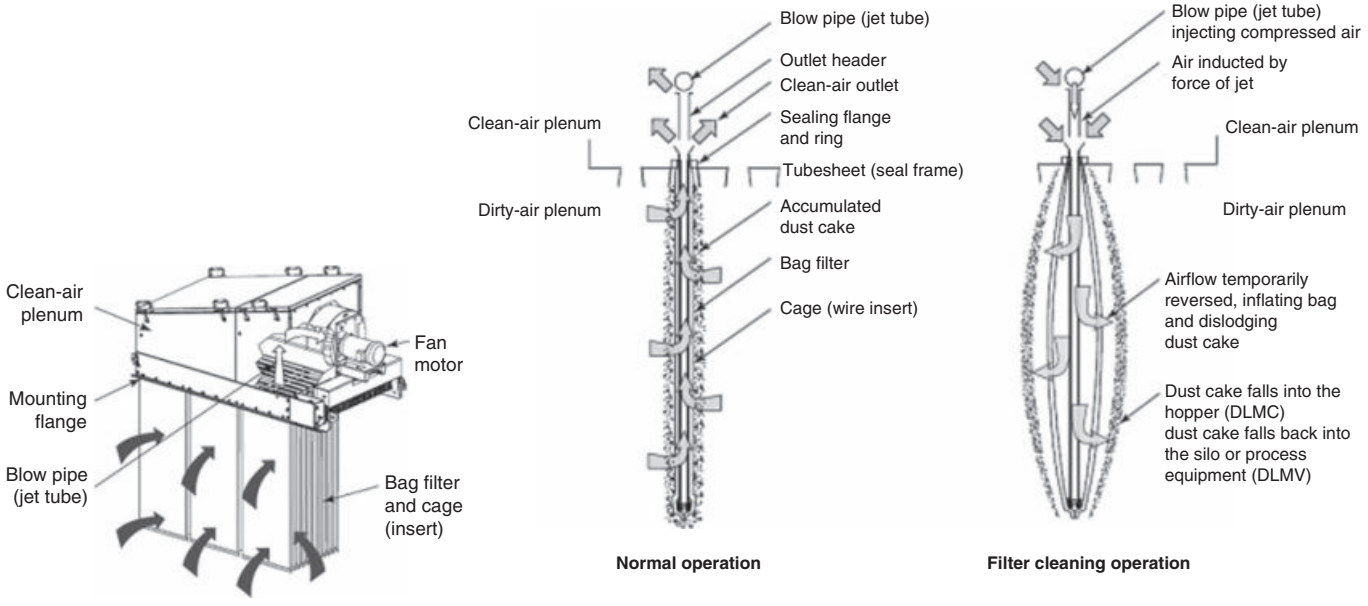

**FIG. 17-76** Envelope-type filter elements. (*Courtesy of Donaldson Company Inc.*)

are typically manufactured from pleated paper or synthetic microfibers that are spunbonded (e.g., spunbonded polyester). Common construction is 150 to 350 mm (6–14 in) in diameter and 400 to 900 mm (14–36 in) long. An open pleated structure (4–8 pleats/in) is recommended for cohesive dust and sticky dusts, whereas higher pleat density (12–16 pleats/in) will be more economical for coarser particles. The pleat depth is between 25 and 75 mm (1–3 in). Deeper pleats are difficult to clean, and dust can get wedged deep into the pleat. The upper limits on operating temperatures (200°F–350°F) are due to the adhesives used for bonding the end caps, even if high-temperature filter media are used.

Cartridges are often recommended as a retrofit upgrade to existing baghouses where the filtration area (cloth area) can be easily doubled. The cartridges are also shorter than bags, which can reduce abrasive wear due to high gas inlet velocities. Unlike bags, the cartridges do not require cages for reinforcement, and they are designed for easier installation. The user is cautioned to check the can velocity in a filter housing with new operating conditions. Cartridges of two different lengths can be used as a practical remedy to this problem.

The high porosity of these media, in combination with small pore size, results in low pressure drop and high collection efficiency for submicron particulates. The paper cartridges can collect 2.5 μm particles at 99.999+ percent efficiency, while the nonwoven (spunbonded polyester) cartridges have an efficiency of 99.99 percent at 2.5 μm. However, limited choices of filter media, high-temperature limitations, and plugging issues with fine/sticky/cohesive powders have hindered broader applicability nonwoven cartridges.

***Selection of Filter Media*** Inappropriate selection of fabric filter media can lead to high operating and maintenance costs due to premature failures and higher emissions. The selection must be based on (1) maximum operating temperature, (2) presence of acidic components in the gas, (3) presence of alkaline components in the gas, (4) presence of moisture or condensed droplets, (5) presence of sticky, hygroscopic, or submicron particles, and (6) abrasiveness of dust. The characteristics of common fabric filter media are summarized in Table 17-10.

The choice of woven versus felted media is largely dictated by the chosen method of cleaning. Woven media (cloth) is used with shaker and reverse air cleaning systems, whereas felt media is suitable for reverse air and pulse-jet systems. Woven cloth is unsuitable for pulse-jet cleaning because the flexing action due to the pressure pulse increases the pore size, which results in a spike in emissions, and it shortens the bag life due to abrasive wear.

Woven media are made from weaving yarn ( filament, staple, or spun) into filter cloth of geometric weave patterns (e.g., plain weave, twill weave, satin weave). The multitude of combinations of raw materials, spinning methods, and weaving processes results in a broad range of filtration characteristics. For example, woven media made with spun or heavyweight staple yarn fabric are suitable for shaker systems, whereas those made with lighter-weight filament yarn fabric are used for reverse air cleaning systems.

The felts made from synthetic fibers are needle felts (i.e., felted on a needle loom) and are normally reinforced with a woven insert. In felted media, there is no clear open path for the particles to pass through, which results in greater efficiencies after the cleaning phase.

The selection of fabric media for a given application must be done in collaboration with the manufacturers, and by leveraging prior experience with similar applications. The key parameters specified for woven and nonwoven ( felt) media are:

- Fiber type (e.g., Polyester)
- Weight (oz./yd$^2$ or g/m$^2$)
- Construction (e.g., weave type, felt structure, spunbonding)
- Thickness
- Count
- Air permeability
- Mullen burst strength
- Tensile strength—warp direction and fill direction
- Maximum operating temperature
- Thermal stability (shrinkage)
- Surface finish (e.g., glazing, singeing, calendaring, membrane)

The cost of the filter bags represents a substantial part of the erected cost of a bag filter—typically 5 to 20 percent, depending on the bag material [Reigel and Bundy, *Power* **121**(1): 68 (1977)]. The cost of bag repair and replacement is the largest component of the cost of bag-filter maintenance. Consequently, the proper choice of filter fabric is critical to both the technical performance and the economics of operating a filter. With the advent of synthetic fibers, it has become possible to produce fabrics having a wide range of properties. However, demonstrating the acceptability of a fabric still depends on experience with prolonged operation under the actual or simulated conditions of the proposed application. The choice of a fabric material for a given service is necessarily a compromise, since no single material possesses all the properties that may be desired. An example of cost analysis for fabric filters can be found in Turner et al., EPA/452/B-02-001 (1998).

***Specification of Filtration Velocity or Air-to-Cloth Ratio*** The specification of filtration face velocity ($V_f$), better known as the air-to-cloth (AC) ratio in commercial practice, is critical for sizing a filter collector. It is defined as

$$V_f = q/A_f \tag{17-38}$$

where $A_f$ is the active filtration area (excluding the filter area that is compartmented for cleaning).

As is evident from Eq. (17-38), it has the units of velocity ( ft/min or m/min). Omission of units while reporting this critical parameter can lead to major design errors. The values reported by U.S. manufacturers are often in ft/min units.

The face velocity (or air-to-cloth ratio) has a direct bearing on filter performance, specifically:

i. Pressure drop and the rate of pressure rise between cleaning cycles, hence cleaning frequency
ii. Media blinding and operational life of filter elements
iii. Emissions
iv. Capital cost, energy cost, and maintenance cost

A first-principles approach to calculate the filtration velocity for a given product, filter media, operating conditions, and cleaning mechanism does not exist because of the complexity of interactions inherent in the filtration process. However, tables of recommended values are available in various texts and references [Croom, *Filter Dust Collectors,* McGraw-Hill, New York, 1995; Turner et al., EPA/452/B-02-001 (1998); Heumann, *Industrial Air Pollution Control System*, McGraw-Hill, New York, 1997; *ASHRAE Handbook 2016*; manufacturers]. These values provide a good starting point. For a new application with no prior experience, pilot-scale testing is highly recommended.

Croom (*Filter Dust Collectors,* McGraw-Hill, New York, 1995, p. 24) has summarized a factored approach that is widely practiced in the industry.

$$V_{fe} = V_f \cdot A \cdot T \cdot P \cdot D$$

where $V_{fe}$ = effective filtration velocity, m/min ( ft/min)

**TABLE 17-10 Temperature Limits and Characteristics of Filter Media (ASHRAE Handbook—2016)**

| Filter media | Maximum operating temperature, °F | Resistance to acid | Resistance of base or alkaline | Resistance to moisture and humidity | Resistance to oxidation | Flex abrasion | Approximate cost compared to cotton |
|---|---|---|---|---|---|---|---|
| Cotton | 180 | Poor | Very good | Poor | Fair | Good | X |
| Acrylic | 270 | Good | Fair | Very good | Very good | Good | 2–3X |
| Glass Fiber | 500 | Fair | Fair | Excellent | Excellent | Poor | 3–5X |
| Polyester | 275 | Good | Good | Fair | Very Good | Very good | 2–3X |
| Polypropylene | 180 | Very good | Very good | Very good | Very good | Very good | 1–2X |
| Polyamide (Nylon) | 200 | Poor | Very good | Good | Fair | Excellent | 2–3X |
| Polyaramide (Nomex™) | 400 | Fair | Good | Good | Very good | Very good | 4–8X |
| PTFE | 500 | Excellent | Excellent | Excellent | Excellent | Fair | 10–30X |
| Wool | 195 | Fair | Poor | Poor | Poor | Good | X |

**TABLE 17-11 Correction Factors for Filtration Velocity or Air-to-Cloth Ratio**

| | | |
|---|---|---|
| $A$ = Application | 0.8 | Oily, moist, or agglomerating |
| | 0.9 | Product collection |
| | 1.0 | Nuisance dust collection |
| $T$ = Temperature | 0.8 | Above 225°F (107°C) |
| | 0.9 | Between 110°F and 225°F (43°C–107°C) |
| | 1.0 | 110°F (43°C) and lower |
| $P$ = Particle size | 0.8 | Less than 3 μm |
| | 0.9 | For 3 μm to 9 μm |
| | 1.0 | For 10 μm to 50 μm |
| | 1.1 | For 51 μm to 100 μm |
| | 1.2 | For above 100 μm |
| $D$ = Dust loading | 0.8 | Above 80 gr/ft$^3$ |
| | 0.9 | For 50 to 80 gr/ft$^3$ |
| | 1.0 | For 20 to 50 gr/ft$^3$ |
| | 1.1 | For 10 to 20 gr/ft$^3$ |
| | 1.2 | Less than 10 gr/ft$^3$ |

Appropriate values of the factors $A$ (application), $T$ (temperature), $P$ (particle size), and $D$ (dust loading) must be selected from Table 17-11.

***Calculation of Pressure Drop Across Filter Media*** The filtration, or superficial face, velocities used in fabric filters are generally in the range of 0.3 to 4.6 m/min (1 to 15 ft/min), depending on the types of fabric, fabric supports, and cleaning methods used. In this range, gas pressure drops conform to Darcy's law for streamline flow in porous media, in which the pressure drop is directly proportional to the flow rate. The pressure drop across the fabric and the collected dust layer may be expressed (Billings and Wilder, *Handbook of Fabric Filter Technology,* vol. I, EPA No. APTD-0690, NTIS No. PB-200648, 1979) by

$$\Delta p = K_1 V_f + K_2 w V_f$$

$$\Delta p = K_1 V_f + K_2 w V_f = (K_1 + K_2 w) V_f = S V_f \qquad (17\text{-}39)$$

where $\Delta p$ = kPa, or in of water; $V_f$ = superficial velocity through filter, m/min, or ft/min; $w$ = dust loading on filter, g/m$^2$, or lbm/ft$^2$; and $K_1$ and $K_2$ are resistance coefficients for the "conditioned" fabric and the dust layer, respectively. The conditioned fabric is that fabric in which a relatively consistent dust load remains deposited in a certain depth following cycles of filtration and cleaning. $K_1$, expressed in units of kPa/(m/min) or in water/(ft/min), may be more than 10 times the value of the resistance coefficient for the original clean fabric. If the depth of the dust layer on the fabric is greater than about 0.2 cm (1/16 in), corresponding to a fabric dust loading on the order of 200 g/m$^2$ (0.04 lbm/ft$^2$), the pressure drop across the fabric (including the dust in the pores) is usually negligible relative to that across the dust layer. It should be noted that increasing the filter area for a given duty (gas flow rate and solids concentration) will reduce both the filtration velocity and dust loading on the filter, and, therefore, has a significant impact on the pressure drop. The rate of increase in pressure drop will also be lower, which reduces the cleaning frequency. Lower cleaning frequency results in longer filter life and lower overall emissions.

The combined term, $S$, is called the system drag, which accounts for pressure drop from the inlet to the outlet [Turner et al., EPA/452/B-02-001 (1998)]. The pressure drop across the fabric filter, and the system drag, is a function of time (see Fig. 17-77). The pressure drop characteristics of a conditioned filter medium is very different than an unused filter medium, and further, the actual dust loading on the filter and the specific resistance coefficient of the dust layer are difficult to estimate from first principles. From a practical perspective, it is best to conduct pilot-scale testing to obtain the drag values of a conditioned filter and the specific resistance coefficient of the dust layer. The performance data from an existing installation can also be used to achieve the same objective.

Equation (17-39) indicates that for filtration at a given velocity, the pressure drop is a linear function of the fabric dust loading, $w$. In some cases, particularly with smooth-surfaced fabrics, this is approximately the case, but in other instances the function displays an upward curvature with increases in $w$, indicating compression of the dust layer, the fabric, or both, and a consequent increase in $K_2$ [Snyder and Pring, *Ind. Eng. Chem.* **47:** 960 (1955); K. T. Semrau, unpublished data, SRI International, Menlo Park, Calif., 1952–1953]. Several investigations have shown $K_2$ to be increased by increases in the filtration velocity [Billings and Wilder, *Handbook of Fabric Filter Technology,* vol. I, EPA No. APTD-0690, NTIS No. PB-200648, 1979; Spaite and Walsh, *Am. Ind. Hyg. Assoc. J.* **24:** 357 (1968)]. However, the various investigators do not agree on the magnitude of the velocity effect. Billings and Wilder suggest assuming as an approximation that $K_2$ is directly proportional to the filtration velocity, but the actual relationship is probably dependent on the nature of the fabric and fabric surface, the characteristics of the dust, the dust loading on the fabric, and the pressure drop.

Clearly, the factors determining $K_2$ are far more complex than is indicated by a simple application of the Kozeny-Carman equation, and when possible, filter design should be based on experimental determinations made under conditions approximating those expected in the planned installation.

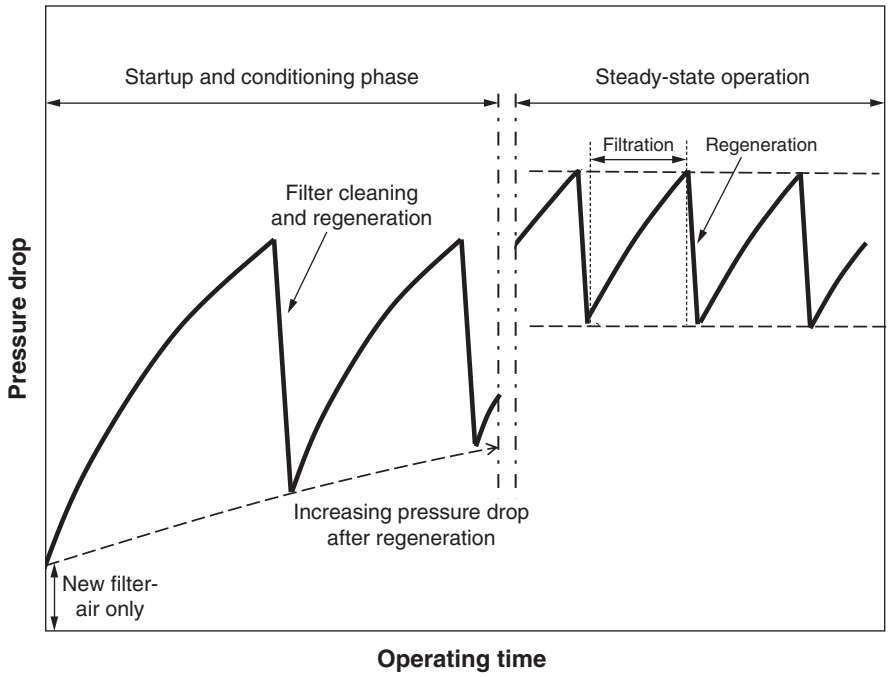

**FIG. 17-77** Typical pressure drop characteristics of a filter collector during operation.

***Collection Efficiency*** The inherent collection efficiency of fabric filters is usually so high that, for practical purposes, the precise level has not commonly been the subject of much concern. Furthermore, for collection of a given dust, the efficiency is usually fixed by the choices of filter fabric, filtration velocity, method of cleaning, and cleaning cycle, leaving few if any controllable variables by which efficiency can be further influenced. Inefficiency usually results from bags that are poorly installed, torn, or stretched from excessive dust loading and pressure drop. Of course, certain types of fabrics may simply be unsuited for filtration of a particular dust, but usually this will soon become obvious.

Few basic studies of the efficiency of bag filters have been made. Increased dust penetration immediately following cleaning has been readily observed while the dust layer is being reestablished. However, field and laboratory studies have indicated that during the rest of the filtration cycle, the effluent-dust concentration tends to remain constant regardless of the inlet concentration [Dennis, *J. Air Pollut. Control Assoc.* **24:** 1156 (1974)]. In addition, there has been little indication that the penetration is strongly related to dust-particle size, except possibly in the low-submicrometer range. These observations appear to be generally consistent with sieving being the principal collection mechanism.

Leith and First [*J. Air Pollut. Control Assoc.* **27:** 534 (1977); **27:** 754 (1977)] studied the collection efficiency of reverse-pulse filters and concluded that once the dust cake has been established, "straight-through" penetration by dust particles that pass through the filter without being stopped is negligible by comparison with penetration by dust that actually deposits initially and then seeps through the fabric to be reentrained into the exit airstream. They also noted that pinholes may form in the dust cake, particularly over pores between yarns in a woven fabric, and that particles may subsequently penetrate straight through at the pinholes. The formation of pinholes, or "cake puncture," had been observed earlier by Stephan et al. [*Am. Ind. Hyg. Assoc. J.* **21:** 1 (1960)], but without measurement of the associated loss of collection efficiency. When a supported flat filter medium with extremely fine pores (e.g., glass-fiber paper, membrane filter) was used, no cake puncture took place, even with very high pressure differentials across the cake. However, puncture did occur when a cotton-sateen filter fabric was used as the cake support. The formation of pinholes with certain combinations of dusts, fabrics, and filtration conditions was also observed by Koscianowski et al. (EPA-600/7-78-056, 1978). Evidently, puncture occurs when the local cake structure is not strong enough to maintain a bridge over the aperture represented by a large pore, and the portion of the cake covering the pore is blown through the fabric. This suggests that the formation of pinholes will be highly dependent on the strength of the surface forces between particles that produce flocculation of dusts. The seepage of a dust through a filter is probably also closely related to the strength of the surface forces.

Surface pores can be greatly reduced in size by coating what will become the dusty side of the filter fabric with a thin microporous membrane that is supported by the underlying fabric. That has the effect of decreasing the effective penetration, both by eliminating cake pinholes and by preventing the seepage of dust that is dragged through the fabric by successive cleanings. A variety of different membrane-forming polymers can be used in compatible service. The most versatile and effective surface filtration membranes are microfibrous Teflon, as already described by Brinckman and Maresca [*ASME Med. Waste Symp.* (1992)] in the section on dry scrubbing.

***Design of Filter Collector*** The most common design objectives are collection efficiency (emissions), operating cost (pressure drop, maintenance, life of filter elements), and capital cost (installed cost). Listed here is a step-by-step approach for designing filter collectors.

***Step 1:*** Define design objectives, performance expectations, and constraints (location, available space, utilities).

***Step 2:*** Define process conditions (gas flow rate range, pressure, temperature, humidity, gas composition, corrosivity, chemical reactivity) and dust properties (particle-size distribution, abrasiveness, explosivity, stickiness, density, bulk density, shape).

***Step 3:*** Select (or shortlist) suitable fabric media (material of construction).

***Step 4:*** Based on prior industry experience and range of gas flow rate, select the *mode of filtration* (inside-out vs. outside-in collection).

- If inside-out flow is selected, the gas flow pattern will most likely be upflow, and shaker or reverse air cleaning mechanisms will be applicable.
- If outside-in flow is selected, the gas flow pattern can be upflow, downflow, or cross-flow based on particle size and abrasiveness. Downflow and cross-flow patterns are preferable for dusts in the micron range, but abrasive dust can cause higher erosive wear.

***Step 5:*** Select suitable air-to-cloth ratio from Table 17-9 or prior experience. Use factors from Table 17-11.

***Step 6:*** Calculate the cloth area (media surface area) required for filtration. For compartmentalized design, the total filter area must include the offline modules.

***Step 7:*** Working with vendors and based on standard available filter element sizes, select appropriate size and number of elements.

***Step 8:*** Estimate the pressure drop. Typical operating range of pressure drops is 3 to 20 inches of water.

***Step 9:*** Based on recommended maximum can velocity, calculate the dimensions of filter housing. This defines the smallest footprint that is feasible.

***Step 10:*** Finalize the design features, namely

*a.* Media replacement: Clean side vs. dirty side
*b.* Gas inlet design: tangential, diffusors
*c.* Design of dust hopper and airlock
*d.* Instrumentation and automation for cleaning
*e.* Tracing/insulation to avoid condensation: In filter operation, it is essential that the gas be kept above its dew point to avoid water-vapor condensation on the bags and the resulting plugging of the bag pores.
*f.* Explosion venting

**Practical Operational Aspects** While it is difficult to cover all combinations of filter designs, product characteristics, and failure modes, an attempt has been made to capture the most frequent problems, potential causes, and remedies in the troubleshooting guides (Tables 17-12, 17-13, and 17-14).

**TABLE 17-12 Troubleshooting Guide: High Pressure-Drop Problems in Dust Collectors**

| Symptom | Possible causes | Solutions |
|---|---|---|
| Normal pressure drop with conditioned bags, which rapidly increases during a cycle. | High dust loading on filters | Install a precleaner before the dust collector.<br>Use cyclonic inlet or velocity reduction in transition piece. |
| | Insufficient cloth area | Increase bag length, if possible.<br>Consider pleated bags/cartridges. |
| Pressure drop with new clean filter media is low, but increases more than tenfold after conditioning with progressive increase in short term. Does not restore even after prolonged off-line cleaning. | Media is blinding due to fines penetration | Choose different filter media with smaller pore size. Consider PTFE membrane filtration.<br>Decrease air-to-cloth ratio or face velocity by choosing longer bags.<br>Moisture or condensation in the gas; operate above dew point.<br>Oil droplet or mist in the air, especially cleaning air in pulse-jet; install filters. |
| Under steady-state operation, the pressure drop does not appreciably change after a cleaning cycle has been completed. | Instrument error or lines plugged | Clean lines, recalibrate ΔP sensor, verify with pressure gage, check for leaks and condensation in lines. |
| | Cleaning mechanism is not effective | Check operation of cleaning system for changes, esp. after media changes.<br>Check all mechanical, electrical, and pneumatic subsystems.<br>Increase duration of cleaning for shaker and reverse air; increase pressure for pulse-jet.<br>Consider augmented cleaning, e.g., using sonic horns. |
| | High reentrainment after cleaning impedes dust removal from filters | Avoid cleaning adjacent filter elements in sequence.<br>Find ways to reduce the can velocity (e.g., filter elements of different lengths).<br>Modify airflow patterns below the filter elements to prevent reentrainment of dust. Cyclonic action or deflectors are useful.<br>For compressible dust, allow dust cake to compact by reducing the cleaning frequency.<br>Confirm reentrainment problem by executing the cleaning cycle off-line. The pressure should recover back to conditioned media. |

**TABLE 17-13 Troubleshooting Guide: High Emission Problems in Dust Collectors**

| Symptom | Possible causes | Solutions |
|---|---|---|
| Emissions are consistently high | Incorrect choice of filter media | Select media with higher efficiency (e.g., woven bags with tighter weave, thicker felt, finer fabric, membrane filtration) |
| | Filter media operated at higher than recommended face velocity | Increase filter area by choosing longer bags or converting bags to pleated elements |
| | Filter elements are damaged—physical integrity | Check filter quality (workmanship); check if the damage is due to shrinkage caused by high temperature—select alternate filter media; reduce intensity of cleaning |
| | Filter elements are damaged—abrasive wear | Check flow pattern within the collector; remove selected filter in the path of high velocity incoming jet; reduce inlet velocity; install baffles |
| | Filter elements are damaged—chemical degradation | Select compatible media |
| | Filter elements are incorrectly installed or have come loose during operation | Check for localized dust accumulation on tubesheet; improve filter design and clamping mechanism; check for high dust level in the hopper; check for damaged cages |
| | Damaged or leaky gaskets | Replace gaskets |
| | Missing filter elements | Confirm with inspection |
| | Leakage at tubesheet due to warping or cracks | Investigate root cause. Mechanical reinforcement and repairs needed |
| Emmissions high only during cleaning cycle | Excessive cleaning energy | Reduce cleaning intensity depending on the cleaning mechanism |
| | Excesive cleaning frequency | Reduce cleaning frequency if based on timer; use dP-based approach to trigger cleaning cycle; use pre-cleaner to reduce dust load; increase filter area to reduce dust loading on filter element |
| | Incorrect selection or specification of filter media | Select thicker media with lower porosity; use membrane filtration |
| | Filter element is damaged—phyiscal integrity | Confirm with inspection; replace |

**TABLE 17-14 Troubleshooting Guide: Filter Failure Problems in Dust Collectors**

| Symptom | Possible causes | Solutions |
|---|---|---|
| Premature failure of filter element resulting in high emissions | Excessive cleaning energy | Reduce cleaning intensity depending on the cleaning mechanism |
| | Excesive cleaning frequency | Reduce cleaning frequency if based on timer; use dP-based approach to trigger cleaning cycle; use pre-cleaner to reduce dust load; increase filter area to reduce dust loading on filter element |
| | Filter elements are damaged—physical integrity | Check filter quality (workmanship); check if the damage is due to shrinkage caused by high temperature—select alternate filter media; reduce intensity of cleaning |
| | Filter elements are damaged—abrasive wear | Check flow pattern within the collector; remove selected filter in the path of high velocity incoming jet; reduce inlet velocity; install baffles to protect bags or distribute the air uniformly |
| | Filter elements are damaged—chemical degradation | Select compatible media |
| | Exposure to high stresses on the filter elements | Check for localized dust accumulation on tubesheet; improve filter design and clamping mechanism; check for high dust level in the hopper; check for damaged cages |
| | Damaged or leaky gaskets | Replace gaskets |
| | Missing filter elements | Confirm with inspection |
| | Leakage at tubesheet due to warping or cracks | Investigate root cause; mechanical reinforcement and repairs needed |
| Media blinding resulting in high pressure drop | Condensation on filter media | Operate above dew point; increase reverse air or pulse-jet air temperature |
| | Moisture or oil on the clean air side | Oil or water in the compressed air–install filters |
| | Incorrect selection or specification of filter media | Select thicker media with lower porosity; use membrane filtration or other surface treatments |
| | Incorrect choice of filter media | Select media with higher efficiency (e.g., woven bags with tighter weave, thicker felt, finer fabric, membrane filtration); condition the filter with precoating dust |
| | Filter media operated at higher than recommended face velocity | Increase filter area by choosing longer bags or converting bags to pleated elements |
| | Dust leakage to the cleanside can get embedded into the media during cleaning cycles | Visual inspection of tubesheet to confirm; analyze the filter bag using microscopy; fix the leak |

The three most common problems encountered in filter operation are related to pressure drop, collection efficiency, and the life of filter elements.

**Granular-Bed Filters** Granular-bed filters may be classified as "depth" filters, since dust particles deposit in depth within the bed of granules. The granules themselves present targets for the deposition of particles by inertia, diffusion, flow-line interception, gravity, and electrostatic attraction, depending on the dust and filter characteristics and the operating conditions. Other deposition mechanisms are minor at most. Although it is physically possible under some circumstances for a dust layer to form on the inlet face of the filter, the practical limits of gas pressure drop will normally have been reached long before a surface dust layer can be established. Typical granular-bed media includes sand, gravel, activated carbon, glass, and ceramics.

Granular-bed filters are synonymous with loose-surface (LS) filters, gravel-bed filters, moving-bed filters, sand filters, expandable-bed filters, panel-bed filters, and porous-bed filters in the literature. All these filters have the same working principle. They are suitable and competitive in high-temperature (>1000°F) and high-pressure gas streams with abrasive, sticky, and combustible dust; especially when combined with the removal of gaseous pollutants by adsorption. They have been used with mixed success in the cement, power, chemical, and nuclear industries. A competitive evaluation of granular-bed filters with media filtration ( fabric or ceramic cartridge filters) and electrostatic precipitators should be based on collection efficiency, filtration capacity, and capital and maintenance costs. While the concept of granular-bed filtration is simple, the ancillary system required to reliably regenerate the media substantially increases the capital and operating costs.

Excellent reviews of theoretical and commercial developments in granular-bed filtration can be found in Tien (*Granular Filtration of Aerosols and Hydrosols*, Butterworth, Boston/London, 1989) and Tardos and Zenz (*Handbook of Powder Science and Technology*, 2d ed., chap. 17, ed. Fayed and Otten, Chapman and Hall, London, 1997).

Granular-bed filters may be divided into three classes:

1. *Fixed-bed, or packed-bed, filters.* These units are not cleaned when they become plugged with deposited dust particles but are broken up for disposal or simply abandoned. If they are constructed from fine granules (e.g., sand particles), they may be designed to give high collection efficiencies on fine dust particles. However, if such a filter is to have a reasonable operating life, it can be used only on a gas containing a low concentration of dust particles.

2. *Cleanable granular-bed filters.* In these devices, provisions are made to separate the collected dust from the granules either continuously or periodically, so that the units can operate continuously on gases containing moderate to high dust concentrations. The necessity for cleaning and recycling the granules generally restricts the practical lower granule size to about 3 to 10 mm. This in turn makes it difficult to attain high collection efficiencies on fine particles with granule beds of reasonable depth and gas pressure drop.

3. *Fluidized-bed filters.* Fluidized beds of granules have received considerable study on theoretical and experimental levels but have not been applied on a practical commercial scale.

***Fixed Granular-Bed Filters*** Fixed-bed filters composed of granules have received considerable theoretical and experimental study [Thomas and Yoder, *AMA Arch. Ind. Health,* **13:** 545 (1956); **13:** 550 (1956); Knettig and Beeckmans, *Can. J. Chem. Eng.* **52:** 703 (1974); Schmidt et al., *J. Air Pollut. Control Assoc.* **28:** 143 (1978); Tardos et al., *J. Air Pollut. Control Assoc.* **28:** 354 (1978); and Gutfinger and Tardos, *Atmos. Environ.* **13:** 853 (1979)]. The theoretical approach is the same as that used in the treatment of deep-bed fibrous filters.

Fibers for filter applications can be produced with diameters smaller than it is practical to obtain with granules. Consequently, most concern with filtration of fine particles has been focused on fibrous-bed rather than granular-bed filters. However, for certain specialized applications, granular beds have shown some superior properties, such as greater dimensional stability. Granular-bed filters of special design (deep-bed sand filters) have been used since 1948 for removing radioactive particles from waste air and gas streams in atomic energy plants (Lapple, "Interim Report—200 Area Stack Contamination," U.S. AEC Rep. HDC-743, Oct. 11, 1948; Juvinall et al., "Sand-Bed Filtration of Aerosols: A Review of Published Information," U.S. AEC Rep. ANL-7683, 1970; and Burchsted et al., *Nuclear Air Cleaning Handbook,* U.S. ERDA 76-21, 1976). The filter characteristics needed included high collection efficiency on fine particles, large dust-holding capacity to give long operating life, and low maintenance requirements. The sand filters are as much as 2.7 m (9 ft) in depth and are constructed in graded layers with about a 2:1 variation in the granule size from one layer to the next. The airflow direction is upward, and the granules decrease in size in the direction of the airflow. The bottom layer is composed of rocks about 5 to 7.5 cm (2 to 3 in) in diameter, and granule sizes in successive layers decrease to 0.3 to 0.6 mm (50 to 30 mesh) in the finest layer. With superficial face velocities of about 1.5 m/min (5 ft/min), gas pressure drops of clean filters have ranged from 1.7 to 2.8 kPa (7 to 11 in water). Collection efficiencies of up to 99.98 percent with a polydisperse dioctyl phthalate aerosol of 0.7-μm mean diameter have been reported (Juvinall et al., "Sand-Bed Filtration of Aerosols: A Review of Published Information," U.S. AEC Rep. ANL-7683, 1970). Operating lives of five years or more have been attained.

***Cleanable Granular-Bed Filters*** The principal objective in the development of cleanable granular-bed filters is to produce a device that can operate at temperatures above the range that can be tolerated with fabric filters. In some of the devices, the granules are circulated continuously through the unit, then are cleaned of the collected dust and returned to the filter bed. In others, the granular bed remains in place but is periodically taken out of service and cleaned by some means, such as backflushing with air. Zenz (*Handbook of Powder Science and Technology*, 2d ed., chap. 17, ed. Fayed and Otten, Chapman and Hall, London, 1997) has provided an insightful chronological review of commercial developments of this technology during the past century and has identified the key challenges for its successful application.

A number of moving-bed granular filters have used cross-flow designs. One form of cross-flow moving-granular-bed filter, produced by the Combustion Power Company (Fig. 17-78), is currently in commercial use in some applications. The granular filter medium consists of one-eighth- to one-quarter-inch (3- to 6-mm) pea gravel. Gas face velocities range from 30 to 46 m/min (100 to 150 ft/min), and reported gas pressure drops are in the range of 0.5 to 3 kPa (2 to 12 in water). The original form of the device [Reese, *TAPPI* **60**(3): 109 (1977)] did not incorporate electrical augmentation. Collection efficiencies for submicron particles were low, and the electrical augmentation was added to correct the deficiency (Parquet, "The Electroscrubber Filter: Applications and Particulate Collection Performance," EPA-600/9-82-005c, 1982, p. 363). The electrostatic grid immersed in the bed of granules is charged to a potential of 20,000 to 30,000 V, producing an electric field between the grid and the inlet and outlet louvers that enclose the bed. No ionizing electrode is used to charge particles in the incoming gas; reliance is placed on the existence of natural charges on the dust particles. Individual dust particles commonly carry either positive or negative charges even though the net charge on the dust as a whole is normally neutral. Depending on their charges, dust particles are attracted or repelled by the electrical field and are therefore caused to deposit on the rocks in the bed.

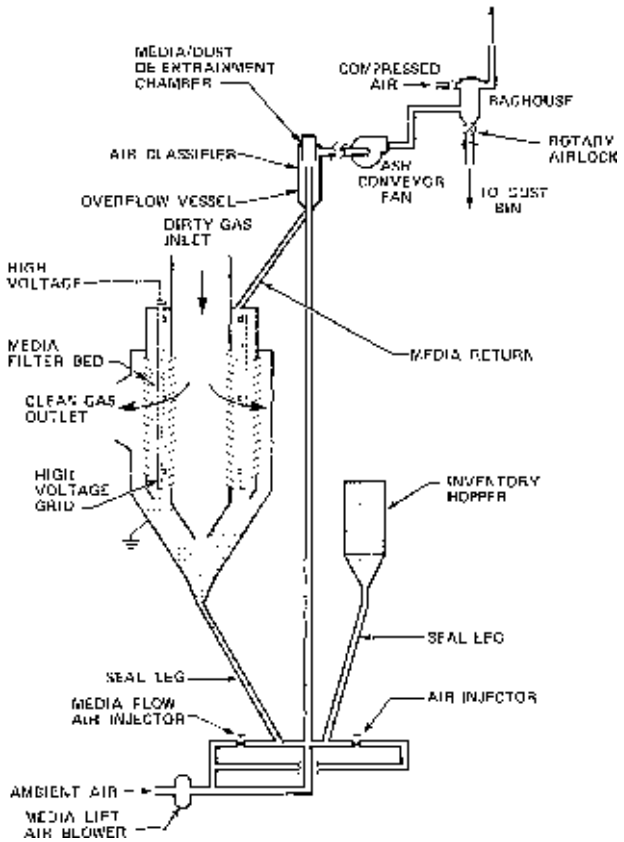

**FIG. 17-78** Electrically augmented granular-bed filter. (*Combustion Power Company.*)

Self et al. ("Electrical Augmentation of Granular Bed Filters," EPA-600/9-80-039c, 1980, p. 309) demonstrated in theoretical studies and laboratory experiments that such an augmentation system should yield substantial increases in the collection efficiency for fine particles if the particles carry significant charges. Significant improvements in the performance of the combustion power units with electrical augmentation have been reported by the manufacturer (Parquet, "The Electroscrubber Filter: Applications and Particulate Collection Performance," EPA-600/9-82-005c, 1982, p. 363).

Another type of gravel-bed filter, developed by GFE in Germany, has had limited commercial application in the United States [Schueler, *Rock Prod.* **76**(7): 66 (1973); **77**(11): 39 (1974)]. After precleaning in a cyclone, the gas flows downward through a stationary horizontal filter bed of gravel. When the bed becomes loaded with dust, the gas flow is cut off, and the bed is backflushed with air while being stirred with a double-armed rake that is rotated by a gear motor. The backflush air also flows backward through the cyclone, which then acts as a dropout chamber. Multiple filter units are constructed in parallel so that individual units can be taken off-line for cleaning. The dust dislodged from the bed and carried by the backflush air is flocculated, and part is collected in the cyclone. The backflush air with the remaining suspended dust is cleaned in the other gravel-bed filter units that are operating on-line. Performance tests made on one installation for the U.S. Environmental Protection Agency (EPA-600/7-78-093, 1978) did not give clear results, but indicated that collection efficiencies were low on particles under 2 μm and that some of the dust in the backflush air was redispersed sufficiently to penetrate the operating filter units.

**Air Filters** The types of equipment previously described are intended primarily for the collection of process dusts, whereas air filters comprise a variety of filtration devices designed for the collection of particulate matter at low concentrations, usually atmospheric dust. The difference in the two categories of equipment is not in the principles of operation but in the adaptations required to deal with the different quantities of dust. Process-dust concentrations may run as high as several hundred grams per cubic meter (or grains per cubic foot), but they usually do not exceed 45 g/m$^3$ (20 gr/ft$^3$). Atmospheric-dust concentrations that may be expected in various types of locations are shown in Table 17-15 and are generally below 12 mg/m$^3$ (5 gr/1000 ft$^3$).

**TABLE 17-15 Average Atmospheric-Dust Concentrations***

1 gr/1000 $ft^3$ = 2.3 $mg/m^3$

| Location | Dust concentration, gr/1000 $ft^3$ |
|---|---|
| Rural and suburban districts | 0.02–0.2 |
| Metropolitan districts | 0.04–0.4 |
| Industrial districts | 0.1–2.0 |
| Ordinary factories or workrooms | 0.2–4.0 |
| Excessive dusty factories or mines | 4.0–400 |

**Heating Ventilating Air Conditioning Guide*, American Society of Heating, Refrigerating and Air-Conditioning Engineers, New York, 1960, p. 77.

The harmful consequences to human health of inhaling particulate matter has been well established by many epidemiological studies. The removal of particulate matter (PM) from urban, rural, and industrial sources to achieve acceptable indoor air quality (IAQ) can be achieved by air filtration. Particulate matter can be a complex mixture of airborne dry solids, wet solids, and liquid droplets. The particles less than 10 μm in size ($PM_{10}$) are considered to be respirable particulate matter. The harmful impact of particulates smaller than 2.5 μm ($PM_{2.5}$) on the respiratory system has been particularly noted. Further, the finer fraction ($PM_{2.5}$) will also contribute to atmospheric haze and visibility.

The World Health Organization (WHO) has proposed the following guidelines for air quality:

$PM_{10}$: 20 $\mu g/m^3$ – annual mean value; 50 $\mu g/m^3$ for a 24-hour mean value

$PM_{2.5}$: 10 $\mu g/m^3$ – annual mean value; 25 $\mu g/m^3$ for a 24-hour mean value

Various regional ambient air quality standards have been developed and enforced. For instance, guidelines from the U.S. EPA are summarized in Table 17-16.

The most frequent application of air filters is in cleaning atmospheric air for building ventilation, which usually requires only moderately high collection-efficiency levels. However, a variety of industrial operations require air of extreme cleanliness, sometimes for pressurizing enclosures such as clean rooms and sometimes for use in a process itself. The presence of particulate matter can adversely affect certain production processes (e.g., the manufacture and assembly of semiconductors, pharmaceutical manufacturing, photographic and optical equipment manufacturing, painting) and the reliability of machinery (e.g., internal combustion engines, turbines, and rotating equipment). High-efficiency air filters are sometimes used for emission control when particulate contaminants are low in concentration but present special hazards; cleaning of ventilation air and other gas streams exhausted from nuclear plant operations is an example.

The recognition of concentration and size of particulate matter has a direct bearing on the performance expectations for the air filtration technology. The recovery of usable product is rarely expected, and in most cases the filter elements are meant for single use.

***Air Filter Types*** Various types of air filters are commonly used, namely

*a.* Panel filters
*b.* Viscous oil-coated panel filters
*c.* Filter or mesh pads
*d.* Bag or pocket filters
*e.* Pleated pockets or panel filters
*f.* Cartridge filters
*g.* Roll filters (dry and viscous oil-coated) for automatic renewal
*h.* High-efficiency filters (EPA—Efficiency Particulate Air filter, HEPA—High Efficiency Particulate Air filter, and ULPA—Ultra Low Penetration Air filter)

Panel filters are constructed in units of convenient size to facilitate installation, maintenance, and cleaning. Each unit consists of a cleanable or replaceable cell or filter pad in a substantial frame that may be bolted to the frames of similar units to form an airtight partition between the source of the dusty air and the destination of the cleaned air.

Panel filters may use either viscous or dry filter media. Viscous filters are so called because the filter medium is coated with a tacky liquid of high viscosity (e.g., mineral oil and adhesives) to retain the dust. The filter pad consists of an assembly of coarse fibers (now usually metal, glass, or polymer). Because the fibers are coarse and the media are highly porous, resistance to airflow is low, and high filtration velocities can be used. Media with decreasing porosity in the direction of flow are used to achieve depth filtration.

Dry filters are usually deeper than viscous filters. The dry filter media have finer fibers and have much smaller pores than the viscous media and need not rely on an oil coating to retain collected dust. Because of their greater resistance to airflow, dry filters must use lower filtration velocities to avoid excessive pressure drops. Hence, dry media must have larger surface areas and are usually pleated or arranged in the form of pockets (Fig. 17-79), generally sheets of cellulose pulp, cotton, felt, or spun glass. A PTFE membrane may be further added to increase collection efficiency. Recent introduction of nanofiber technology with a fiber diameter less than 0.5 μm to fabricate fibrous filter media has resulted in higher collection efficiencies and lower pressure drops compared to conventional media.

Bag or pocket filters are suitable for dust streams with high loading. They are usually fabricated as an array with the same frontal dimensions as the flat panel, but they provide much higher filter area and dust retention capacity. They can be designed for HEPA and ULPA performance duty.

Automatic filters are made with either viscous-coated or dry filter media. However, the cleaning or disposal of the loaded medium is essentially continuous and automatic. In most such devices, the air passes horizontally through a movable filter curtain. As the filter loads with dust, the curtain is continuously or intermittently advanced to expose clean media to the airflow and to clean or dispose of the loaded medium. Movement of the curtain can be provided by a hand crank or a motor drive. Movement of a motor-driven curtain can be actuated automatically by a differential-pressure switch connected across the filter.

***Selection of Air Filters*** The selection of a suitable air filter for a given application is about matching the process conditions and performance requirements with the performance characteristics of the filter.

*Process conditions:* Airflow rate, temperature, dust loading, particle-size distribution of dust, hazards (combustibility, toxicity), presence of liquid/mist

*Performance requirement:* Minimum acceptable efficiency (or maximum penetration) for various size fractions ($PM_{10}$, $PM_{2.5}$ and submicron), measurement of efficiency (mass vs. number of particles)

The quantification of the performance characteristics of air filters has been an evolutionary process. Having a verifiable and a meaningful rating system that is indicative of filter performance in real-world conditions has been the main goal of various standards. There are four key standards (national and international) that are relevant to air filters (see Table 17-17):

*a.* ANSI/ASHRAE 52.2-2012 (Method of Testing General Ventilation Air Cleaning Devices for Removal Efficiency by Particle Size) proposed by American Society of Heating, Refrigeration and Air-conditioning Engineers (ASHRAE)

*b.* EN 779:2012 (Particulate air filters for general ventilation—Determination of the filtration performance) proposed by CEN (Comite Europeen des Normalisations) and EUROVENT (European Committee of Air Handling & Refrigerating Equipment Manufacturers)

**TABLE 17-16 National Air Quality Standards from U.S. EPA**

| Final rule/decision | Primary (health based)/ secondary (welfare based) | Indicator | Averaging time | Level | Form |
|---|---|---|---|---|---|
| 2012<br><br>78 FR 3085<br>Jan 15, 2013 | Primary | $PM_{2.5}$ | Annual | 12.0 $\mu g/m^3$ | Annual arithmetic mean, averaged over 3 years |
| 2012<br><br>78 FR 3085<br>Jan 15, 2013 | Secondary | $PM_{2.5}$ | Annual | 15.0 $\mu g/m^3$ | Annual arithmetic mean, averaged over 3 years |
| 2012<br><br>78 FR 3085<br>Jan 15, 2013 | Primary and secondary | $PM_{2.5}$ | 24 hour | 35 $\mu g/m^3$ | 98th percentile, averaged over 3 years |
| 2012<br><br>78 FR 3085<br>Jan 15, 2013 | Primary and secondary | $PM_{10}$ | 24 hour | 150 $\mu g/m^3$ | Not to be exceeded more than once per year on average over a 3-year period |

**FIG. 17-79** Typical air filters: (*a*) panel, (*b*) pleated, (*c*) bag or pocket, (*d*) V-filter. (*American Air Filter Co.*)

*c.* Eurocode 1822 from European Committee for Standardization (see Table 17-18): This standard is applied for very high efficiency filters for ventilation and air-conditioning, such as clean rooms.

- CSN EN 1822-1: 2009—High-efficiency air filters (EPA, HEPA, and ULPA)—Part 1: Classification, performance testing, marking
- CSN EN 1822-2: 2009—High-efficiency air filters (EPA, HEPA, and ULPA)—Part 2: Aerosol production, measuring equipment, particle counting statistics
- CSN EN 1822-3: 2009—High-efficiency air filters (EPA, HEPA, and ULPA)—Part 3: Testing flat sheet filter media
- CSN EN 1822-4: 2009—High-efficiency air filters (EPA, HEPA, and ULPA)—Part 4: Determining leakage of filter elements (scan method)
- CSN EN 1822-5: 2009—High-efficiency air filters (EPA, HEPA, and ULPA)—Part 5: Determining the efficiency of filter elements

*d.* ISO 16890 (2016) for air filters for general ventilation by international standards

- ISO16890-1, Air filter for general ventilation—Part 1: Technical specifications, requirements and efficiency classification systems based on particulate matter (PM)
- ISO16890-2, Air filter for general ventilation—Part 2: Measurement of fractional efficiency and airflow resistance
- ISO16890-3, Air filter for general ventilation—Part 3: Determination of the gravimetric efficiency and the airflow resistance versus the mass of test dust captured
- ISO16890-4, Air filter for general ventilation—Part 4: Conditioning method to determine the minimum fractional test efficiency

A detailed discussion and comparison of these standards is beyond the scope of this chapter. These standards are interrelated and have followed similar evolutionary paths by addressing the deficiencies and limitations in previous versions. The reader is advised to review all the standards along with the recent prior versions for completeness.

***Air-Filtration Theory*** Current high-efficiency air- and gas-filtration methods and equipment have resulted largely from the development of filtration theory since about 1930 and particularly since the 1940s. Much of the theoretical advance was originally encouraged by the requirements of the military and atomic energy programs. The fibrous filter has served both as a practical device and as a model for theoretical and experimental investigation. Extensive reviews and new treatments of air-filtration theory and experience have been presented by Chen [*Chem. Rev.* **55:** 595 (1955)], Dorman ("Filtration," in *Aerosol Science,* ed. Davies, Academic, New York, 1966), Pich (*Theory of Aerosol Filtration by Fibrous and Membrane Filters,* in in *Aerosol Science,* ed. Davies, Academic, New York, 1966), Davies (*Air Filtration,* Academic, New York, 1973), Kirsch and Stechkina ("The Theory of Aerosol Filtration with Fibrous Filters," in *Fundamentals of Aerosol Science,* ed. Shaw, Wiley, New York, 1978), and Hinds (*Aerosol Technology: Properties, Behavior, and Measurement of Airborne Particles,* Wiley, New York, 1998).

The theoretical treatment of filtration starts with the processes of dust-particle deposition on collecting bodies, as outlined in Fig. 17-42 and Table 17-3. All the mechanisms shown in Table 17-3 may come into play, but inertial deposition, flow-line interception, and diffusional deposition are usually dominant. Electrostatic precipitation may become a major mechanism if the collecting body, the dust particle, or both, are charged. Gravitational settling is a minor influence for particles in the size range of usual interest. Thermal precipitation is nil in the absence of significant temperature gradients. Sieving is a possible mechanism only when the pores in the filter medium are smaller than or approximately equal to the particle size, and they will not be encountered in fibrous filters unless they are loaded sufficiently for a surface dust layer to form.

Filtration theory assumes that a dust particle that touches a collector body adheres to it. This assumption appears to be valid in most cases, but evidence of nonadherence, or particle bouncing, has appeared in some

**TABLE 17-17 Comparison of U.S and European Standards**

| ASHRAE 52.2-2012 Standard | | | | | |
|---|---|---|---|---|---|
| Composite Average Particle Size Efficiency, % | | | | | |

instances. Wright et al. ("High Velocity Air Filters," WADC TR 55-457, ASTIA Doc. AD-142075, 1957) investigated the performance of fibrous filters at filtration velocities of 0.091 to 3.05 m/s (0.3 to 10 ft/s), using 0.3-μm and 1.4-μm supercooled liquid aerosols and a 1.2-μm solid aerosol. The collection efficiencies agreed well with theoretical predictions for the liquid aerosols, and apparently also for the solid aerosol at filtration velocities under 0.3 m/s (1 ft/s). But at filtration velocities above 0.3 m/s, some of the solid particles failed to adhere. With a filter composed of 30-μm glass fibers and a filtration velocity of 9.1 m/s (30 ft/s), there were indications that 90 percent of the solid aerosol particles striking a fiber bounced off.

**TABLE 17-18 Classification of High-Efficiency Filters per EN 1822:2009**

| Filter class description | Filter class code | Integral value of collection efficiency,* % | Local value of penetration,* % |
|---|---|---|---|
| EPA: efficient particulate air filter | E10 | 85 | — |
| | E11 | 95 | — |
| | E12 | 99.5 | — |
| HEPA: high efficiency particulate air filter | H13 | 99.95 | 0.25 |
| | H14 | 99.995 | 0.025 |
| ULPA: ultra low penetration air filter | U15 | 99.9995 | 0.0025 |
| | U16 | 99.99995 | 0.00025 |
| | U17 | 99.999995 | 0.0001 |

*Measured for most penetrating particle size (MPPS).

Bouncing may be regarded as a defect in the particle-deposition process. However, particles that have been deposited in filters may subsequently be blown off and reentrained into the airstream (Corn, "Adhesion of Particles," in *Aerosol Science,* ed. Davies, Academic, New York, 1966; and Davies, 1966).

The theories of filtration by a fibrous filter relate only to the initial efficiency of the clean filter in the "static" period of filtration before the deposition of any appreciable quantity of dust particles. The deposition of particles in a filter increases the number of targets available to intercept particles, so collection efficiency increases as the filter loads. At the same time, the filter undergoes clogging and the pressure drop increases. No theory is available for dealing with the "dynamic" period of filtration in which collection efficiency and pressure drop vary with the loading of collected dust. The theoretical treatment of this filtration period is incomparably more complex than that for the static period. Investigators have noted that both the increase in collection efficiency and the increase in pressure drop are exponential functions of the loading of collected dust or are at least roughly so (Davies, 1966). Some empirical relationships have been derived for correlating data in particular instances.

The dust particles collected by a fibrous filter do not deposit in uniform layers on fibers, but tend to deposit preferentially on previously deposited

particles (Billings, "Effect of Particle Accumulation in Aerosol Filtration," Ph.D. dissertation, California Institute of Technology, Pasadena, 1966), forming chainlike agglomerates called *dendrites*. The growth of dendritic deposits on fibers has been studied experimentally [Billings, op. cit.; Bhutra and Payatakes, *J. Aerosol Sci.* **10:** 445 (1979)], and Payatakes and coworkers [Payatakes and Tien, *J. Aerosol Sci.***7:** 85 (1976); Payatakes, *Am. Inst. Chem. Eng. J.* **23:** 192 (1977); Payatakes and Gradon, *Chem. Eng. Sci.* **35:** 1083 (1980)] have tried to model the growth of dendrites and its influence on filter efficiency and pressure drop.

**Electrical Precipitators** When particles suspended in a gas are exposed to gas ions in an electrostatic field, they will become charged and migrate under the action of the field. The functional mechanisms of electrical precipitation may be listed as follows:

1. Gas ionization
2. Particle collection
   *a.* Production of electrostatic field to cause charging and migration of dust particles
   *b.* Gas retention to permit particle migration to a collection surface
   *c.* Prevention of reentrainment of collected particles
   *d.* Removal of collected particles from the equipment

There are two general classes of electrical precipitators: (1) single-stage, in which ionization and collection are combined; (2) two-stage, in which ionization is achieved in one portion of the equipment, followed by collection in another. Various types in each class differ essentially in the details by which each function is accomplished.

The underlying theory presented in the following paragraphs assumes that the dust concentration is small, since only very incomplete evaluations for conditions of high dust concentration have been made.

***Field Strength*** Whereas the applied potential or voltage is the quantity commonly known, it is the field strength that determines behavior in an electrostatic field. When the current flow is low (i.e., before the onset of spark or corona discharge), these are related by the following equations for two common forms of electrodes:

Parallel plates:

$$\mathscr{E} = E/B_e \tag{17-40}$$

Concentric cylinders (wire-in-cylinder):

$$\mathscr{E} = \frac{E}{r\ln(D_t/D_d)} \tag{17-41}$$

The field strength is uniform between parallel plates, whereas it varies in the space between concentric cylinders, being highest at the surface of the central cylinder. After corona sets in, the current flow will become appreciable. The field strength near the center electrode will be less than given by Eq. (17-41), and that in the major portion of the clearance space will be greater and more uniform [see Eqs. (17-46) and (17-47)].

***Potential and Ionization*** In order to obtain gas ionization, it is necessary to exceed, at least locally, the electrical breakdown strength of the gas. Corona is the name applied to such a local discharge that fails to propagate itself. Sparking is essentially an advanced stage of corona in which complete breakdown of the gas occurs along a given path. Since corona represents a local breakdown, it can occur only in a nonuniform electrical field (Whitehead, *Dielectric Phenomena—Electrical Discharge in Gases,* Van Nostrand, Princeton, N.J., 1927, p. 40). Consequently, for parallel plates, only sparking occurs at a field strength or potential difference given by the empirical expressions

$$\mathscr{E}_c = \mathscr{E}_o = \left[ k_\rho \left( 1 + \sqrt{\frac{K_o}{k_\rho B_e}} \right) \right] \tag{17-42}$$

$$E_s = \mathscr{E}_o k_\rho B_e + K_o \mathscr{E}_o \tag{17-43}$$

For air in the range of $k_\rho B_e$ from 0.1 to 2, $\mathscr{E}_o = 111.2$ and $K_o = 0.048$. Thornton [*Phil. Mag.* **28**(7): 666 (1939)] gives values for other gases. For concentric cylinders (Loeb, *Fundamental Processes of Electrical Discharge in Gases,* Wiley, New York, 1939; Peek, *Dielectric Phenomena in High-Voltage Engineering,* McGraw-Hill, New York, 1929; and Whitehead, *Dielectric Phenomena—Electrical Discharge in Gases,* Van Nostrand, Princeton, N.J., 1927, p. 40), corona sets in at the central wire when

$$\mathscr{E}_c = \mathscr{E}_o \; k_\rho \left( 1 + \sqrt{\frac{K_o}{k_\rho D_d}} \right) \tag{17-44}$$

$$E_c = \left( \frac{\xi_o k_\rho D_d}{2} \right) \left( 1 + \sqrt{\frac{K_o}{k_\rho D_d}} \right) \ln\left( \frac{D_t}{D_d} \right) \tag{17-45}$$

**TABLE 17-19 Sparking Potentials* (Small Wire Concentric in Pipe)**

| Pipe diameter, in | Sparking potential,† volts | |
|---|---|---|
| | Peak | Root mean square |
| 4 | 59,000 | 45,000 |
| 6 | 76,000 | 58,000 |
| 9 | 90,000 | 69,000 |
| 12 | 100,000 | 77,000 |

*Data reported by Anderson in Perry, *Chemical Engineers' Handbook,* 2d ed., p. 1873, McGraw-Hill, New York, 1941.

†For gases at atmospheric pressure, 100°F, containing water vapor, air, $CO_2$, and mist, and negative-discharge-electrode polarity.

For air, approximate values are $\mathscr{E}_o = 110$, $K_o = 0.18$. Corona, however, will set in only if $(D_t/D_d) > 2.718$. If this ratio is less than 2.718, no corona occurs, and only sparking will result, following the laws given by Eqs. (17-44) and (17-45) (Peek, *Dielectric Phenomena in High-Voltage Engineering,* McGraw-Hill, New York, 1929).

In practice, precipitators are usually operated at the highest voltage practicable without sparking, since this increases both the particle charge and the electrical precipitating field. The sparking potential is generally higher with a negative charge on the discharge electrode and is less erratic in behavior than a positive corona discharge. It is the consensus, however, that ozone formation with a positive discharge is considerably less than with a negative discharge. For these reasons, negative discharge is generally used in industrial precipitators, and a positive discharge is used in air-conditioning applications. Table 17-19 shows some typical values for the sparking potential for the case of small wires in pipes of various sizes. The sparking potential varies approximately directly with the density of the gas but is very sensitive to the character of any material collected on the electrodes. Even small amounts of poorly conducting material on the electrodes may markedly lower the sparking voltage. For positive polarity of the discharge electrode, the sparking voltage will be very much lower. The sparking voltage is greatly affected by the temperature and humidity of the gas, as shown in Fig. 17-80.

***Current Flow*** Corona discharge is accompanied by a relatively small flow of electric current, typically 0.1 to 0.5 mA/m$^2$ of collecting-electrode area (projected, rather than actual area). Sparking usually involves a considerably larger flow of current, which cannot be tolerated except for occasional periods of a fraction of a second duration, and then only when suitable electrical controls are provided to limit the current. However, when suitable controls are provided, precipitators have been operated continuously with a small amount of sparking to ensure that the voltage is in the correct range to ensure corona. Besides disruptive effects on the electrical equipment and electrodes, sparking will result in low collection efficiency because of reduction in applied voltage, redispersion of collected dust, and current channeling. Although an exact calculation can be made for the current flow

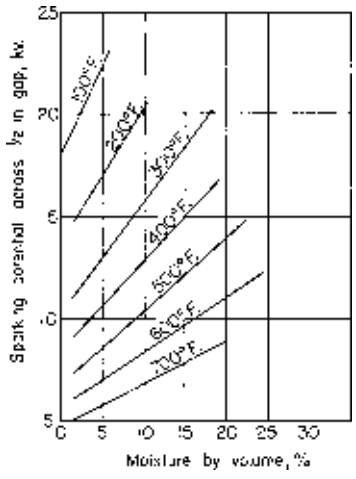

**FIG. 17-80** Sparking potential for negative point-to-plane ½-in (13-cm) gap as a function of moisture content and temperature of air at 1-atm (101.3 kPa) pressure. [*Sproull and Nakada*, Ind. Eng. Chem. ***43:*** *1356* (*1951*).]

for a direct-current potential applied between concentric cylinders, the following simpler expression, based on the assumption of a constant space charge or ion density, gives a good approximation of corona current [Ladenburg, *Ann. Phys.* **4**(5): 863 (1930)]:

$$I = \frac{8\lambda_i E(E - E_c)}{D_t^2 \ln(D_t/D_d)} \tag{17-46}$$

and the average space charge is given by (Whitehead, *Dielectric Phenomena—Electrical Discharge in Gases,* Van Nostrand, Princeton, N.J., 1927, p. 40)

$$\sigma_{avg} = \frac{4(E - E_c)}{\pi D_t^2 \varepsilon} \tag{17-47}$$

In the space outside the immediate vicinity of corona discharge, the field strength is sensibly constant, and an average value is given by

$$\mathscr{E} = \sqrt{2I/\lambda_i} \tag{17-48}$$

which applies if the potential difference is above the critical potential required for corona discharge so that a significant current flows.

Ionic mobilities are given by Loeb (*International Critical Tables,* vol. 6, McGraw-Hill, New York, 1929, p. 107). For air at 0°C, 760 mmHg, $\lambda_i$ = 624 (cm/s)/(statV/cm) for negative ions. Positive ions usually have a slightly lower mobility. Loeb (*Basic Processes of Gaseous Electronics,* University of California Press, Berkeley and Los Angeles, 1955, p. 53) gives a theoretical expression for ionic mobility of gases which is probably good to within ±50 percent:

$$\lambda_i = \frac{100.0}{k_\rho \sqrt{(\delta_g - 1)M}} \tag{17-49}$$

In general, ionic mobilities are inversely proportional to gas density. Ionic velocities in the usual electrostatic precipitator are on the order of 30.5 m/s (100 ft/s).

***Electric Wind*** By virtue of the momentum transfer from gas ions moving in the electrical field to the surrounding gas molecules, a gas circulation, known as the "electric" or "ionic" wind, is set up between the electrodes. For conditions encountered in electrical precipitators, the velocity of this circulation is on the order of 0.6 m/s (2 ft/s). Also, as a result of this momentum transfer, the pressure at the collecting electrode is slightly higher than at the discharge electrode (Whitehead, *Dielectric Phenomena—Electrical Discharge in Gases,* Van Nostrand, Princeton, N.J., 1927, p. 167).

***Charging of Particles*** [Deutsch, *Ann. Phys.* **68**(4): 335 (1922); **9**(5): 249 (1931); **10**(5): 847 (1931); Ladenburg, *Ann. Phys.* **4**(5): 863 (1930); and Mierdel, *Z. Tech. Phys.* **13:** 564 (1932).] Three forces act on a gas ion in the vicinity of a particle: attractive forces due to the field strength and to the ionic image, and repulsive forces due to the Coulomb effect. For spherical particles larger than 1 μm diameter, the ionic image effect is negligible, and charging will continue until the other two forces balance according to the equation

$$N_o = \left(\frac{\zeta \xi D_p^2}{4\varepsilon}\right)\left(\frac{\pi\sigma\varepsilon t\lambda_i}{1 + \pi\sigma\varepsilon\lambda_i t}\right) \tag{17-50}$$

The ultimate charge acquired by the particle is given by

$$N_o = \zeta \mathscr{E} D_p^2/4\varepsilon \tag{17-51}$$

and is very nearly attained in a fraction of a second. For particles smaller than 1 μm diameter, the initial charging will occur according to Eq. (17-50). However, owing to the ionic-image effect, the ultimate charge will be considerably greater because of penetration resulting from the kinetic energy of the gas ions. For charging times of the order encountered in electrical precipitation, the ultimate charge acquired by spherical particles smaller than about 1 μm diameter may be approximated (±30 percent) by the empirical expression

$$N_o = 3.4 \times 10^3 D_p T \tag{17-52}$$

Values of $N_o$ for various sizes of particles are listed in Table 17-20 for 70°F, $\zeta = 2$, and $\mathscr{E} = 10$ statV/cm.

***Particle Mobility*** By equating the electrical force acting on a particle to the resistance due to air friction, as expressed by Stokes' law, the particle velocity or mobility may be expressed by

1. For particles larger than 1 μm diameter:

$$\lambda_p = \left(\frac{u_e}{E_p}\right) = \frac{\zeta D_p E_i K_m}{12\pi\mu} \tag{17-53}$$

**TABLE 17-20 Charge and Motion of Spherical Particles in an Electric Field**

For $\zeta = 2$, and $\varepsilon = \varepsilon_i = \varepsilon_p = 10$ statV/cm

| Particle diam., μ | Number of elementary electrical charges, $N_0$ | Particle migration velocity,* $u_e$, ft/sec |
|---|---|---|
| 0.1 | 10 | 0.27 |
| .25 | 25 | .15 |
| .5 | 50 | .12 |
| 1.0 | 105 | .11 |
| 2.5 | 655 | .26 |
| 5.0 | 2,620 | .50 |
| 10.0 | 10,470 | .98 |
| 25.0 | 65,500 | 2.40 |

NOTE: To convert feet per second to meters per second, multiply by 0.3048.

2. For particles smaller than 1 μm diameter:

$$\lambda_p = \left(\frac{u_e}{\xi_p}\right) = \frac{360 K_m \varepsilon T}{\mu} \tag{17-54}$$

For single-stage precipitators, $\mathscr{E}_i$ and $\mathscr{E}_p$ may be considered essentially equal. It is apparent from Eq. (17-54) that the mobility in an electric field will be almost the same for all particles smaller than about 1 μm diameter, and hence, in the absence of reentrainment, collection efficiency should be almost independent of particle size in this range. Very small particles will actually have a greater mobility because of the Stokes-Cunningham correction factor. Values of $u_e$ are listed in Table 17-20 for 70°F, $\zeta = 2$, and $\mathscr{E} = \mathscr{E}_i = \mathscr{E}_p = 10$ statV/cm.

***Collection Efficiency*** Although actual particle mobilities may be considerably greater than would be calculated on the basis given in the preceding paragraph because of the action of the electric wind in single-stage precipitators, the latter acts in a compensating fashion, and the overall effect of the electric wind is probably to provide an equalization of particle concentration between the electrodes similar to the action of normal turbulence [Mierdel, *Z. Tech. Phys.* **13:** 564 (1932)]. On this basis, Deutsch (op. cit.) has derived the following equations for collection efficiency, the form of which had previously been suggested by Anderson on the basis of experimental data:

$$\eta = 1 - e^{-(u_e A_e/q)} = 1 - e^{-K_e u_e} \tag{17-55}$$

For the concentric-cylinder (or wire-in-cylinder) type of precipitator, $K_e = 4L_e/D_t V_e$; for rod-curtain or wire-plate types, $K_e = L_e/B_e V_e$. Strictly speaking, Eq. (17-55) applies only for a given particle size, and the overall efficiency must be obtained by an integration process for a specific dust distribution, as described in the subsection Cyclone Separators. However, over limited ranges of performance conditions, Eq. (17-55) has been found to give a good approximation of overall collection efficiency, with the term for particle migration velocity representing an empirical average value. Such values, calculated from overall collection-efficiency measurements, are given in Table 17-21 for specific installations.

For two-stage precipitators with close collecting-plate spacings (see Fig. 17-91), the gas flow is substantially streamlined, and no electric wind exists. Consequently, with reentrainment neglected, collection efficiency may be expressed as [Penny, *Electr. Eng.* **56:** 159 (1937)]

$$\eta = u_e L_e / V_e B_e \tag{17-56}$$

which holds for values of $\eta \le 1.0$. In practice, however, extraneous factors may cause the actual efficiency to approach a relationship of the type given by Eq. (17-55).

***Application*** The theoretical considerations that have been expounded should be used only for order-of-magnitude estimates, since a number of extraneous factors may enter into actual performance. In actual installations, rectified alternating current is employed. Hence the electric field is not fixed but varies continuously, depending on the waveform of the rectifier, although Schmidt and Anderson [*Electr. Eng.* **57:** 332 (1938)] report that the waveform is not a critical factor. Allowances for high dust concentrations have not been fully studied, although Deutsch (op. cit.) has presented a theoretical approach. In addition, irregularities on the discharge electrode will result in local discharges. Such irregularities can readily result from dust incrustation on the discharge electrodes due to charging of particles with opposite polarity within the thin but appreciable flow or ionization layer surrounding this electrode. Very high dust loadings increase the potential difference required for corona and reduce the current due to the space

**TABLE 17-21 Performance Data on Typical Single-Stage Electrical Precipitator Installations***

| Type of precipitator | Type of dust | Gas volume, cu ft/min | Average gas velocity, ft/sec | Collecting electrode area, sq ft | Over-all collection efficiency, % | Average particle migration velocity, ft/sec |
|---|---|---|---|---|---|---|
| Rod curtain | Smelter fume | 180,000 | 6 | 44,400 | 85 | 0.13 |
| Tulip type | Gypsum from kiln | 25,000 | 3.5 | 3,800 | 99.7 | .64 |
| Perforated plate | Fly ash | 108,000 | 6 | 10,900 | 91 | .40 |
| Rod curtain | Cement | 204,000 | 9.5 | 26,000 | 91 | .31 |

*Research-Cottrell, Inc. To convert cubic feet per minute to cubic meters per second, multiply by 0.00047; to convert feet per second to meters per second, multiply by 0.3048; and to convert square feet to square meters, multiply by 0.0929.

charge of the particles. This tends to reduce the average particle charge and reduces collection efficiency. This can be compensated for by increasing the potential difference when high dust loadings are involved.

Several investigators have tried to modify the basic Deutsch equation so that it would more nearly describe precipitator performance. Cooperman ("A New Theory of Precipitator Efficiency," Pap. 69-4, APCA meeting, New York, 1969) introduced correction factors for diffusional forces arising from variations in particle concentration along the precipitator length and also perpendicular to the collecting surface. Robinson [*Atmos. Environ.* **1**(3): 193 (1967)] derived an equation for collection efficiency in which two erosion or reentrainment terms are introduced.

An analysis of precipitator performance based on theoretical considerations was undertaken by the Southern Research Institute for the National Air Pollution Control Administration (Nichols and Oglesby, "Electrostatic Precipitator Systems Analysis," AIChE annual meeting, 1970). A mathematical model was developed for calculating the particle charge, electric field, and collection efficiency based on the Deutsch-Anderson equation. The system diagram is shown in Fig. 17-81. This system-analysis method, using high-speed computers, makes it possible to analyze what takes place in each increment of precipitator length. Collection efficiency versus particle size is computed for each 1 ft (0.3 m) of gas travel, and the inlet particle-size distribution is modified accordingly. Computed overall efficiencies compare well with measured values on three precipitators. The model assumes that field charging is the only charging mechanism. The authors considered the addition of several refinements to the program: the influence of diffusion charging; reentrainment effects due to rapping and erosion; and loss of efficiency due to maldistribution of gas, dust resistivity, and gas-property effects. The modeling technique appeared promising, but much more work was needed before it could be used for design. The same authors prepared a general treatise (Oglesby and Nichols, *A Manual of Electrostatic Precipitator Technology,* parts I and II, Southern Research Institute, Birmingham, Ala., U.S. Government Publications PB196360, 196381, 1970).

***High-Pressure, High-Temperature Electrostatic Precipitation*** In general, increased pressure increases precipitation efficiency, although a somewhat higher potential is required, because it reduces ion mobility and hence increases the potential required for corona and sparking. Increased temperature reduces collection efficiency because ion mobility is increased, lowering critical potentials, and because gas viscosity is increased, reducing migration velocities.

Precipitators have been operated at pressures up to 5.5 MPa (800 psig) and temperatures to 800°C.

The effect of increasing gas density on sparkover voltage has been investigated by Robinson [*J. Appl. Phys.* **40:** 5107 (1969); *Air Pollution Control,* part 1, Wiley-Interscience, New York, 1971, chap. 5]. Figure 17-82 shows the effect of gas density on corona-starting and sparkover voltages for positive and negative corona in a pipe precipitator. The sparkover voltages are experimental and are given by the solid points. Experimental corona-starting voltages are given by the hollow points. The solid lines are corona-starting voltage curves calculated from Eq. (17-57). This is an empirical relationship developed by Robinson.

$$\frac{E_c}{\rho'} = A\frac{B}{\sqrt{D_d\rho'/2}} \tag{17-57}$$

$E_c$ is the corona-starting field, kV/cm. $\rho'$ is the relative gas density, equal to the actual gas density divided by the density of air at 25°C, 1 atm. $D_d$ is the

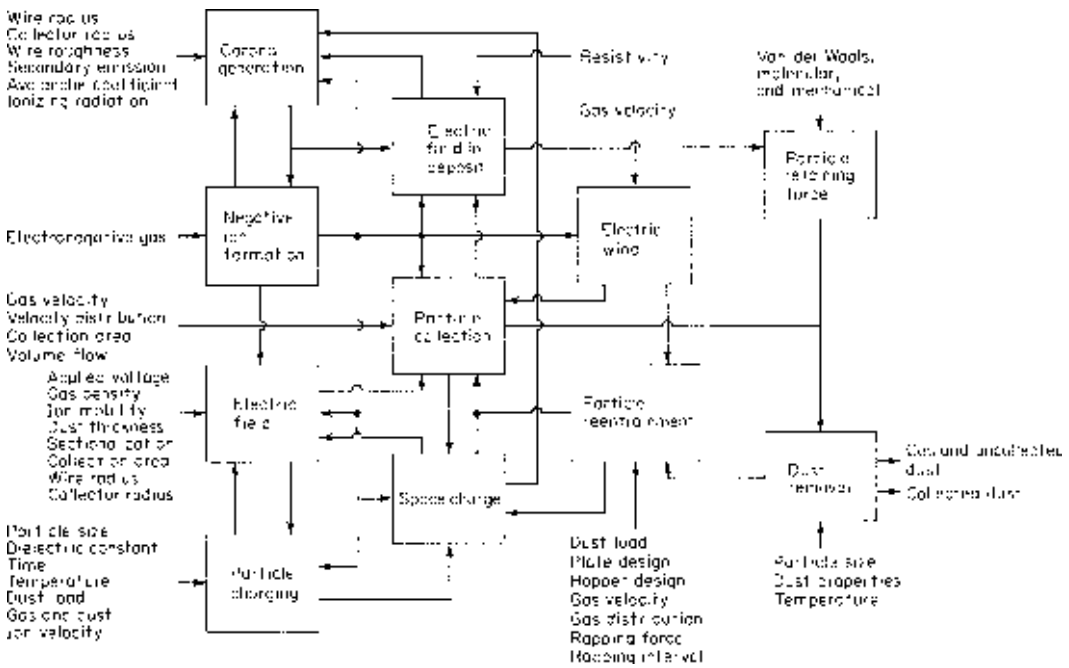

**FIG. 17-81** Electrostatic precipitator-system model. (*Nichols and Oglesby. "Electrostatuc or 300° Precipitator Systems Analysis," AIChE Annual Meeting, 1970.*)

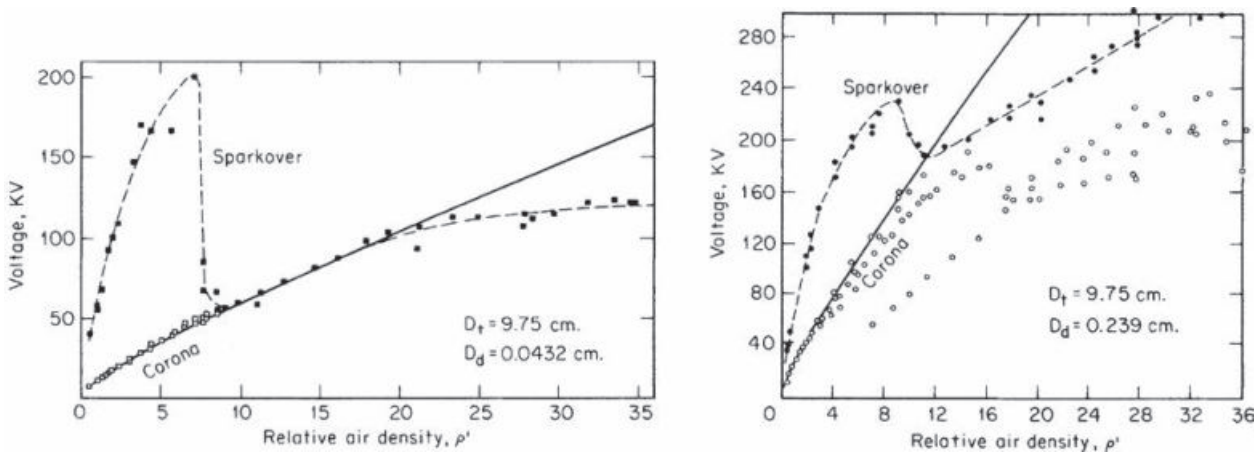

**FIG. 17-82** Corona-starting and sparkover voltages for coaxial wire-pipe electrodes in air (25°C). $D_t$ and $D_d$ are the respective pipe and wire diameter. The voltage is unvarying direct current. (*Robinson,* Air Pollution Control*, part 1, Wiley-Interscience, New York, 1971, chap. 5.*)

diameter of the ionizing wire, cm. $A$ and $B$ are constants that are characteristics of the gas. In dry air, $A = 32.2$ kV/cm and $B = 8.46$ kV/cm$^{1/2}$. Agreement between experimental and calculated starting voltages is good for the case of positive corona, but in the case of negative corona the calculated line serves as an upper limit for the data. This lower-than-expected starting-voltage characteristic of negative corona is confirmed by Hall et al. [*Oil Gas J.* **66:** 109 (1968)] in a report of an electrostatic precipitator that removes lubricating-oil mist from natural gas at 5.5 MPa (800 psig) and 38°C (100°F). The use of electrostatic precipitators at elevated pressure is expected to increase because the method requires very low pressure drop [approximately 69 Pa (0.1 lbf/in$^2$)]. This results from the fact that the electric separation forces are applied directly to the particles themselves rather than to the entire mass of the gas, as in inertial separators. The use of electrostatic precipitators at temperatures up to 400°C is well developed for the powerhouse fly-ash application, but in the range of 600°C to 800°C they are still in the experimental phase. The U.S. Bureau of Mines has tested a pilot-scale tubular precipitator for fly ash. See Shale [*Air Pollut. Control Assoc. J.* **17:** 159 (1967)] and Shale and Fasching (*Operating Characteristics of a High-Temperature Electrostatic Precipitator,* U.S. Bur. Mines Rep. 7276, 1969). It operated over a temperature range of 27°C to 816°C (80°F to 1500°F) and a pressure range of 552 kPa (35 to 80 psig). Initial collection efficiencies ranged from 90 to 98 percent at 793°C (1460°F), 552 kPa (80 psig), but continuous operation was not achieved because of excessive thermal expansion of internal parts.

***Resistivity Problems*** Optimum performance of electrostatic precipitators is achieved when the electrical resistivity of the collected dust is sufficiently high to result in electrostatic pinning of the particles to the collecting surface, but not so high that dielectric breakdown of the dust layer occurs as the corona current passes through it. The optimum resistivity range is generally considered to be from $10^8$ to $10^{10}$ Ω·cm, measured at operating conditions. As the dust builds up on the collecting electrode, it impedes the flow of current, so a voltage drop is developed across the dust layer:

$$E_d = j\rho_d L_d \tag{17-58}$$

If $E_d/L_d$ exceeds the dielectric strength of the dust layer, sparks occur in the deposit and form back-corona craters. Ions of both polarities are formed. Positive ions formed in the craters are attracted to the negatively charged particles in the gas stream, whose charge level is reduced so that collection efficiency decreases. Some of the positive ions neutralize part of the negative-space-charge cloud normally present near the wire, thereby increasing total current. Collection efficiency under these conditions will not correlate with total power input (Owens, E. I. du Pont de Nemours & Co. internal communication, 1971). Under normal conditions, collection efficiency is an exponential function of corona power (White, *Industrial Electrostatic Precipitation,* Addison-Wesley, Reading, Mass., 1963). With typical ion density in the range of $10^9$/cm$^3$, overall voltage gradient would be about 4000 V/cm, and current about 1 μA/cm$^2$. Dielectric breakdown of the dust layer (at about 10,000 V/cm) would therefore be expected for dusts with resistivities above $10^{10}$ Ω·cm.

Problems due to high resistivity are of great concern in fly-ash precipitation because air-pollution regulations require that coals have low (<1 percent) sulfur content. Figure 17-83 shows that the resistivity of low-sulfur coal ash exceeds the threshold of $10^{10}$ Ω·cm at common operating temperatures. This has resulted in the installation of a number of precipitators that have failed to meet guaranteed performance. This has occurred to an alarming extent in the United States, but it has also been encountered in Australia, where the sulfur content is typically 0.3 to 0.6 percent. Maartmann (Pap. EN-34F, 2d International Clean Air Congress, Washington, 1970) reports the installation of a number of precipitators that performed below guarantees, so the Electricity Commission of New South Wales decided that each manufacturer wishing to bid on a new station must first make pilot tests to prove performance on the actual coal to be burned in that station. Problems of back corona and excessive sparking with low-sulfur coal usually require that the operating voltage be reduced. This reduces the migration velocity and

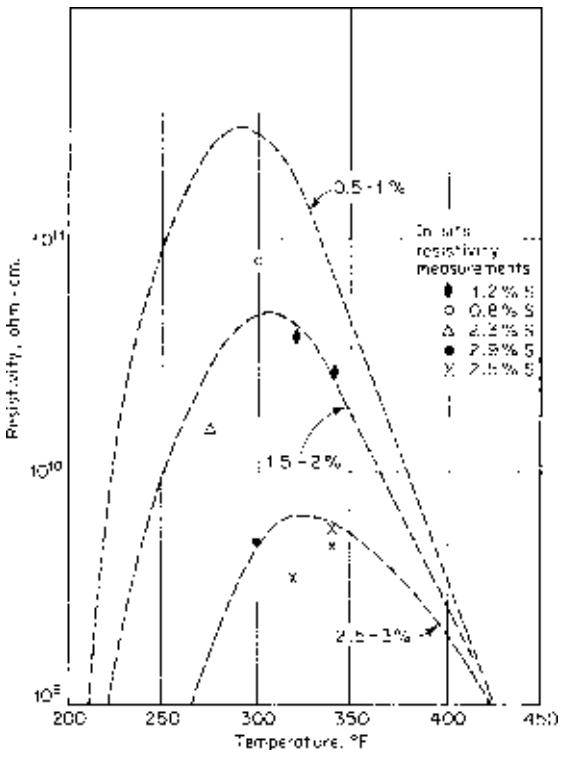

**FIG. 17-83** Trends in resistivity of fly ash with variations in the flue-gas temperature and coal sulfur content. °C = (°F − 32) × 5/9. (*Oglesby and Nichols,* A Manual of Electrostatic Precipitator Technology*, part II, Southern Research Institute, Birmingham, Ala., 1979.*)

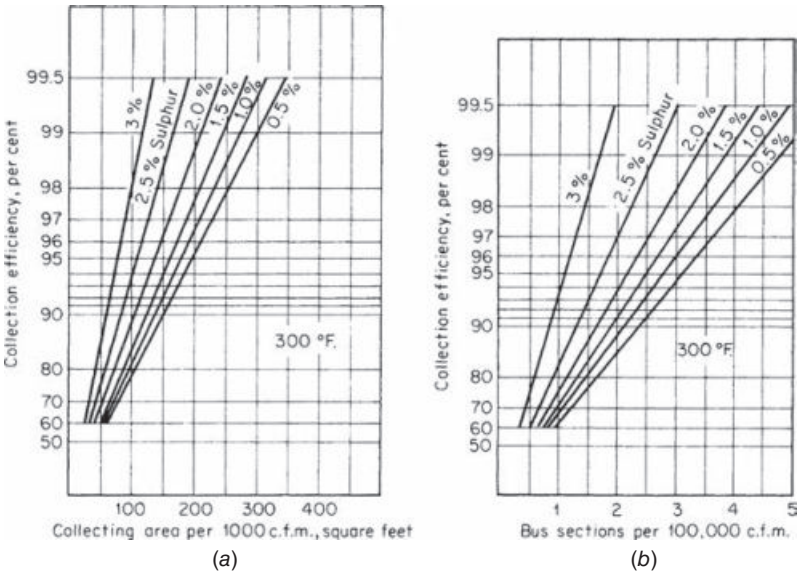

**FIG. 17-84** Design curves for electrostatic precipitators for fly ash. Collection efficiency for various levels of percent sulfur in coal versus (*a*) specific collecting surface, and (*b*) bus sections per 100,000 $ft^3$/min (4.7 $m^3$/s). °C = (°F − 32) × 5/9. (*Ramsdell*, Design Criteria for Precipitators for Modern Central Station Power Plants. *American Power Conference, Chicago, Ill., 1968.*)

leads to larger precipitators. Ramsdell (*Design Criteria for Precipitators for Modern Central Station Power Plants,* American Power Conference, Chicago, 1968) developed the curves in Fig. 17-84. They show the results of extensive field tests by the Consolidated Edison Co. In another paper ("Anti-Pollution Program of Consolidated Edison Co. of New York," ASCE, May 13–17, 1968), Ramsdell traces the remarkable growth in the size of precipitators required for high efficiency on low-sulfur coals. The culmination of this work was the precipitator at boiler 30 at Ravenswood Station, New York. Resistivity problems were avoided by operating at high temperature [343°C (650°F)]. The mechanical (cyclone) collector was installed after the precipitator to clean up puffs due to rapping.

Maartmann (Pap. EN-34F, 2d International Clean Air Congress, Washington, 1970) agrees that sulfur content is important but feels that it should not be the sole criterion for the determination of collecting surface. He points to specific collecting-surface requirements as high as 500 $ft^2/(1000\ ft^3 \cdot min)$ for 95 percent collection efficiency with high-resistivity Australian ash.

Schmidt and Anderson [*Electr. Eng.* **57:** 332 (1938)] and Anderson [*Physics,* **3:** 23 (July 1932)] claim that resistivity of the collected dust may be a controlling factor that is very sensitive to moisture. They state that an increase in relative humidity of 5 percent may double the precipitation rate because of its effect on the conductivity of the collected dust layer.

*Conditioning agents* have been added to the flue gas to alter dust resistivity. Steam, sodium chloride, sulfur trioxide, and ammonia have all been successfully used. Research by Chittum and others [Schmidt, *Ind. Eng. Chem.* **41:** 2428 (1949)] led to a theory of conditioning by alteration of the moisture-adsorption properties of dust surfaces. Chittum proposed that an intermediate chemical-adsorption film, which was strongly bound to the particle and which in turn strongly adsorbed water, would be an effective conditioner. This explains how acid conditioners, such as $SO_3$, help resistivity problems associated with basic dusts, such as many types of fly ash, whereas ammonia is a good additive for acidic dusts such as alumina. Moisture alone can be used as a conditioning agent. This is shown in Fig. 17-80. Moisture is beneficial in two ways: It reduces the electrical resistivity of most dusts (an exception is powdered sulfur, which apparently does not absorb water), and it increases the voltage, which may safely be employed without sparking, as shown in Fig. 17-80.

*Low resistivity* can sometimes be a problem. If the resistivity is below $10^4\ \Omega \cdot cm$, the collected particles are so conductive that their charges leak to ground faster than they are replenished by the corona. The particles are no longer electrostatically pinned to the plate, and they may then be swept away and reentrained in the exit gas. The particles may even pick up positive charges from the collecting plate and then be repelled. Low-resistivity problems are common with dusts of high carbon content and may also occur in fly-ash precipitators that handle the ash from high-sulfur coal and operate at low gas temperatures. Low resistivity in this case results from excessive condensation of electrically conductive sulfuric acid.

***Single-Stage Precipitators*** The single-stage type of unit, commonly known as a Cottrell precipitator, is most generally used for dust or mist collection from industrial-process gases. The corona discharge is maintained throughout the precipitator and, besides providing initial ionization, serves to prevent redispersion of precipitated dust and recharges neutralized or discharged particle ions. Cottrell precipitators may be divided into two main classes, the so-called plate type (Fig. 17-85), in which the collecting electrodes consist of parallel plates, screens, or rows of rods, chains, or wires; and the pipe type (Fig. 17-86), in which the collecting electrodes consist of a nest of parallel pipes that may be square, round, or of any other shape. The discharge or precipitating electrodes in each case are wires or rods, either round or edged, which are placed midway between the collecting electrodes or in the center of the pipes and may be either parallel or perpendicular to the gas flow in the case of plate precipitators. When the collecting electrodes are screens or rows of rods or wires, the gases are usually passed parallel to the plane of each, but they may also be passed through it. In pipe precipitators, the gas flow is generally vertical up through the pipe, although downflow is not unusual. The pipe-type precipitator is usually used for the removal of liquid particles and volatilized fumes [Cree, *Am. Gas J.* **162:** 27 (March 1945)], and the plate type is used mainly on dusts. In the pipe type, the discharge electrodes are usually suspended from an insulated support and kept taut by a weight at the bottom. Cree [*Am. Gas J.* **162:** 27 (March 1945)] discusses the application of electrical precipitators to tar removal in the gas industry.

***Rapping*** Except when liquid dispersoids are being collected or, in the case of film precipitators, when a liquid is circulated over the collecting-electrode surface (Fig. 17-87), thus continuously removing the precipitated

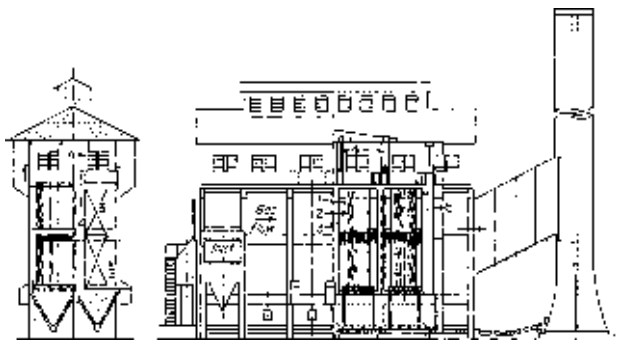

**FIG. 17-85** Horizontal-flow plate precipitator used in a cement plant. (*Western Precipitation Division, Joy Manufacturing Company.*)

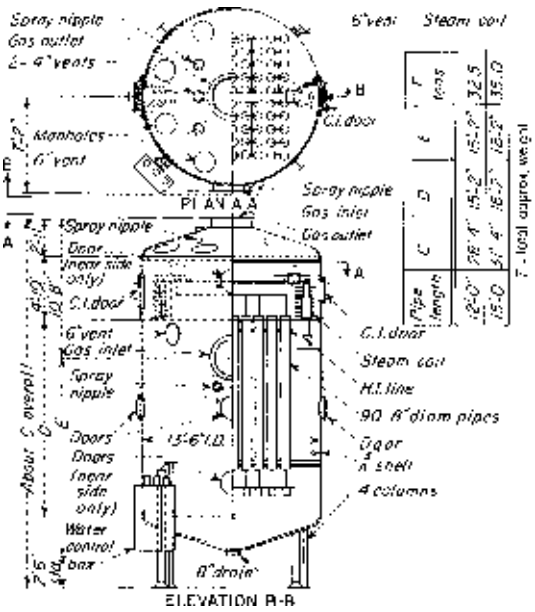

**FIG. 17-86** Blast-furnace pipe precipitator. (*Research-Cottrell, Inc.*)

material, the collected dust is dislodged from the electrodes either periodically or continuously by mechanical rapping or scraping, which may be performed automatically or manually. Automatic rapping with either impact-type or vibrator-type rappers is common practice. White (*Industrial Electrostatic Precipitation,* Addison-Wesley, Reading, Mass., 1963) recommends fairly continuous rapping with magnetic-impulse rappers. Rapping with excessive force leads to dust reentrainment and possible mechanical failure of the plates, while insufficient rapping leads to excessive dust buildup with poor electrical operation and reduced collection efficiency. Intermittent rapping at intervals of an hour or more causes heavy puffs of reentrained dust. Sproull [*Air Pollut. Control Assoc. J.* **15:** 50 (1965)] reports the importance of electrode acceleration and shows that it varies with the type of dust, whether the electrode is rapped perpendicularly (normally) to the plate or parallel to it. Figure 17-88 shows the accelerations required for

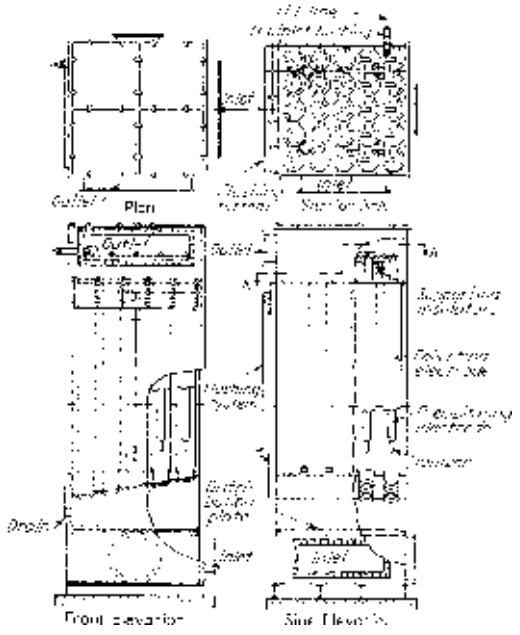

**FIG. 17-87** Two-stage water-film pipe precipitator. (*Western Precipitation Division, Joy Manufacturing Company.*)

rapping normally to the plate. Difficult dusts may require as much as 100 G acceleration for 90 percent removal, and even higher accelerations are required when the vibrating force is applied in the plane of the plate.

Perforated-plate or rod-curtain precipitators are often rapped without shutting off the gas flow and with the electrodes energized. This procedure, however, results in a tendency for reentrainment of collected dust. Sectional or composite-plate collecting electrodes (sometimes known as hollow, pocket, or tulip electrodes) are used to minimize this tendency in the continuous removal of the precipitated material, provided that it is free-flowing. These are generally designed for vertical gas flow and comprise a collecting electrode containing a dead air space and provided with horizontal protruding slots that guide the dust into this space (see Fig. 17-89), although some types use horizontal flow.

The choice of size, shape, and type of electrode is based on economic considerations and is usually determined by the characteristics of the gas and suspended matter and by mechanical considerations such as flue arrangement, the available space, and previous experience with the electrodes on similar problems. The spacing between collecting electrodes in plate-type precipitators and the pipe diameter in pipe-type precipitators usually ranges from 15 to 38 cm (6 to 15 in). The smaller the spacing, the lower the necessary voltage and overall equipment size, but the greater the difficulties involved in maintaining proper alignment and resulting from disturbances due to collected material. Large spacings are usually associated with high dust concentration in order to minimize sparkover due to dust buildup. For very high dust concentrations, such as those encountered in fluid-catalyst plants, it is advantageous to use greater spacings in the first half of the precipitator than in the second half. Precipitators, especially of the plate type, are often built with groups of collecting electrodes in series in a common housing. Collecting electrodes are generally on the order of 0.9 to 1.8 m (3 to 6 ft) wide and 3 to 5.5 m (10 to 18 ft) high in plate-type precipitators and 1.8 to 4.6 m (6 to 15 ft) high in pipe types. It is essential for good collection efficiency that the gas be evenly distributed across the various electrode elements. Although this can be achieved by proper gas-inlet transitions and guide vanes, perforated plates or screens located on the upstream side of the electrodes are generally used for distribution. Perforated plates or screens located on the downstream side may be used in special cases.

Electrical precipitators are generally designed for collection efficiency in the range of 90 to 99.9 percent. It is essential, however, that the units be properly maintained in order to achieve the required collection efficiency. Electric power consumption is generally 0.2 to 0.6 kW/(1000 $ft^3 \cdot min$) of gas handled, and the pressure drop across the precipitator unit is usually less than 124 Pa (0.5 in water), ranging from 62 to 248 Pa (¼ to 1 in) and representing primarily distributor and entrance-exit losses. Applied potentials range from 30,000 to 100,000 V. Gas velocities and retention times are generally in the range of 0.9 to 3 m/s (3 to 10 ft/s) and 1 to 15 s, respectively. Velocities are kept low in conventional precipitators to avoid reentrainment of dust. There are, however, precipitator installations on carbon black in which the precipitator acts to flocculate the dust so that it may be subsequently collected in multiple small-diameter cyclone collectors. By not trying to collect the particles in the precipitator, higher velocities may be used with a correspondingly lower investment cost.

***Power Supply*** Electrical precipitators are generally energized by rectified alternating current of commercial frequency. The voltage is stepped up to the required value by means of a transformer and then rectified. The rectifying equipment has undergone an evolution that began with the synchronous mechanical rectifier in 1904 and was followed by mercury-vapor rectifiers in the 1920s; the first solid-state selenium rectifiers were introduced about 1939. Silicon rectifiers are the latest and most widely used type, since they provide high efficiency and reliability. Automatic controls commonly are tied to voltage, current, spark rate, or some combination of these parameters. Modern precipitators use control circuits similar to those on Fig. 17-90. A high-voltage silicon rectifier is used together with a saturable reactor and means for limiting current and controlling voltage and/or spark rate. One popular method adjusts the voltage to give a specified sparking frequency (typically 50 to 150 sparks per minute per bus section). Half-wave rectification is sometimes used because of its lower equipment requirements and power consumption. It also has the advantage of longer decay periods for sparks to extinguish between current pulses.

Electrode insulators must also be designed for a particular service. The properties of the dust or mist and gas determine their design as well as the physical details of the installation. Conducting mists require special allowances such as oil seals, energized shielding cups, or air bleeds. With saturated gas, steam coils are often used to prevent condensation on the electrodes.

Typical applications in the chemical field include detarring of manufactured gas, removal of acid mist and impurities in contact sulfuric acid plants, recovery of phosphoric acid mists, removal of dusts in gases from roasters, sintering machines, calciners, cement and lime kilns, blast furnaces, carbon-black furnaces, regenerators on fluid-catalyst units, chemical-recovery

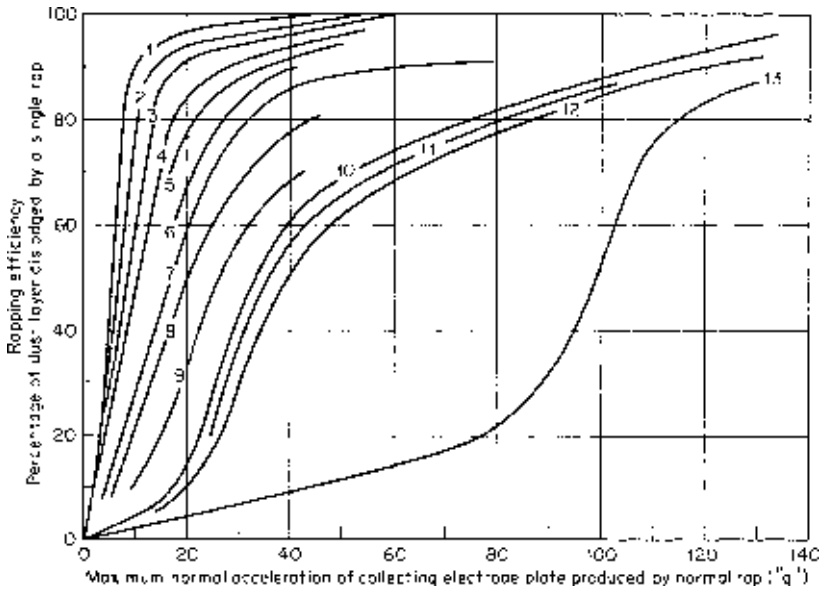

**FIG. 17-88** Normal (perpendicular) rapping efficiency for various precipitated dust layers having about 0.03 g dust/cm$^2$ (0.2 g dust/in$^2$) as a function of maximum acceleration in multiples of *g*. furnaces in soda and sulfate pulp mills, and gypsum kettles. Figure 17-89 shows a vertical-flow steel-plate-type precipitator similar to a type used for catalyst-dust collection in certain fluid-catalyst plants.

A development of interest to the chemical industry is the tubular precipitator of reinforced-plastic construction (Wanner, *Gas Cleaning Plant after $TiO_2$ Rotary Kilns,* technical bulletin, Lurgi Corp., Frankfurt, Germany, 1971). Tubes made of polyvinyl chloride plastic are reinforced on the outside with polyester-fiber glass. The use of modern economical materials of construction to replace high-maintenance materials such as lead has been long awaited for corrosive applications.

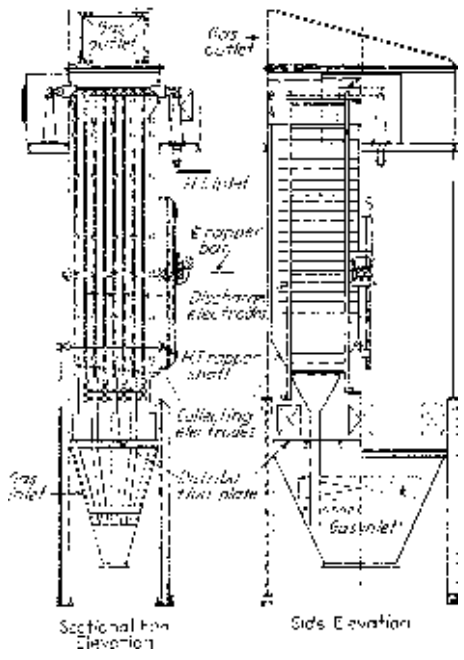

**FIG. 17-89** Vertical-flow heavy-duty plate precipitator. (*Western Precipitation Division, Joy Manufacturing Company.*)

Electrical precipitators are probably the most versatile of all types of dust collectors. Very high collection efficiencies can be obtained regardless of the fineness of the dust, provided that the precipitators are given proper maintenance. The chief disadvantages are the high initial cost and, in some cases, high maintenance costs. Furthermore, caution must be exercised with dusts that are combustible in the carrier gas.

***Two-Stage Precipitators*** In two-stage precipitators, corona discharge takes place in the first stage between two electrodes having a nonuniform field (see Fig. 17-91). This is generally obtained by a fine-wire discharge electrode and a large-diameter receiving electrode. In this stage the potential difference must be above that required for corona discharge. The second stage involves a relatively uniform electrostatic field in which charged particles are caused to migrate to a collecting surface. This stage usually consists of either alternately charged parallel plates or concentric cylinders with relatively close clearances compared with their diameters. The only voltage requirement in this stage is that no sparking occur, though higher voltages will result in increased collection efficiency. Since collection occurs in the absence of corona discharge, there is no way of recharging reentrained and discharged particles. Consequently, some means must be provided for avoiding reentrainment of particles from the collecting surface. It is also essential that there be sufficient time and mixing between the first and second stages to the secure distribution of gas ions across the gas stream and proper charging of the dust particles.

A unit is available in which electrostatic precipitation is combined with a dry-air filter of the type shown in Fig. 17-79. In another unit an electrostatic field is superimposed on an automatic filter. In this case, the ionizer wires are located on the leading face of the unit, and the collecting electrodes consist of alternate stationary and rotating parallel plates. Cleaning in this case is automatic and continuous.

Although intended primarily for air-conditioning applications, these units have been successfully applied to the collection of relatively nonconducting mists such as oil. However, other process applications have been limited largely to experimental installations. The large cost advantage of these units over the Cottrell precipitator lies in the smaller equipment size made possible by the close plate spacing, in the lower power consumption due to the two-stage operation, and primarily in the mass production of standardized units. In process applications, the close plate spacing is objectionable because of the relatively high dust concentrations involved. Special material or weight requirements for the structural members may eliminate the mass-production advantage except for individual wide applications.

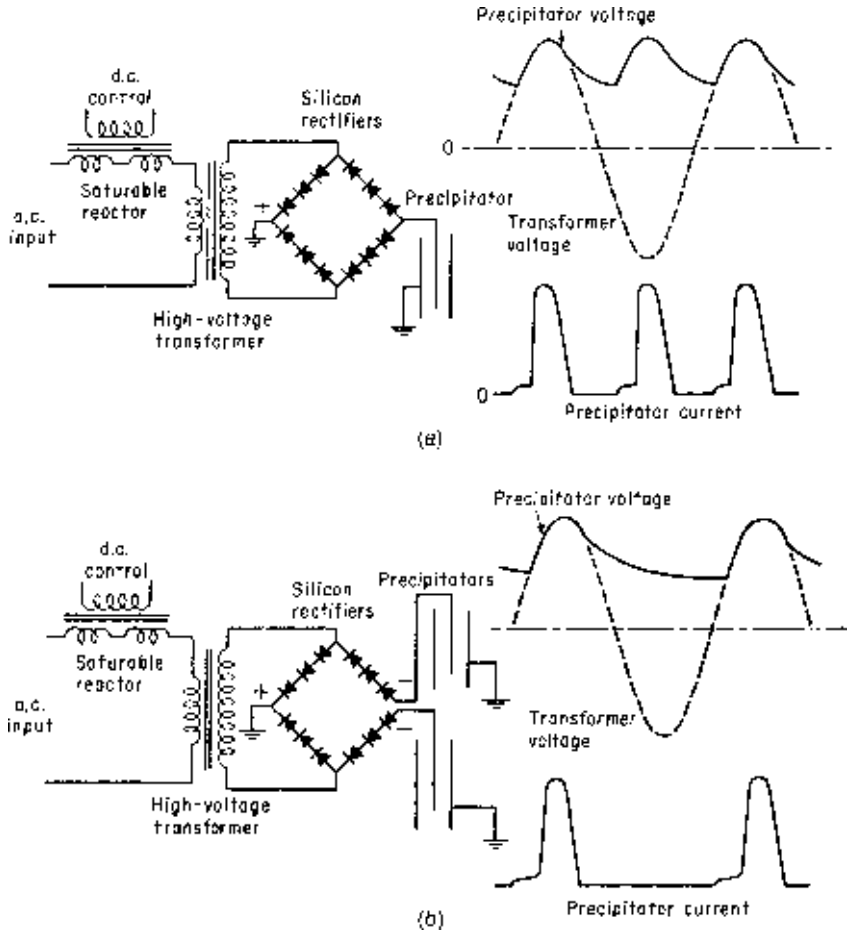

**FIG. 17-90** Schematic circuits for silicon rectifier sets with saturable reactor control. (*a*) Full-wave silicon rectifier. (*b*) Half-wave silicon rectifier. (*White,* Industrial Electrostatic Precipitation. *Addison-Wesley. Reading, Mass., 1963.*)

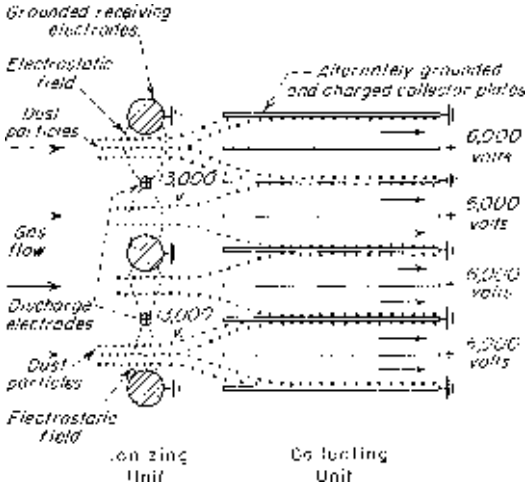

**FIG. 17-91** Two-stage electrical precipitation principle.

***Alternating-Current Precipitators*** High-voltage alternating current may be employed for electrical precipitation. Corona discharge will result in a net rectification, provided that no spark gaps are used in series with the precipitator. However, the equipment capacity for a given efficiency is considerably lower than for direct current. In addition, difficulties due to induced high-frequency currents may be encountered. The simplicity of an ac system, on the other hand, has permitted very satisfactory adaptation for laboratory and sampling purposes [Drinker, Thomson, and Fitchet, *J. Ind. Hyg.* **5:** 162 (September 1923)].

Some promising work with alternating current has been undertaken at the University of Karlsruhe. Lau [*Staub,* English ed. **29:** 10 (1969)] and coworkers found that ac precipitators operated at 50 Hz were more effective than dc precipitators for dusts with resistivities higher than 1011 $\Omega \cdot$ cm. An insulating screen covering the collecting electrode permitted higher-voltage operation without sparkover.

**Nomenclature**

| Symbol | Definition | SI units | U.S. Customary units |
|---|---|---|---|
| $c$ | Specific heat | J/(kg·k) | Btu/(lb·°F) |
| $C$ | Off-bottom impeller clearance | m | in |
| $C_o$ | Orifice coefficient | Dimensionless | Dimensionless |
| $d_o$ | Orifice diameter | m | in |
| $d_{p,\max}$ | Drop diameter | m | ft |
| $d_t$ | Pipe diameter | m | in |
| $d_t$ | Tube diameter | m | ft |
| $D$ | Impeller diameter | m | ft |
| $D_a$ | Impeller diameter | m | ft |
| $D_j$ | Diameter of jacketed vessel | m | ft |
| $D_T$ | Tank diameter | m | ft |
| $g$ | Acceleration of gravity | 9.8 m/s$^2$ | 32.2 ft/s$^2$ |
| $g_c$ | Dimensional constant | $g_c = 1$ when using SI units | 32.2 (ft·lb)/(lbf·s$^2$) |
| $h$ | Local individual coefficient of heat transfer, equals $dq/(dA)(\Delta T)$ | J/(m$^2$·s·K) | Btu/(h·ft$^2$·°F) |
| $H$ | Velocity head | m | ft |
| $k$ | Thermal conductivity | J/(m·s·K) | (Btu·ft)/(h·ft$^2$·°F) |
| $k_La$ | Overall mass transfer coefficient | s$^{-1}$ | s$^{-1}$ |
| $N$ | Agitator rotational speed | s$^{-1}$, (r/s) | s$^{-1}$, (r/s) |
| $N_{\mathrm{Fr}}$ | Froude number | Dimensionless | Dimensionless |
| $N_{js}$ | Agitator speed for just suspension | s$^{-1}$ | s$^{-1}$ |
| $N_{\mathrm{Re}}$ | $D_a^2N\rho/\mu$ impeller Reynolds number | Dimensionless | Dimensionless |
| $N_p$ | Power number = $(g_cP)/\rho N^3D_a^5$ | Dimensionless | Dimensionless |
| $N_Q$ | Impeller pumping coefficient = $Q/ND_a^3$ | Dimensionless | Dimensionless |
| $N_r$ | Impeller speed | s$^{-1}$ | s$^{-1}$ |
| $N_t$ | Impeller speed | s$^{-1}$ | s$^{-1}$ |
| $P$ | Power | (N·m/s) | ft·lb$_f$/s |
| $Q$ | Impeller flow rate | m$^3$/s | ft$^3$/s |
| $T$ | Tank diameter | m | ft |
| $\upsilon$ | Average fluid velocity | m/s | ft/s |
| $\upsilon'$ | Fluid velocity fluctuation | m/s | ft/s |
| $V$ | Bulk average velocity | m/s | ft/s |
| $Z$ | Liquid level in tank | m | ft |
| | Greek symbols | | |
| $\gamma$ | Rate of shear | s$^{-1}$ | s$^{-1}$ |
| $\Delta p$ | Pressure drop across orifice | | lbf/ft$^2$ |
| $\mu$ | Viscosity of liquid at tank temperature | Pa·s | lb/(ft·s) |
| $\mu$ | Stirred liquid viscosity | Pa·s | lb/(ft·s) |
| $\mu_b$ | Viscosity of fluid at bulk temperature | Pa·s | lb/(ft·s) |
| $\mu_c$ | Viscosity, continuous phase | Pa·s | lb/(ft·s) |
| $\mu_D$ | Viscosity of dispersed phase | Pa·s | lb/(ft·s) |
| $\mu_f$ | Viscosity of liquid at mean film temperature | Pa·s | lb/(ft·s) |
| $\mu_{\mathrm{wt}}$ | Viscosity at wall temperature | Pa·s | lb/(ft·s) |
| $\rho$ | Stirred liquid density | g/m$^3$ | lb/ft$^3$ |
| $\rho$ | Density of fluid | kg/m$^3$ | lb/ft$^3$ |
| $\rho_{\mathrm{av}}$ | Density of dispersed phase | kg/m$^3$ | lb/ft$^3$ |
| $\rho_c$ | Density | kg/m$^3$ | lb/ft$^3$ |
| $\sigma$ | Interfacial tension | N/m | lbf/ft |
| $\Phi_D$ | Average volume fraction of discontinuous phase | Dimensionless | Dimensionless |

## FLUID MIXING TECHNOLOGY

Fluid mixers are found in almost every process industry. Processes may center around one key mixer essential to the process or numerous mixers each contributing to the total process. The size of mixers can range from small laboratory mixers to large industrial mixers capable of handling many thousands of liters of product and powered by motors exceeding 750 kW (1000 hp). In many cases the power of the drive is secondary to the amount of torque (power divided by speed) transmitted by the mixer to the fluid. The diversity of applications in nearly all categories makes a simple description of mixing and agitation impossible. About the only common characteristic of fluid mixing is the promotion and improvement of uniformity in composition, dispersion, suspension, temperature, and/or other fluid properties.

Fluid mixers perform a key role in process industries, such as chemicals, polymers, pharmaceuticals, mineral processing, corn wet milling, food, pulp and paper, water and wastewater treatment, and many others. The diversity and uniqueness of fluid mixing become evident when process categories are broken down into subgroups. For instance, the mixing requirements and equipment for chemical production might be quite different depending on whether the chemical is a mass quantity of a primary chemical or a small batch of a specialty chemical. If the reaction rate is fast, intense local mixing may affect not only the productivity of the process, but also the selectivity of the products. The control of a process may depend on secondary processes, such as heat removal from an exothermic reaction. All of which may depend in part on the agitation contributed by the fluid mixer.

As further examples of different types of fluid mixing, polymerization may be done in bulk, by suspension, or in an emulsion. Each type of process has different fluid mixing requirements that must be quantified and controlled within an acceptable range. Mineral processing typically involves large quantities of material that must be processed. In some cases the processes involve the suspension of solids for dissolution or chemical reaction, including the dispersion of air for the purpose of floatation. In other mineral processing, a liquid-liquid dispersion created by fluid mixing equipment uses an ion exchange to extract the valuable metal from the ore. Corn wet milling involves several processes linked together as different parts of the corn are cooked, separated, and converted into different products. Each product stream involves multiple mixers. Pulp processing involves several chemical and physical steps to extract the fibers that go into the paper product. The chemical steps involve the addition of chemicals to help break down pulp sources, adjust the pH, and dilute or control the moisture content of the pulp on its way to the paper machine. Other fluid mixers are found beneath the paper machine, where they add water and repulp the paper if it fails to meet acceptable quality standards. Waste water processing is a necessary part of environmental control, often involving extremely large quantities of liquid, with variable composition and flow rate, but of limited intrinsic value. The objective is to get the best possible results from the minimum amount of expended energy. In all of these cases, the fluid mixers are the key processing equipment needed to convert the raw materials into the desired product. Poor mixing is rarely an acceptable alternative.

One of the difficulties in fluid mixing is describing the desired result in a way that can be related to the effects of a mixer. Mixers move fluids, which may be various combinations of liquids, solids, gases, and other liquids. The problem is that the liquid motion is not the end product. The conversion of the liquid motion into a result that promotes the production of the desired product must follow some categorization and quantification to be a practical method for the design or evaluation of mixing equipment.

One method of categorizing mixing separates applications according to the phases of the material present. One category may include just liquids, but even liquids may represent two different categories, depending on whether liquids are miscible or immiscible. Miscible liquids may involve a blending process to create uniformity, while immiscible liquids may involve a dispersion process. The dispersion might need to be separable for mass transfer or stable to form an emulsion. Applications involving both solids and liquids may be suspensions for various applications, including suspension products, dissolving solids, or even crystal formation for separation. Sometimes the mixing problem is creating the solids suspension in the first place. The addition of a powder to a liquid is sometimes quite difficult and may focus on surface motion. Gas dispersion into a liquid may have applications in mass transfer processes or even final products containing dispersed bubbles, such as air dispersions in a viscous or solid oil to make shortening for cooking. The problems only get more complicated when the mixing applications involve combinations of multiple phases, since almost any combination makes the mixing more difficult.

Combinations of miscible liquids typically are the simplest mixing category, especially for low-viscosity fluids. However, even the mixing requirements for miscible liquids will involve some description of the motion. Certainly, no motion at any place in a tank is an insufficient condition for effective mixing. Once all of the liquid is moving, some applications will require intense local turbulence to promote a fast chemical reaction. In other cases any amount of motion able to promote general uniformity may be sufficient. However, even with a single liquid, the effects of viscosity may become a problem for uniform mixing. A rotating impeller is capable of directly moving only the liquid near the impeller. However, that liquid must have sufficient momentum to move surrounding liquid, especially reaching to the sides of the tank or the surface of the liquid. Even combining two miscible liquids can be difficult if the viscosities are different. A simple blending operation may take both more time and intensity if the liquids have different viscosities. However, adding a high-viscosity liquid to a low-viscosity liquid almost always goes faster than adding the low-viscosity liquid to the high-viscosity liquid.

In addition to categorizing mixing applications by the phases of the materials present, processes can be categorized by the predominant fluid-dynamic mechanism. A simple blending application may be controlled by the bulk motion of the liquid. That motion might be characterized by the time required to accomplish blending to some degree of uniformity. Blend time correlations will be discussed later in this section. Rapid mixing in the turbulent region near the impeller can be quantified in terms of the energy dissipation, especially as power per mass. Other dynamic mixing characteristics include dispersion, whether liquid-liquid dispersion or gas-liquid dispersion. Mixer applications involving solid-liquid processes are most likely to be limited by solids suspension requirements. However, fine particles may settle slowly enough to be treated as part of the moving fluid while the mixer is running and effectively change the limitations to fluid motion, when behaving as a viscous or nonnewtonian fluid. The dispersion that might apply to solid-liquid systems is most likely to involve the breakup of agglomerates as opposed to actual particle breakage. The shear effect produced by most mixers is hydraulic shear, as opposed to mechanical shear. Hydraulic shear rarely has sufficient force to break any but the most fragile solids or weak biological cells.

Other ways of categorizing mixing include continuous or batch processes, stirred-tank or in-line mixers, rapid or slow process requirements, chemical reactions or formulations, and many other more complicated or subtle requirements. Continuous processes are expected to keep the mixer contents near a steady-state condition, with ingredient materials constantly entering, a steady conversion or blending operation, and consistent product materials constantly leaving. Batch processes may go through many different conditions, involving different liquid levels as ingredients are added or products are removed. In addition to quantity changes, the physical properties may change. Often processes designed to make products with unique physical properties may experience increased viscosity during the process, as polymer blends or emulsions are formed. Stirred tanks may operate continuously or in batches. In-line mixers always involve continuous flow through them, but they may be either single pass or recirculated flow. Some processes require rapid mixing for chemical reactions, other processes are relatively slow and may require consistent mixing for long periods of time. Chemical reactions often cause physical properties to change as a result of the reaction. Mixing will not directly cause reactions to take place, but mixing will assist the combination of reactants, circulation of products, transport of heat, or promote uniformity. Many processes done by mixing do not involve

any chemical reactions, or at least no more than pH adjustment. Such formulation processes involve the combination and blending of multiple ingredients, sometimes accompanied by dispersion or other physical mixing processes.

In all cases, mixing equipment design comes down to a combination of three basic considerations, described by: (1) the quantity of material to be processed, (2) the difficulty of the material being processed, and (3) the required mixing intensity. Each of those three factors are independent process considerations. The more material to be processed, the larger the mixer needs to be, even if the other factors are identical. Some materials are more difficult to mix—for example, a high-viscosity fluid will be more difficult to mix than a low-viscosity liquid. Similarly, rapidly settling particles will be more difficult to suspend or larger quantities of gas will be more difficult to disperse. The third factor involves how much fluid motion or mixing intensity is required for a successful process. Mixing intensity is difficult to quantify or describe on a measurable scale. Most methods for estimating mixing intensity are based on experience with similar processes or small-scale experimentation. All mixing characteristics are developed in some way from empirical studies. The empiricism is simply observation that has been sufficiently documented to be repeatable and useful.

Another problem with mixer design comes because the mixer is often purchased separately from the tank, at least in the United States. The problem is not just one of preference, but also one of practicality. Transporting a large tank is much more difficult and expensive than transporting a large mixer. Consequently, tanks are typically built and shipped regionally, but mixers can be built and shipped nationally and even internationally. Making sure that the mixer fits the tank and the mixer design in that tank provides adequate intensity for the application is part of a communication problem, requiring considerable coordination between the suppliers and users.

The final complexity of mixer design is strictly mechanical. Mechanical mixers are rotating machines with all of the design requirements for adequate strength and reliability. Most mixers have some sort of speed reduction, which must provide efficient power transmission and increased torque. The speed reduction may be accomplished by a gear reducer or belt drive or a combination of both. The output from the drive must be transferred to the impeller located some distance away in the fluid. The shaft between the drive and impeller must have adequate strength to handle torque and bending loads and be capable of operating without any destructive vibration caused by a natural frequency. Impeller blades and their attachment to the shaft must have adequate strength to operate successfully. The materials of construction must be compatible with the process fluids. The mechanical design of a mixer can be as important and sometimes as difficult as the process design.

Two important measures of power transmission that directly affect the process results are power and torque. Power input to the fluid relates to turbulent energy dissipation. Torque input is more closely related to momentum transfer to the fluid. Momentum can be interpreted as the ability of a mixer to create a velocity and move some quantity of fluid. All mixers supply power and momentum to mix fluid. The relative quantities of power and momentum will affect mixing performance, equipment design, and cost.

The available power for mixing is set by the motor size. The motor power needs to be greater than the power required to rotate the impeller(s) in the fluid. The only power applied to mixing is that which is transmitted to the fluid by the impellers. The impeller power may be considerably less than the available motor power for some mixers. For liquid blending, impeller power is a function of impeller type, impeller diameter, rotational speed, fluid density, and viscosity. Reasonably accurate estimates of impeller power can be calculated from known or measured power numbers, operating conditions, and fluid properties. The available power from the motor will have internal motor losses, friction losses through speed reducers, and possible losses through shaft seals, before it is available to the impellers and process. All of these losses must be a small percentage of the motor power for typical process mixing equipment because any power losses will create heat. High power losses are not only inefficient, but the heat may cause mechanical failures.

The amount of torque delivered to the fluid depends on both the power and the speed reduction. With the same power, the greater the speed reduction, the more torque can be transmitted to the fluid. Of course, for the torque to be applied to the fluid at a lower speed, the impeller diameter must be larger for the same amount of power. Higher torque also requires stronger speed reducers, mixer shafts, and impeller blades. Speed reducers can be seen as constant power and increased torque transmission devices.

In simplest terms common drive components should give nearly constant power transmission. Power requirements will be closely related to the operating cost of a mixer. Speed reducers will increase torque and require larger, heavier, and stronger mechanical components. Torque requirements will be closely related to the capital cost of a mixer.

## INTRODUCTION TO FLUID MECHANICS

An understanding of fluid dynamics is essential to understanding and using mixing equipment. However, some of the applicable fluid dynamics are different from those of other engineering situations. For instance, the fluid dynamics applied to the design of aircraft and naval ships both involve linear motion through an initially stagnant fluid. The boundary conditions at the wing of an aircraft or hull of a ship can be critical to performance, but the flow past the surfaces is not as complicated as the flow around a mixing impeller. Other fluid dynamics applications, such as river flow or pipe flow, involve forms of constrained, but again essentially linear, flow. Physical models such as wind tunnels, flow channels, and pump loops have been used successfully for many years to model constrained flow processes. The physical models have provided data for the validation of computer models. The successful design and improvement of aircraft and ships have been widely demonstrated using both physical and computer models.

Many of the same modeling techniques have been applied to mixing applications, with increasing success as hardware and software improve, but the limitations are often greater than the successes. Mixer geometry is more complicated, with a rotating impeller and a stationary tank providing boundary conditions for both physical and computer models. The many combinations of geometry and operating conditions are only the beginning of the complexities. In process applications, the detailed requirements of local velocities or turbulence intensities are not always well understood with respect to the corresponding process performance. It is easier to observe solids suspension performance on the basis of off-bottom suspension in a transparent tank than it is to quantify the equivalent local velocities needed at the bottom of the tank. Most mixing requirements are a cumulative average of many individual fluid dynamic effects. A successful chemical reaction carried out in a stirred tank may be a function of bulk fluid motion needed for uniformity or heat transfer, local turbulence intensity needed to bring reactants together, and flow directions needed to move reactants from one location to another.

As with other fluid dynamics applications, dimensionless groups can be developed to generalize empirical results based on the interaction between fluid motion and physical properties. The dimensionless groups used in mixing applications are different from those used in other applications. The dimensionless groups in mixing are based on the same physical principles and often represent a ratio of forces or dimensions, which generalize results, especially for scale-independent behavior.

**Impeller Reynolds Number** As with other fluid dynamics applications, mixing has a Reynolds number, which can be interpreted as the ratio of inertial to viscous forces on the impeller and is defined as:

$$N_{\mathrm{Re}} \equiv \frac{D^2 N \rho}{\mu} \tag{18-1}$$

where $D$ is the impeller diameter, $N$ is the rotational speed (as in revolutions/time, not radians/time), $\rho$ is the fluid density, and $\mu$ is the dynamic viscosity of the fluid. The impeller Reynolds number differs from a pipe Reynolds number because instead of the pipe diameter, the impeller diameter is the length dimension and instead of flow velocity, the product of impeller diameter times the rotational speed is used as a representation of impeller tip speed, not including a factor of pi. The impeller Reynolds number is a dimensionless group defined as it appears in Eq. (18-1). The magnitudes of the Reynolds number are also considerably different from pipe flow Reynolds numbers. For impeller Reynolds numbers, ranges are typically represented as:

| | |
|---|---|
| Turbulent | $N_{\mathrm{Re}} \geq 20{,}000$ |
| Transition | $20{,}000 > N_{\mathrm{Re}} > 10$ |
| Laminar | $N_{\mathrm{Re}} \leq 10$ |

These values may adequately represent the conditions in the impeller region and have been found to effectively correlate other dimensionless groups, such as the impeller power number. However, conditions away from the impeller, such as in the recirculation zone in the top third of the tank, may require a $N_{\mathrm{Re}} \geq 300{,}000$ to be fully turbulent [Machado et al., *Chem. Eng. Sci.* **98:** 218–230 (2013).]

Another essential dimensionless group for mixing is the impeller power number, which is effectively a ratio of imposed forces to inertial forces:

$$N_P \equiv \frac{P}{\rho N^3 D^5} \tag{18-2}$$

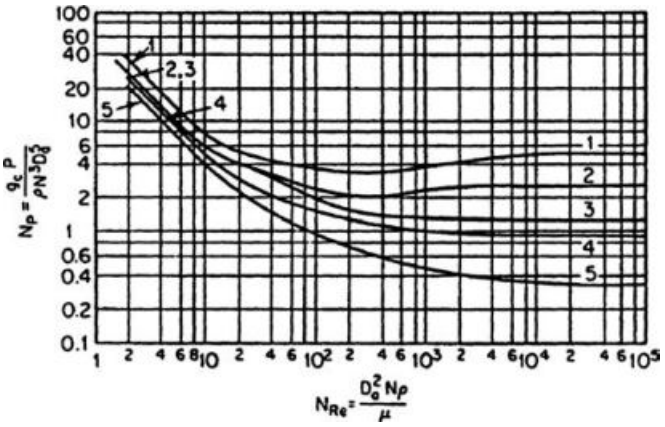

**FIG. 18-1** Impeller power number correlations as a function of Reynolds number for different impellers: Curve 1, disk-style turbine, $W/D = 1/5$, like Fig. 18-30, with six blades, in a tank with four baffles each $T/12$ wide; Curve 2, straight-blade, $W/D = 1/8$, similar to Fig. 18-4, but with six blades, in a tank with four baffles each $T/12$ wide; Curve 3, 45° pitched-blade turbine similar to Fig. 18-5, but with six blades, in a tank with four baffles, each $T/12$ wide; Curve 4, marine-style propeller, like Fig. 18-7, with pitch $2.0D$, in a tank with four baffles, each $T/10$ wide, also the same propeller in angle offset position, like Fig. 18.13, in a tank with no baffles; Curve 5, marine-style propeller, like Fig. 18-7, with pitch $1.0D$ or hydrofoil impeller like Fig. 18-6, in tank with four baffles, each $T/10$ wide, also the same propeller or hydrofoil in an angle offset position, like Fig. 18-13, in a tank with no baffles; Where $D$ = impeller diameter, $T$ = tank diameter, $g_c$ = gravitational force constant, $N$ = impeller rotational speed, $P$ = impeller power requirement, $W$ = impeller blade height, $\mu$ = dynamic viscosity of stirred fluid, and $\rho$ = density of stirred fluid. Any set of consistent units may be used, but $N$ must be rotations (rather than radians) per unit time. In metric system, $g_c$ is dimensionless and unity. [Curves 1, 2, and 3 from Bates, Fondy, and Corpstein, *Ind. Eng. Chem. Process Des. Dev.* **2:** 310 (1963) by permission of American Chemical Society, Curves 4 and 5 from Rushton, Costich, and Everett, *Chem Eng. Prog.* **46:** 395 & 467 (1950) by permission of American Institute of Chemical Engineers.]

To make the power number dimensionless, the numerator may require a gravitational force constant to convert units of force to mass.

Power numbers are shown for several different impeller types in Fig. 18-1.

The power number is defined relative to inertial forces. For baffled tanks, the impeller power number is a constant under turbulent conditions. The turbulent power number is often used as a descriptor for different types of impellers. Radial-flow impellers typically have higher power numbers than axial-flow impellers. Other impeller features have anticipated effects: wider blades increase the power number, more blades increase the power number, and so on. Power number is not the only characteristic of an impeller, but it is usually the most important characteristic and is often related to other features, such as pumping, blend time, and heat transfer.

**Impeller Power Number and Power Draw** In the turbulent range, $N_{Re} \geq 20{,}000$, the power number is a constant in a baffled tank, which means that power is proportional to the power number, density, speed cubed, and impeller diameter to the fifth power:

$$P = \rho N^3 D^5 \tag{18-3}$$

Therefore, the impeller power is a function of the impeller type as reflected in the power number. Turbulent power is directly proportional to liquid density, which is similar to a centrifugal pump for turbulent conditions.

The obvious missing effect on power is viscosity. For turbulent conditions, viscosity has no effect on power. However, as viscosity increases and Reynolds number decreases, viscosity gradually becomes a factor as indicated by the increasing power numbers in Fig. 18-1. In the viscous range at low Reynolds numbers, $N_{Re} \leq 10$, the power number becomes inversely proportional to the Reynolds number. At those conditions, impeller power becomes proportional to viscosity, but independent of density, and proportional to rotational speed squared and impeller diameter cubed.

**Dimensionless Groups** Another dimensionless group of potential interest in mixing is the Froude number, which is a ratio of inertial to gravitational forces and is expressed for impeller mixing as:

$$N_{Fr} \equiv \frac{N^2 D}{g} \tag{18-4}$$

where $g$ is the acceleration of gravity (not the gravitational force constant). The significance of the Froude number to mixing applications should be limited, since the force of gravity is a constant. The most relevant effect of the Froude number is deformation of the liquid surface, whether it is the depth of a central vortex or the height of ripples on the surface. Most other correlations involving the Froude number are more likely fortuitous relationships involving a strong function of rotational speed, rather than a gravitational effect.

Many other dimensionless ratios can be formed from mixing equipment dimensions. Geometric similarity can be a useful method for constructing and evaluating model systems. All of the length variables can be used to form geometric ratios, the most common of which are the impeller-diameter-to-tank-diameter ratio or $D/T$, the liquid-level-to-tank-diameter ratio or $H/T$, and the impeller off-bottom-clearance ratio that can be expressed in terms of tank diameter, $C/T$, impeller diameter, $C/D$, or liquid level, $C/H$.

Other dimensionless groups can be formed for process variables, such as volumetric flow rates or fluid velocities. An impeller pumping number can be written in terms of a pumping capacity as:

$$N_Q \equiv \frac{Q}{N D^3} \tag{18-5}$$

A dimensionless velocity is often written as:

$$N_v \equiv \frac{v}{N D} \tag{18-6}$$

where $v$ can be a fluid velocity measured at any location in the tank. The dimensionless velocity can be considered like a flow pattern for turbulent conditions, where all velocities are proportional to each other. Velocities near the impeller will be high, and velocities near the wall will be lower. For a given impeller type, axial or radial, the corresponding velocities will represent a typical recirculating pattern. Local velocities will be some proportion of the impeller tip speed, $v_{tip} = \pi ND$. Conservation of momentum and fluid dynamics should mean that doubling the tip speed, or rotational speed for a given impeller, should double local velocities elsewhere in a tank. Combinations of geometric similarity and dimensionless groups can be used to do scale-up from small-scale mixing tests. Other dimensionless and dimensional variables will be used to evaluate and design mixing equipment.

## MIXING EQUIPMENT

One of the essential tasks in the design of mixing equipment is accurate and effective communication. Therefore, knowing and understanding some commonly used nomenclature and impeller descriptions are an important start for the communication process. The communication must also include an accurate description of the desired process and how mixing is expected to contribute the process. For instance, "good mixing" or "well mixed" are probably not adequate descriptions for defining mixing requirements. What is good mixing for solids suspension may be quite different from good mixing for blending, especially for viscous blending. The operating conditions with similar equipment or the preferred impeller type may be different depending on the actual process requirements.

**Nomenclature for a Mixed Tank** Some widely used nomenclature for a mixed tank is shown in Fig. 18-2.

The capital letters commonly used for primary mixer dimensions are $D$ for impeller diameter, $T$ for tank diameter, and $H$ for liquid level, measured in meters for metric units. Liquid level is commonly measured from the

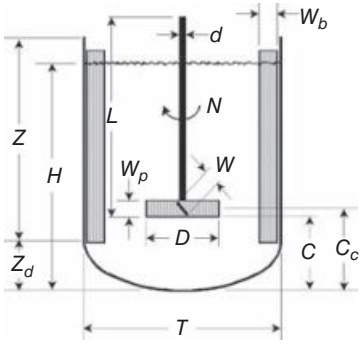

**FIG. 18-2** Typical nomenclature for an agitated tank with a center-mounted mixer.

center of the bottom of a tank. Other units either metric or imperial can be used for lengths, provided appropriate factors are used in evaluating or using dimensionless groups. A capital letter $N$ is used for rotational speed, as in revolutions per second (1/s). Other variables shown in Fig. 18-2 use forms of the capital letter $Z$ to represent the vertical dimensions of the tank, such as straight side and head depth. The baffle width, $W_b$, may sometimes be represented by the capital letter $B$. The off-bottom clearance of an impeller can be measured to either the bottom of the impeller or the centerline of the impeller. Impeller blade widths can be either actual width, $W$, or projected blade width, $W_P$, for angled blades.

A subtle, but potentially important, distinction can be made for measuring the impeller diameter. Some impeller diameters are measured as the centerline distance between opposite blades or in the case of an odd number of blades, twice the radial distance from the center of the impeller to the center of the blade tips. In the case of angled or shaped blades, the center diameter and the maximum diameter of a blade may be different, leading to some confusion about the best measurement of the diameter. This question of the diameter becomes more complicated, even with rectangular blades, which are mounted at an angle. The leading and trailing edge tips are further from the center of the impeller than the center of the blade tip. A different measure that eliminates some confusion, but can be difficult to measure, is the swept diameter of the impeller. The swept diameter is the maximum diameter measured to any point on the tip of a blade. The measurement of an impeller diameter would not be such a problem if it were not that an impeller diameter enters the power calculation to the fifth power for turbulent conditions. Taking the dimensions of a standard pitched-blade turbine (PBT), the diameter based on the edge tips of the blade is about 1 percent greater than the diameter based on the center of the blade tips. This difference results in about a 5 percent difference in a power number, depending on the impeller diameter definition. Knowing what diameter measurement was used in a power number can be important when doing power calculations. Other factors, such as baffles, impeller-to-tank-diameter ratio, and off-bottom-clearance ratio, may have a greater effect on the impeller power number [Mack and Kroll, *Chem. Eng. Prog.* **44:** 189 (1948); Bates, Fondy, and Corpstein, *I&EC Proc Des. Develop.* **2:** 310 (1963); Chapple, Kresta, Wall, and Afacan, *Trans. I. Chem. E.* **80:** 364 (2002)].

**Influence of Baffles** The largest tank effect on both mixing intensity and impeller power in turbulent agitation is the effect of baffles. In low-viscosity applications, for $N_{Re} > 1000$, baffles are essential for good mixing flow patterns with center-mount mixers. Without baffles, the predominant flow pattern is solid-body rotation of the liquid, which gives only minimal radial and axial mixing. Impeller power without baffles may be as little as one-third of the power input of a fully baffled tank. "Standard" baffles in a cylindrical tank with a center-mounted mixer, as shown in Fig. 18-2, are four vertical plates, spaced at 90-degree intervals around the tank, one-twelfth the tank diameter in width, set a short distance, about one-sixth the baffle width, off the wall of the tank. In some cases three baffles are used instead of four with little loss of performance, or baffles one-tenth of the tank diameter are used with a minor increase in the required power. Without baffles, the flow pattern often looks like what is shown in Fig. 18-3.

In Fig. 18-3, the rotational flow does not mix the fluid, and the surface vortex may draw air into the liquid. The presence of a deep vortex, especially one that reaches the impeller, is a sign of poor mixing. Baffles restrict the naturally occurring rotational flow caused by the rotating impeller. Redirection of the rotational flow by the baffles creates vertical motion at the tank wall, which also results in radial mixing because of recirculating flow patterns, as discussed in the next subsection.

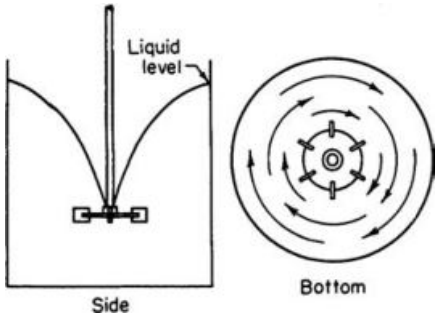

**FIG. 18-3** Typical flow pattern for either axial- or radial-flow impellers in an unbaffled tank.

**FIG. 18-4** Chemineer straight-blade turbine. (*Mixing Technologies Group of NOV.*)

Depending on the initial discharge direction from an impeller, impellers are typically categorized as either radial flow or axial flow. The straight-blade turbine shown in Fig. 18-4 drives flow outward toward the walls of a tank.

Radial-flow turbines have relatively high power numbers as shown in curves 1 and 2 in Fig. 18-1. The high power number and high power input may have advantages in applications where local energy dissipation is needed, such as for fast chemical reactions and liquid or gas dispersion. Radial-flow impellers are some of the older designs, which have been useful for many years.

By angling the blades, the pitched-blade turbine, Fig. 18-5, creates a more axial discharge.

However, because the discharge from the impeller begins to spread almost immediately, it is sometimes called a mixed-flow impeller, creating a mix of axial and radial flow. The pitched-blade turbine is almost always used to create a down-pumping flow pattern. Better circulation is achieved when the flow is directed at the solid bottom of the tank, rather than at the free surface of the liquid. Pitched-blade turbines have advantages over straight-blade turbines in liquid blending and solids suspension applications.

Further improvements in axial flow can be achieved with hydrofoil impellers, Fig. 18-6.

The term *hydrofoil* comes from the curved cross section of the blades, called camber in propeller design. The shape acts like the airfoil design of an aircraft wing by increasing the velocity across the top of the blade, gradually directing the flow downward, and increasing the axial discharge from the impeller. The three-blade, narrow-blade design shown in Fig. 18-6 is the most common hydrofoil design used in low- to moderate-viscosity liquid mixing. The combination of narrow blades and shallow pitch gives these hydrofoil impellers a low power number while efficiently creating axial flow.

**FIG. 18-5** Chemineer pitched-blade turbine (PBT). (*Mixing Technologies Group of NOV.*)

**FIG. 18-6** Chemineer narrow-blade hydrofoil impeller. (*Mixing Technologies Group of NOV.*)

These impellers are often more efficient than pitched-blade turbines in liquid blending and solids suspension applications. The shallow angle and narrow blades have limitations in some mixing applications, such as moderately viscous fluids or gas dispersion. The higher power numbers with steeper angles and wider blades on hydrofoil impellers make smaller-diameter impellers possible for side-entry mixers.

The original basis for the hydrofoil designs was the marine-type mixing impeller, Fig. 18-7.

The marine propeller efficiently converts rotational motion into axial fluid flow when applied in a mixing application. The three-blade design is common. The propeller is usually a casting, so blade shape can be almost anything, with smooth curves, helical pitch (a steeper angle nearer the hub than at the tip), and variable cross section (thicker at the center and tapered at the leading and trailing edges). While a casting has advantages for shape, castings tend to be heavy and more expensive than fabrications. The hydrofoil designs have replaced most marine propellers in mixing applications. If nothing else, large hydrofoil impellers more than 3.0 m (120 in) in diameter can be fabricated and applied in mixing applications.

**Glass-Lined Agitators** Many reactors are glass-lined for an inert, low-adhesion surface. The glass lining of the vessel and glass coating of the impeller are fragile and have a potential to crack with rapid temperature changes or at sharp corners. The tradition impeller design for glass-lined reactors is the retreat-curve impeller (RCI), Fig. 18-8.

Improved glass and coating techniques have allowed greater flexibility for impeller design in recent years, but the retreat-curve impeller remains in wide use. Also related to the limitations of glass lining, the impeller is placed near the bottom of the vessel, and a single baffle is mounted from a nozzle in the vessel head. This configuration results in a circulating flow pattern near the bottom and mixed flow near the top [Dickey et al., *CEP* **11** (2004)].

**High-Shear Devices** Applications involving the dispersion of immiscible liquids to form emulsions, the dispersion of solids for dissolving, the dispersion of particle agglomerates, such as those found in pigments, and similar dispersion processes often require special impellers. Typical dispersion impellers operate at high rotational speeds, with high tip speeds and relatively low pumping rates. One type of open-style impeller used for dispersion is a sawtooth impeller similar to the one in Fig. 18-9.

The sawtooth impellers come in many different forms with smaller or larger teeth, some aligned around the circumference of a disk, others with teeth set at angles to act more like radial-flow turbines. Because of the high tip speeds and abrasive characteristics of many dispersions, especially powder agglomerates, sawtooth blades wear out and must be replaced from time to time. Another type of high-shear device, called a rotor-stator mixer, is often used for even more intense dispersion. The rotor-stator style dispersers/homogenizers have a rotating impeller inside a close-fitting, but nonrotating, housing. The rotor and stator may have various combinations of blades, slots, and holes through which rapid changes in velocity and direction result in velocity gradients (shear) to cause dispersion. Mixers may have adequate shear to disperse immiscible liquids and break particle agglomerates, but most do not actually grind solid particles. The shear is usually more hydraulic than mechanical.

For high-viscosity and high-concentration slurry applications, several types of close-clearance impellers are used for mixing. Close-clearance impellers are typically 90 to 95 percent of the tank diameter. The use of these impellers will be discussed in more detail in the next subsection on Mixing of Viscous Fluids, Pastes, and Doughs.

## FLUID BEHAVIOR IN MIXING VESSELS

An essential part of mixer design is understanding what is needed for a process result and how the mixer will accomplish that result. One of the most important parts of understanding the mixer performance is knowing about the flow pattern and energy dissipation. Testing and understanding mixing is empirical, which means it is by observation. The observation can be visual in the laboratory using transparent vessels, indirect by instruments in pilot-plant or production equipment, or aided by computer modeling. In all cases, the more experience or sources available for evaluation, the better the mixing analysis will be.

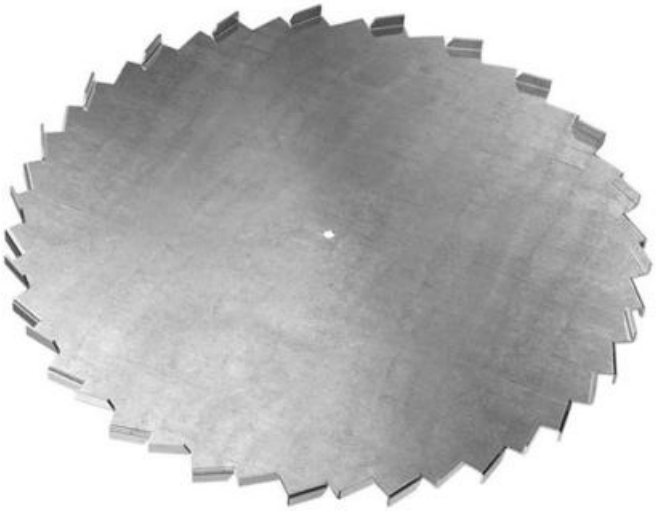

**FIG. 18-9** High-shear sawtooth impeller. (*MixerDirect, Inc.*)

Design for a process application in a stirred tank usually starts with the tank dimensions and internals. Then mixer selections need to be made for the impeller type, an impeller diameter, a rotational speed, an off-bottom clearance, and other variables. A final step should include the mechanical design of the mixer and tank support. The quantity of material to be mixed will come from the tank dimensions, or the tank dimensions will come from the desired quantity of material to be mixed. The fluid properties, such as viscosity and density for blending, will establish how difficult the mixing will be. Finally, the intensity of the mixing will be established by the impeller type, size, and rotational speed. The last three mixer characteristics will establish the power and torque input to the fluid, which will in turn provide information about the flow pattern, fluid velocities, and energy dissipation.

**Mixing Flow Patterns and CFD** Mixing flow patterns are a good place to start understanding fluid behavior in mixing vessels. Through visual observation in transparent vessels, our eyes integrate fluid motion into general flow patterns, such as axial flow with a pitched-blade turbine as shown in the computational fluid dynamics (CFD) vector plot in Fig. 18-10.

The CFD vector plot is intended to show the turbulent flow pattern of a pitched-blade turbine (PBT) in a baffled tank with the liquid level equal to the tank diameter. High velocities in the impeller discharge are represented by longer arrows, and the flow pattern is indicated by the direction of the arrows. The impeller depicted has a diameter one-third of the tank diameter and is located about the same distance off the bottom of the tank. These conditions are typical, but not essential for good mixing. For a similar tank, the impeller diameter would normally be between 25 and 50 percent of the tank diameter, with optimal diameters between 30 and 40 percent of the tank diameter, but in the extreme diameters could be between 15 and 60 percent of the tank diameter. The off-bottom clearance might be between 25 and 33 percent of the liquid level, but less for mixing partially filled tanks. A second impeller about halfway between the bottom impeller and the liquid surface may give better general mixing or extend the successful operating range to higher viscosities. Multiple impellers are needed in tall tanks.

This vector plot is easy to understand, but it presents some questionable results. If the vectors show velocities and directions, then why are the vectors at the bottom center of the tank so small? Is there a dead spot? The vectors show a downward flow pattern from the impeller to the bottom of the tank, and then up the sides of the tank to recirculate back to the top of the impeller. Why are the velocities near the surface and in the center of the recirculation loops so small? Does this impeller provide good mixing throughout the tank? The general response to all of these questions is that the CFD vector plot is a time average of velocities, but turbulent mixing is anything but average. Velocity magnitudes fluctuate greatly, probably plus or minus 75 percent or more in most locations. Velocity directions can make similar changes. The net effect of similar velocity magnitudes in opposite directions results in a zero average velocity. Average velocities may also approach zero where flow directions make sharp turns. Small velocity vectors away from the impeller may represent a combined result of a wide range of velocity magnitudes and fluctuating directions. Actual mixing is impossible to adequately represent in a still picture. Whether visually watching mixing or doing computer model calculations, the amount of local information about velocity magnitude and direction can be beyond comprehension. To make a decision about whether a mixing pattern or rotational speed is sufficient, the thousands of local velocities represented in the CFD plot must be distilled into a few key values or into an integrated quantity that represents a successful range of operating conditions. In nearly all cases, some minimum level of mixing intensity is needed to be sure that all of the tank contents move. In other situations, too much mixing intensity can be a problem.

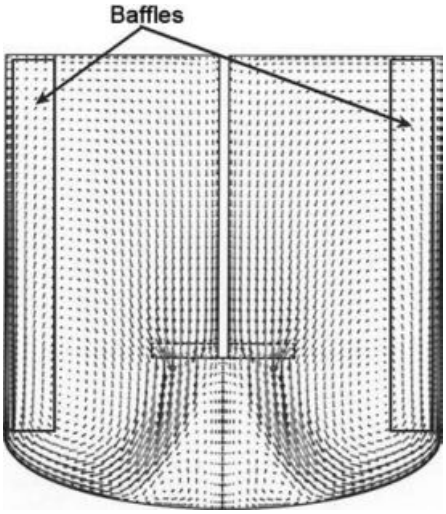

**FIG. 18-10** Typical CFD flow pattern in a baffled tank with a pitched-blade turbine.

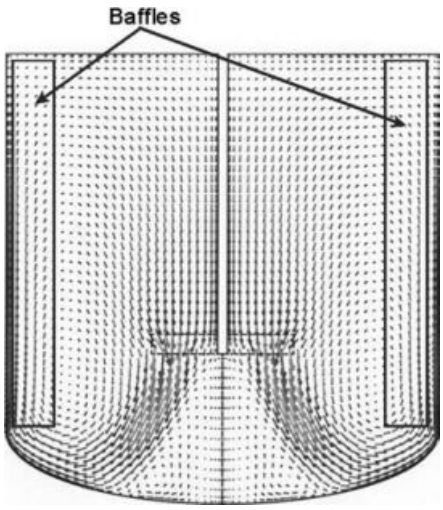

**FIG. 18-11** Typical CFD flow pattern in a baffled tank with a hydrofoil impeller.

The CFD vector plot in Fig. 18-11 represents the flow pattern for a hydrofoil impeller.

Comparing the flow pattern for the hydrofoil impeller with the pitched-blade turbine shows that the hydrofoil discharge does not spread as much as the PBT, and more of the tank bottom appears to be swept by high velocities, although vector length does not represent identical velocity magnitudes in these hydrofoil and PBT vector plots. The narrow axial discharge of the hydrofoil impeller provides excellent solids suspension with less sensitivity to off-bottom clearance than the PBT. Other axial-flow impellers have flow patterns similar to the ones shown in Figs. 18-10 and 18-11, with variations for factors like different degrees of axial flow, impeller-to-tank-diameter ratio, and off-bottom clearance.

The radial-flow pattern for a straight-blade turbine is shown in Fig. 18-12.

The radial-flow pattern shows velocities extending outward from the blade tips toward the tank walls. At the tank wall, part of the flow goes upward and part goes downward. The two directions of flow create two

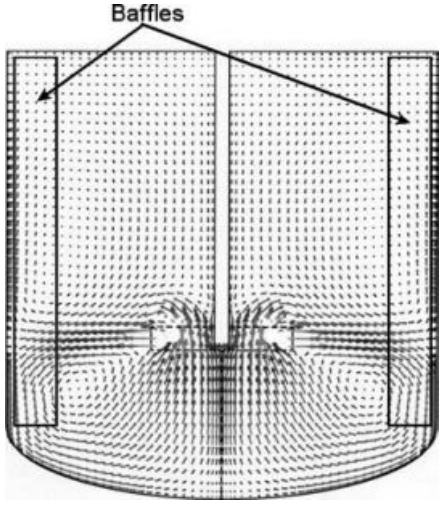

**FIG. 18-12** Typical CFD flow pattern in a baffled tank with a straight-blade turbine.

recirculating loops, one in the bottom portion of the tank and one in the top portion. The loop in the bottom of the tank appears to be stronger, primarily because the loop is smaller and tighter. The presence of two loops can create a staging effect in the tank. If a quantity of material is added to the liquid surface it will mix more quickly into the upper portion of the tank, followed by a modest delay as the material is exchanged in the impeller region, and then blend into the loop in the lower portion of the tank. This staging effect may be advantageous for liquid or gas dispersion, but disadvantageous for blending and solids suspension. If the radial-flow impeller is placed near the bottom of the tank, the discharge outward to the tank wall has only one path upward, which creates a circulation loop similar to the axial-flow impeller patterns.

Various other ways of measuring and representing flow velocities are available for the investigation of mixing patterns. Laser Doppler anemometry (LDA) uses crossed laser beams to measure velocity in a small region of a tank. For LDA to be used, the vessel and the fluid must be transparent, and obvious distortion caused by looking through a curved tank wall must be corrected to make effective measurements.

Another way to represent computationally the more complicated flow patterns in real mixing is through the simulation of tracer particle paths. These tracer paths show some of the random and variable direction of flow simulated in a dynamic model of stirred tank mixing.

**Unbaffled Tanks** Not all cylindrical tanks have baffles, and with an angled and/or an off-center mount they may not need baffles for moderate mixing requirements. Remember that an unbaffled tank with a center-mounted mixer in a low-viscosity liquid creates solid body rotation and poor mixing, as shown in Fig. 18-3. The presence of a strong surface vortex is indicative of this poorly mixed condition. To counteract the rotational flow, an off-center, angle-mounted mixer with a hydrofoil impeller or marine propeller can use the discharge flow from the impeller to counteract the natural rotational flow, Fig. 18-13.

The angle mounting provides flow that sweeps across the bottom of the tank. The off-center mounting uses the axial discharge from the impeller to counteract the inherent rotational flow. The resulting flow pattern is as close as possible to the axial-flow pattern in a baffled tank, Fig. 18-11. This type of mounting works well with small mixers [less than 2 kW (3 hp)] in small tanks (less than 5000 L). Mixing larger and taller tanks is not practical with angle-mounted mixers. Mounting a mixer at an angle with a long shaft may cause the shaft to bend or may place excessive loads on the mixer mount.

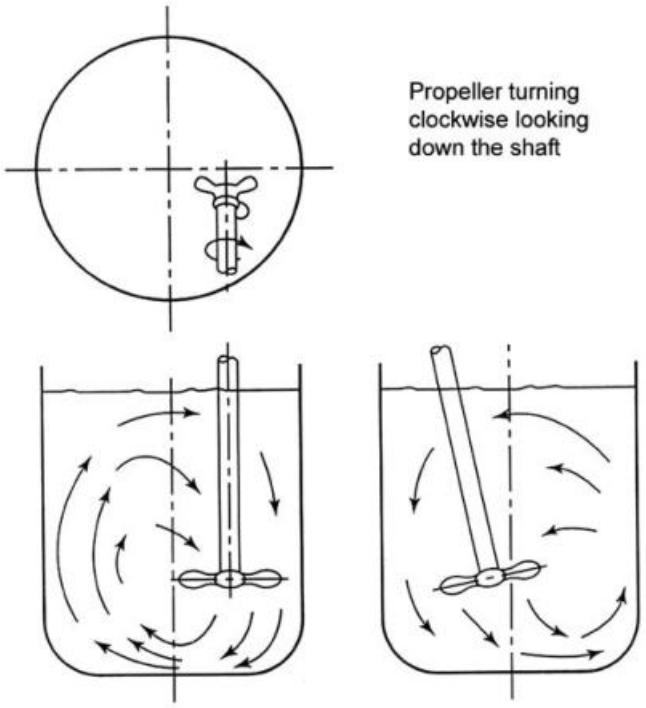

**FIG. 18-13** Typical flow pattern with a propeller or hydrofoil in an angled off-center position without baffles.

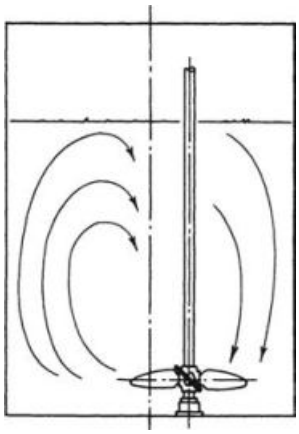

**FIG. 18-14** Typical flow pattern with propeller or hydrofoil in vertical off-center position without baffles.

An alternative mounting found in some liquid storage applications uses off-center, vertical mounting. All of these mountings can provide moderate axial, radial, and vertical mixing in tanks without baffles. For intense mixing, baffles are necessary.

Another variation for use in unbaffled vessels is a vertical off-center mount, Fig. 18-14.

These mixers are often found in pulp stock chests. The stock chest may be a concrete chamber, lined with corrosion resistant material, such as brick backed by rubber. The chest can be square or rectangular with a flat bottom. To reduce or eliminate dead spots in the corners, a concrete fillet is built to mimic the otherwise dead spot that could collect pulp. If the pulp is not moving, it will eventually rot and flake dark spots into the white paper coming off the machine.

Many other types of impellers and tank configurations are used for mixing. Draft tubes are sometimes used to create a more controlled circulation pattern in a tank. The draft tube is an open-ended cylinder perhaps half to two-thirds of the tank diameter, with an impeller placed in or below the tube to create a vertical circulation pattern, Fig. 18-15.

The draft tube often has baffles inside it to restrict rotational flow and create strong axial flow. Some draft tube impellers look like sophisticated hydrofoil impellers to take advantage of the restricted flow pattern. Draft tube mixers are often used in crystallization applications.

**Simplified Descriptions of Mixing** Some of the simplified methods representing fluid mixing intensity are power per volume, tip speed, torque per volume, turnover rate, and bulk fluid velocity. Each of these methods tries to take quantifiable impeller inputs, distribute them in the tank, and estimate how effective the mixing will be. The impeller type will have a power number and a pumping number, which will be primary factors in the estimation of power, torque, and pumping. Turnover rate and bulk fluid velocity depend on both the impeller pumping and the tank variables, like volume and impeller-to-tank-diameter ratio. The impeller size and rotational speed will establish the tip speed, or peripheral velocity, of the impeller.

The impeller diameter relative to the tank diameter, tank baffles, and discharge direction of the impeller will all influence the recirculation pattern. The recirculation influences the effectiveness of the other mixing measures. None of these fluid motion variables assure adequate or effective mixing for all applications. Some applications, such as blending, may be more influenced by liquid motion and circulation. Solids suspension applications may

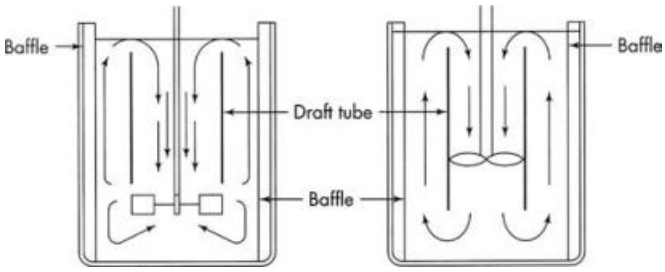

**FIG. 18-15** Different arrangements for draft tube agitation.

depend more on local velocities near the bottom of the vessel or vertical velocities in the upper part of the tank. Chemical reactions and other processes may depend on the local turbulence in the liquid.

***Power per Volume*** Power per volume, or more scientifically power per mass, would seem to be an effective measure of the energy dissipation in the tank. However, power will not be evenly distributed throughout the tank. More of the power will be dissipated near the impeller than at other locations in the tank, especially near the surface. If carrying out a chemical reaction is the process objective, one or more of the reactants may need to be introduced near the impeller. Power per volume gives a relative measure for power input in different-sized vessels or quantities of fluid. The volume used to compute power per volume is typically either the total volume of the fluid or the swept volume for the impeller rotation. Swept volume accounts for both the impeller diameter and the blade width.

***Impeller Tip Speed*** Impeller tip speed will have an obvious effect on fluid velocities near the impeller. Tip speed will be a function of both impeller diameter and rotational speed. Larger impellers and higher rotational speeds will result in higher tip speeds. The tip speed not only establishes the fluid velocity near the end of the blade, but the tip speed will also influence the relative velocity between the impeller blade and the surrounding fluid. Tip vortices are shed from each blade tip in turbulent flow. The velocity gradient between the rotational flow in the vortex and the surrounding fluid can be a major contributor to fluid shear. Velocity gradients can be related to fluid shear and may have an effect on dispersion processes. However, with a constant flow pattern in turbulent conditions, local velocities at other locations in the tank should be some fraction of the impeller tip speed. Increasing the rotational speed of a given impeller in a specific tank will also increase local fluid velocities, which may also improve mixing performance for blending and solids suspension.

***Torque per Volume*** Torque per volume is not a direct measure of mixing behavior, but it can be indirectly related to momentum transfer. Momentum transfer from the impeller to fluid does relate to the fluid motion, and conservation of momentum is a basic fact of fluid motion. On a per volume, or more accurately per mass basis, the mixing input is related to the total quantity of fluid present in a tank. The difference between a volume and mass basis is usually indistinguishable because the forces exerted on the fluid are proportional to the density, as is the fluid momentum. The unique feature of torque as a measure of mixing intensity is that the amount of fluid motion generated by torque per volume is less dependent on the impeller-diameter-to-tank-diameter ratio and more dependent on impeller type than some other measures of mixing intensity. Different impeller types require different levels of torque per volume to achieve similar amounts of fluid motion.

***Turnover Rate*** Turnover rate is pumping rate, a volumetric flow, divided by the tank volume to get a measure of the time required for impeller pumping to move a volume equivalent to the contents of the tank. The turnover rate may approximate some fraction of blend time, since multiple circulations of fluid would be required for uniform blending. The measure is not accurate because it fails to account for a flow pattern, which can be important in accomplishing a blend. However, the measure does take the pumping rate and relate it to fluid volume, much like other per-volume measures.

***Bulk Fluid Velocity*** Bulk fluid velocity is an artificial measure of mixing intensity, which uses an impeller-to-tank-diameter-ratio influenced pumping rate and averages it over the cross-sectional area of the tank. The result of a pumping rate divided by an area does have the units of a velocity. Velocity is in fact an observed measure of mixing intensity. Fluid velocity, whether observed on the surface of a production vessel or through the side of a transparent laboratory vessel, is often equated visually to mixing intensity. Higher velocities look like more intense mixing and similar velocities in different-sized vessels may appear to have similar mixing intensities. The relationship between velocity and mixing intensity is a reason for using tip speed as a scale-up criterion for liquid mixing, primarily in geometrically similar vessels.

While power per mass may have some direct relevance to energy dissipation, power per volume, tip speed, torque per volume, turnover rate, and bulk fluid velocities are all indirect measures of mixing intensity. However, these measures can be more quantifiable and accessible than more direct measures of mixing performance, like reaction rate, blend time, or solids suspension. In any case, the real measures of mixing success depend on the process result, which is often a complicated combination of mixer input and fluid dynamic effects.

**Macro Mixing** Macro mixing or bulk motion is an essential and often primary mechanism for mixing. Without transport from one location in a tank, such as on the surface, to another location, such as the region near the impeller, uniform mixing can never be achieved. A rotating impeller always creates rotational bulk motion, but radial and axial-flow impellers require baffles in low-viscosity fluids to achieve radial and vertical fluid motion. Axial flow is perhaps the most important aspect of macro mixing. Axial flow brings surface additions to the impeller region for recirculation and dispersion. Axial flow takes bottom velocity for solids suspension and moves settling solids from the bottom into the upper portion of the tank. Without effective macro mixing, stagnant or slowly moving portions of a fluid batch will not be mixed to uniformity.

**Micro Mixing** Micro mixing describes the smallest turbulent eddies before they degenerate into molecular motion, which is simply heat. All power transferred from a mixer to the fluid results in heat, regardless of the impeller type, tank size, fluid flow mechanism, or other mechanism descriptor. All mixers are 100 percent effective in converting power applied by the impeller to heat in the fluid. In the case of viscous fluids, where power requirements for mixing may be high and heat transfer may be low, fluid temperatures may rise measurably even over relatively short periods of time. Estimates for the temperature rise in a batch of fluid can be made from the applied impeller power and the heat capacity of the fluid batch. Micro mixing may be a critical mechanism for bringing reactants for a chemical reaction together.

**Meso Mixing** Meso mixing describes the mixing mechanisms between macro and micro mixing, but it has many important effects. Perhaps the best description of meso mixing involves flow structures, such as tip vortices shed by impeller blades. Tip vortices are well defined and observable forms of meso mixing. A trailing vortex leaving the tip of an axial-flow impeller blade creates a rotating velocity that moves through the surrounding fluid in a helical path. The higher velocity in the vortex passes through regions of lower velocities in the surrounding fluid. The difference between the vortex velocity and the surrounding fluid accounts for the velocity gradient that can be called fluid shear. This fluid shear may create dispersions, such as immiscible liquid-droplet dispersion, gas-bubble dispersion, or solids-agglomerate dispersion. Such mechanisms may be essential in some process mixing requirements or secondary in others. The relative importance of macro, micro, and meso mixing effects depends on the specific mixing requirements for a process.

## DESIGN OF AGITATION EQUIPMENT

Perhaps the single biggest problem in the design of agitation equipment is the diversity of mixing applications for which agitation equipment can be used. In addition to the extreme range of applications, a large diversity of equipment sizes and shapes can be used to provide the needed agitation. To further complicate the design process, different fluid properties, materials of construction, and ultimately equipment cost must all be considered in design. Agitation equipment design is different from equipment rating. In design, the starting point is effectively a clean sheet of paper onto which a series of decisions or restrictions develops the equipment configuration. In rating, the starting point is existing equipment for which mixing performance needs to be evaluated, used, improved, or modified. A *well-designed* agitator should take advantage of as many optimum characteristics as possible. A properly *rated* agitator may involve some compromises in the process performance because of equipment limitations.

**Tank Dimensions** The design of most agitation equipment begins with selection of the tank or vessel. The most widely used and studied tank design is a vertical cylinder. To serve as a fluid container, at least the bottom of the cylinder must be enclosed, and it typically has either a flat or a dished bottom, although sloped, conical, and hemispherical heads may be used. If the vessel is expected to contain a vapor or pressure, then a top head is also necessary. In the case of a pressure requirement, the head must be dished or shaped in some way to effectively transmit forces to the walls of the cylinder. Other vessels, such as square or rectangular chests and horizontal cylinders, sometimes are used for agitation applications.

Most applications and studies involve a fluid batch size where the liquid level is approximately equal to the diameter of the tank. A cylindrical tank with the liquid level equal to the tank diameter is called a square batch, which has nothing to do with the shape of the tank cross section. Most of the studied, reported, and correlated relationships for either design or rating of agitation equipment are based on the square batch geometry. In the real world, large tanks are often tall tanks because of transportation limitations on the tank's diameter. In batch processes, liquid levels may change at different points in the process, increasing as the batch is being created or decreasing as the product is being emptied. In agitation equipment design, a square batch will usually provide the best results or at least the most information about potential results.

**Impact of Baffles** For applications involving low-viscosity fluids, especially for turbulent conditions, baffles are needed to effectively control rotational flow with vertical, center-mounted agitation equipment. Standard baffles are typically four vertical plates, one-twelfth of the tank diameter in width, extending up the entire straight side of the vessel. A similar effect is created by three baffles, one-tenth the tank diameter in width. As critical as

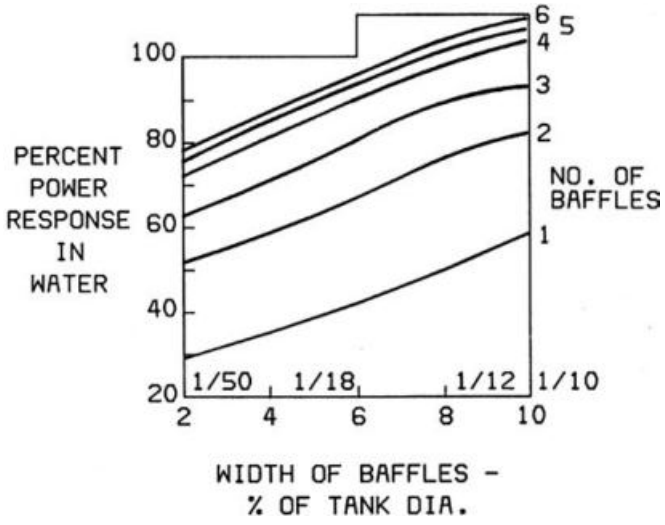

**FIG. 18-16** Baffle number and width effects on power.

impeller diameter can be for defining mixing intensity, baffle dimensions are much less important. Baffle width, length, and number can change considerably without a loss of essential function.

Figure 18-16 shows how the number of baffles and the baffle width affect impeller power in turbulent conditions. In this graph, 100 percent power is identified with standard baffles, which are four baffles each with a width of one-twelfth the tank diameter. More baffles or wider baffles will increase the impeller power requirement slightly. Narrower baffles down to 1/50 of the tank diameter are shown to decrease the power gradually. Changing the number of baffles has a relatively small effect between four, five, and six baffles, but the effect becomes more pronounced with three, two, and one baffle. The power requirement without any baffles is effectively represented by the curve for one baffle at the narrowest width, which is less than 30 percent of the power with standard baffles.

While decreased power with fewer baffles may reduce the motor load, the process results are also reduced.

Figure 18-17 shows the effect of no baffles, one baffle, and four baffles on some simple solids suspension with a pitched-blade turbine set one-quarter the liquid level off the bottom. Without any baffles, the primarily rotational flow creates a vortex on the surface and leaves a pile of unsuspended solids at the center of the bottom. The small quantity of solids near the wall of the tank is rotating around the tank with little vertical or recirculating motion. The presence of just one baffle almost eliminates the vortex on the surface and the pile of solids on the bottom. Four baffles completely suspend the solids and drive them well up into the upper part of the tank. The increased power for multiple baffles and the development of vertical motion effectively made the solids suspension successful. A strong vortex on the surface and rotational flow is usually a sign of poor mixing. The addition of baffles can drastically improve mixing by creating vertical motion and using power to create turbulence. Other information about the effect of baffles can be found in the following references: Myers, K. J., M. F. Reeder, and J. B. Fasano, *CEP* (February 2002), pp. 42-47; Fořt, I., A. Gračková, and V. Koza, *Coll. Czech. Chem. Commun.* **37:** 2371–2385 (1972).

**Mounting of Equipment** Mounting of agitation equipment has many options. The most common is top mounting, which can be either on an open tank or a closed tank. Open tank mounting can either be a vertical center mount, typically on a beam bridge support, or an offset angle mount with a clamp or external support. Closed tank mounting is usually on a nozzle, which is gusseted for support. Seals for a closed tank can be a lip seal, for dust exclusion, or a stuffing box or mechanical seal, for pressure containment. Mechanical seals can be single or double seals. Double seals with pressurized seal fluid between them can provide positive leak protection. Other mounting options include side or bottom mounting, both of which require some type of seal that can be similar to the top-mounted seal options. An additional option, primarily for a bottom entering mixer, is a magnetic drive. The magnetic drive has an external motor with rotating magnet, and on the inside of the tank is a magnetic impeller, which can link through a stationary can arrangement. The magnetic drive has no rotating seal penetration, and it provides a positive seal to prevent leakage or contamination.

**Identifying Process Requirements** Identifying process requirements can be the most difficult step in the design of agitation equipment, primarily because understanding the connection between fluid motion and process results can involve multiple factors. A simple blending problem, such as uniform storage of multiple batches of the same product, requires that all of the fluid must move and that the movement must involve transport from different regions to all other regions. Fluid motion may not be sufficient if the motion does not penetrate stratified layers or adequately move material from the bottom to the top of the tank. The presence of solids may make the problem more difficult, as will be discussed in a later subsection. Agitation problems become more difficult when formulation processes involve multiple ingredients with different properties, changing liquid levels, and various addition steps. In such cases, identifying the critical or limiting step is important, but because the agitation intensity required for one step may exceed the allowable intensity for another step, multiple impellers or variable speed may be required for successful process results. Multiple impellers may include different types of impellers, even multiple drives operating at different speeds and at different locations in the tank. In nearly all agitation applications, some minimum level of mixing intensity is required. Above that level, hopefully the mixing intensity is sufficient for good results and can be maintained over a range of process conditions. At high mixing intensity, adverse process conditions may develop, even as simply as air being drawn into a liquid batch. Understanding agitation requirements means identifying the minimum and maximum conditions for process success. Operating below the minimum or above maximum conditions may be accompanied by a rapid decline in process performance. Identifying and avoiding those rapid changes can mean the difference between process success and failure.

Process material properties directly influence the performance of agitation equipment with respect to process success. One of the most obvious material properties that must be considered in agitation is fluid viscosity. Even simple newtonian viscosities are temperature dependent, which may influence blending or heat transfer results. Viscosity is not necessarily an easy property to measure or describe, because high viscosities often include other variable properties, such as an apparent viscosity that is shear or time dependent. Nonnewtonian fluid behavior includes time-independent properties of shear thinning or shear thickening. The shear rate affecting fluid viscosity is proportional to the rotational speed of the mixer. Such shear-dependent behavior may be accompanied by a yield stress, often exhibited by a "gel" characteristic. Time-dependent fluid behavior may also be shear

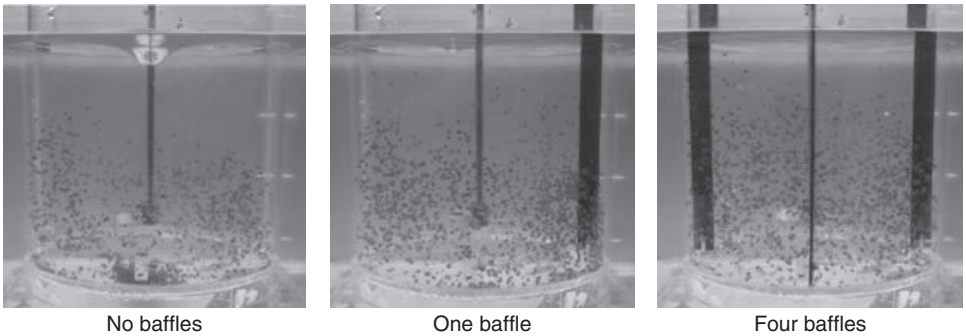

**FIG. 18-17** Effects of baffles on solids suspension with a pitched-blade turbine.

thinning or thickening, usually resulting in a hysteresis effect, which exhibits different viscosities at the same operating conditions, but depends on previous operations. Some materials also exhibit elastic return, like bread dough. Each of these viscosity characteristics will influence the selection of the most appropriate agitation equipment.

Fluid density is also an important property in agitation because impeller power is directly proportional to density in turbulent conditions. Liquid density is a relatively easy property to measure until it involves different phases, such as solids dispersed or suspended in liquid. In the case of power requirements for a solids suspension problem, fluid density includes the suspended solids at the conditions in the region of the impeller. Even though liquid density is usually a constant for agitator design, slurry density may depend on the concentration and uniformity of the suspension. Dispersed gas has an even greater effect on impeller power than just a bulk density. Gas bubbles formed in low-pressure regions behind impeller blades will alter local drag, resulting in much greater power reduction than predicted by density alone. In all multiphase agitation applications, the material properties are only part of the problem. The interaction between the phases, whether considered as dispersions or suspensions, influences the process results and the agitation requirements. Factors such as particle density relative to liquid density and particle shape are factors in solids suspension. Interfacial tension in immiscible liquid or gas dispersion is an important effect. Viscosity differences between liquid phases can be even more important than surface tension forces.

Materials of construction are also important aspects of agitator design. Materials of construction are usually chosen on the basis of the fluid chemistry or the application requirements. Because metals and metal alloys are commonly used in both tanks and mixer components, corrosion and erosion resistance can be extremely important. Corrosion resistance may be determined by previous experience or in special cases by testing. Erosion problems are usually limited to applications that involve suspended particles. Cavitation is rarely a problem in agitator design because the tip speeds are not very high, and the liquid head above the impeller is sufficiently large to prevent formation of vapor bubbles.

Equipment cost is always a consideration, but with mixing equipment the cost should not be the primary concern. In most cases, the agitation equipment is used to combine and convert raw materials into the product. The importance of selecting the right equipment can make the difference between a successful process or an expensive failure. The value of a little more than the minimum agitation intensity can mean a more rapid start-up, more reliable operation, and even additional capacity.

## LIQUID BLENDING

Uniform liquid blending is typically a minimum requirement for all types of agitation, even in multiphase processes. Few processes will cause miscible liquids to separate to an appreciable degree once they are mixed. Most multiphase processes involving mass transfer improve with uniform concentration in the continuous liquid phase.

**Fluid Motion** Fluid motion is the direct result of rotating a mixer in a quantity of fluid. The consequences of that fluid motion will hopefully provide the desired process results. Understanding the flow patterns created by a mixer is an essential first step in deciding what mixer design will accomplish specific process results. Most of the understanding of flow patterns in a stirred tank comes from experience, through observation, modeling, and process evaluation. Simply observing mixing patterns in a transparent pilot-scale vessel, using some suspended solids for flow followers, can provide insight into both the basic patterns and the complicated motion that provides effective blending uniformity.

One measure of solids suspension is called complete off-bottom suspension. This condition is observed when none of the particles remain on the bottom for more than one second. More about other degrees of solids suspension will be discussed in a following subsection. A photo of off-bottom suspension created by a pitched-blade turbine is shown in Fig. 18-18.

In this photo, a transparent baffled tank is filled with water, and a modest quantity of plastic beads are added to show both solids suspension and flow patterns. The diameter of the pitched-blade turbine is approximately one-third of the tank diameter. The tank has a dished bottom, and the impeller is located about one-fourth of the liquid level from the center of the dished bottom. The four-blade, pitched-blade turbine is operated at a speed sufficient to achieve off-bottom suspension. The picture shows that the solids are swept cleanly from the bottom of the tank and driven approximately two-thirds of the way to the liquid surface. A pitched-blade turbine is often called a mixed-flow, axial-flow impeller because the discharge flow is not strictly axial and has a significant radial component that spreads the flow across the tank cross section.

For comparison, the flow pattern and suspension capability of a hydrofoil impeller are shown in Fig. 18-19.

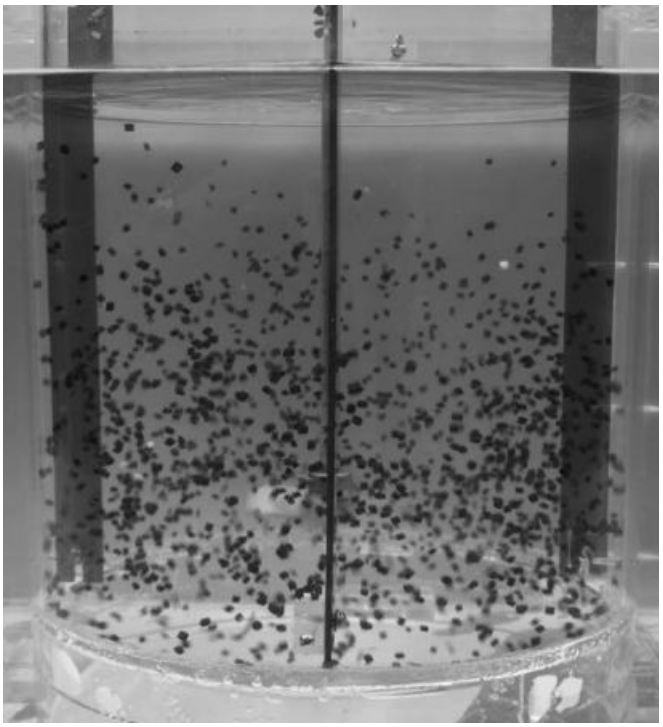

**FIG. 18-18** Off-bottom suspension with a pitched-blade turbine in a baffled tank.

The hydrofoil impeller easily achieves off-bottom suspension and drives the suspended particles further into the upper part of the tank than the pitched-blade turbine. The hydrofoil impeller has more axial flow with less of a radial component than the pitched-blade turbine. The resulting flow pattern does a more effective job of lifting settled particles from the bottom and creates a higher vertical recirculation loop in the upper part of the tank.

**FIG. 18-19** Solids suspension with a hydrofoil impeller at the same power, speed, and torque as off-bottom suspension with a pitched-blade turbine in Fig. 18-18.

The method for comparing the hydrofoil impeller to the pitched-blade turbine is intended to be industrially significant, even if a bit unconventional for academic design of experiments. The hydrofoil impeller is operated at the same speed as the pitched-blade turbine, with the same power input, which also means the same torque. With the same power, speed, and torque, the mixer drive could be identical for the two impellers. However, because the hydrofoil impeller has a lower power number ($N_P = 0.3$) than the pitched-blade turbine ($N_P = 1.3$), the hydrofoil impeller must have a larger diameter (34 percent larger) than the pitched-blade turbine. While the impeller diameter and the impeller-to-tank diameter change in the comparison, the comparison is made as if the mixer motor, drive, and essential parts of the mixer are unchanged; only the impeller is replaced and sized properly for the mixer. This type of comparison seems more practical than keeping the impeller diameter constant and trying to explain a comparison where the speed, power, or torque must be adjusted to obtain a similar level of solids suspension. While this comparison is based on solids suspension, similar comparisons can be done for other process results, such as blend time, heat transfer, or gas dispersion, with different relative results for different impellers.

A third impeller comparison with a straight-blade, radial-flow turbine is provided in Fig. 18-20.

The straight-blade turbine is running at the same speed, power, and torque as the pitched-blade turbine in Fig. 18-18. Because the straight-blade turbine has a higher power number ($N_P = 3.96$) than the pitched-blade turbine, the straight-blade turbine is smaller (80 percent of the pitched-blade diameter). However, the poorer solids suspension, with a pile sitting in the bottom center of the tank, is not just a function of the potential mixing capability of the straight-blade turbine, but rather a function of the flow pattern. The radial-flow pattern goes outward toward the tank wall and then both upward and downward. The downward pattern does not sweep the settled solids off the bottom as the axial impellers did, but rather tries to draw the solids upward off the bottom. The upward flow under the straight-blade turbine is much less effective than the downward flow from the axial impellers. The radial-flow impellers can be more effective when placed lower in the tank, as will be shown in the solids suspension subsection. Radial-flow impellers can be more effective for liquid-liquid dispersion and gas dispersion than the axial impellers. Different impeller types have different functions and are used successfully in different applications.

**Blend Time** Blend time for miscible liquids can be an effective measure of process performance for single-phase liquid applications. A typical "blend time" is considered to be the time required to blend to some degree of uniformity, for example, 95 percent, the surface addition of a small quantity of miscible liquid with similar density and viscosity to an agitated batch of liquid. The two most common measurement techniques are either a color change observation in a transparent tank or a concentration measuring probe located at a slowly mixed location in the tank. Blend time measurements have been made for several impeller types, liquid levels, and fluids of different viscosities. The product of rotational speed times blend time forms a dimensionless blend time, which can be correlated with geometry and fluid property variables. In effect, the rotational speed of the impeller becomes the clock for blending, and the uniformity is a function of the number of revolutions of the impeller. For turbulent conditions, this dimensionless blend time is a constant for turbine impellers rotating in a baffled tank.

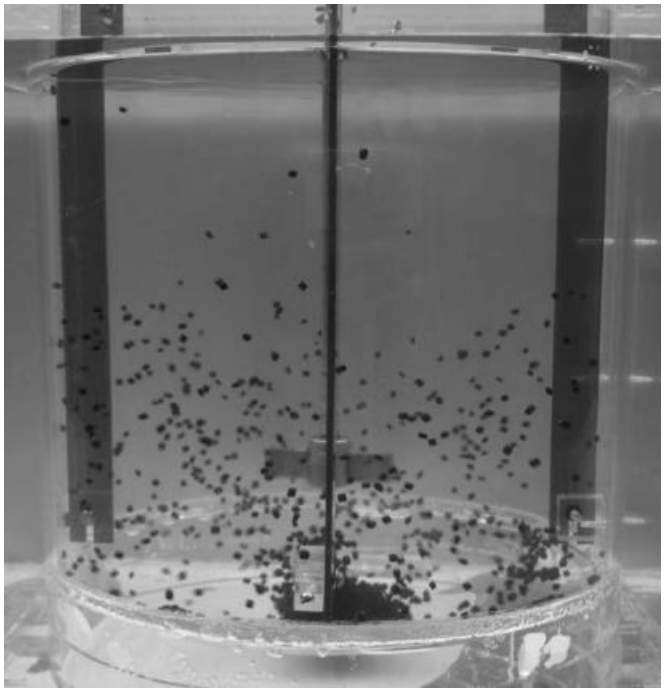

**FIG. 18-20** Solids suspension with a straight-blade turbine at the same power, speed, and torque as off-bottom suspension with a pitched-blade turbine in Fig. 18-18.

The simplest visual observation method for blend time involves just the addition of a quantity of dye to the agitated batch of liquid. This method, while simple and quick, has limitations. The most obvious limitation, even in a clear liquid, is that the dye will obstruct a view of the last area of clear liquid. Not knowing when the last location of incomplete mixing disappeared gives only an approximation to the total mixing time. However, the addition of a dye will give a quick indication of blend time or blending problems, even in an opaque liquid.

The better method for visual observation of blend time is with a color change indication, going from color to clear. With this method, the final location of complete mixing is the place where the color is last to disappear. One of the simplest color change methods is using a pH indicator, such as phenolphthalein. Phenolphthalein goes from a pink color to clear around a pH of 7.0. So the addition of a quantity of acid to a caustic solution with an indicator will cause the color indicator to disappear at the final point of mixing. To give a strong color change without uncertainty, the change is often done at 50 percent uniformity, resulting from a sufficient acid addition to change the blended pH from 8.0 to 6.0. Then, by assuming that the blending process involved an exponential decay from unmixed to mixed percentages of uniformity, we can estimate other degrees of uniformity. The time for 95 percent uniformity can be estimated from the 50 percent color change by the following formula:

$$\Theta_{95} = \Theta_{50} \frac{\ln(1-0.95)}{\ln(1-0.50)} = 4.32\Theta_{50} \tag{18-7}$$

Achieving 95 percent uniformity will take 4.32 times as long as the observed 50 percent uniformity blend time. Other degrees of uniformity can be estimated by adjusting the fractions in Eq. (18-7). The two obvious limitations of observing blending color changes are (1) that the experiments need to be conducted in a transparent tank and (2) the liquid must also be transparent.

To conduct blend time experiments in a metal tank, some type of measurement probe is more practical. Studies have been done using ionic solutions and temperature changes. Of course, the response time of the measurement device needs to be considered depending on the tank size and anticipated blend time. For turbulent conditions ($N_{Re} > 6400$) dimensionless blend times measured by a conductivity probe were found to correlate with the following expression:

$$N\Theta_{95} = \frac{5.20}{N_P^{1/3}} \left(\frac{T}{D}\right)^2 \tag{18-8}$$
