**Enzyme Kinetics** Enzymes are homogeneous catalysts, e.g., for cellular and enzymatic reactions. The enzyme $E$ and the reactant $S$ are assumed to form a complex $ES$ that then dissociates into product $P$ and releases the enzyme:

$$S + E \Leftrightarrow ES$$

$$ES \Rightarrow E + P$$

Assuming equilibrium for the first step results in the following rate, developed by Michaelis and Menten [*Biochem. Zeit.* **49:** 333 (1913)] and named *Michaelis-Menten kinetics,*

$$r_p = -r_s = \frac{k(S)}{K_m + (S)} \tag{7-70}$$

Here $K_m$ is the inverse of the equilibrium constant for the first reaction.

## AUTOCATALYSIS

In an autocatalytic reaction, a reactant reacts with a product to make more product. For the reaction to proceed, therefore, the product must be present initially in a batch or in the feed of a continuous reactor. Examples are cell

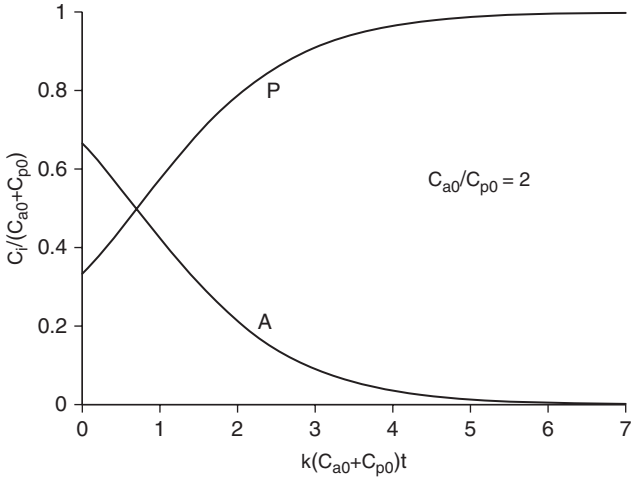

**FIG. 7-5** Product concentration profile for the autocatalytic reaction $A + P \Rightarrow 2P$ with rate $r = kC_aC_p$.

growth in fermentation and combustion of fuels. For instance, the irreversible elementary reaction $A + P \Rightarrow 2P$ has the mass action kinetics

$$r = kC_aC_p \tag{7-71}$$

For an ideal batch reactor (see, e.g., Steinfeld, Francisco, and Hase, *Chemical Kinetics and Dynamics*, Prentice-Hall, 1989):

$$\frac{dC_a}{dt} = -kC_aC_p \qquad \frac{dC_p}{dt} = kC_aC_p \qquad C_a + C_p = C_{a0} + C_{p0} \tag{7-72}$$

Integration results in the following concentration profile:

$$C_p = \frac{C_{a0} + C_{p0}}{1 + (C_{a0}/C_{p0})e^{-k(Ca0+Cp0)t}} \qquad C_a = C_{a0} + C_{p0} - C_p \tag{7-73}$$

Figure 7-5 illustrates the dimensionless concentration profile for reactant $A$ and product $P$, $C_i/(C_{a0} + C_{p0})$, for $C_{a0}/C_{p0} = 2$. If the initial concentration of $P$ is lower than that of $A$ (which is mostly the case for these autocatalytic reactions), then a maximum rate is indicated by the inflection point.

# INTRINSIC KINETICS FOR FLUID-SOLID CATALYTIC REACTIONS

There are a large number of fluid-solid catalytic reactions, mostly gas-solid, including catalytic cracking, oxidation of polluting gases in automotive and power generation catalytic converters, partial oxidation synthesis reactions, HCN synthesis, chemical vapor deposition, etc. (see, e.g., Sec. 19 for more examples). Examples of solid catalysts include, among others, supported metals, transition metal oxides and sulfides, solid acids and bases, and immobilized homogeneous catalysts and enzymes. Solid catalysts can be a fine powder (suspended in a liquid or fluidized by a flowing gas), cylindrical, spherical, and more complex-shaped particles (in a packed bed), a thin layer of active components (on the walls of a monolith or a foam) and gauzes. The solid catalyst can be porous with active component distributed throughout the particle volume, or nonporous with active component present just on the catalyst external surface.

The analysis of Langmuir [*J. Am. Chem. Soc.* **40:** 1361 (1918)] and Hinshelwood (*Kinetics of Chemical Change,* Oxford, 1940) forms the basis for the simplified treatment of kinetics on heterogeneous catalysts. For a solid catalyzed reaction between gas-phase reactants $A$ and $B$, the postulated mechanism may consist of the following steps in series:

1. The reactants from the gas adsorb to bond to active sites on the catalyst surface as molecules or dissociated atoms. The rate of adsorption is proportional to the partial pressure of reactants and to the fraction of uncovered surface sites $\vartheta_v$. More than one type of active site can be present. The adsorption isotherms such as the Langmuir isotherm relate the partial pressure of an adsorbed species to its surface coverage, and the form of this relationship is indicative of the type of adsorption process taking place (for more details, see Masel, *Chemical Kinetics and Catalysis*, Wiley, 2001).
2. The adsorbed species react on the surface to form adsorbed products. The rate of reaction between adsorbed species is proportional to their concentration on the surface.
3. The adsorbed products desorb into the gas. The rate of desorption of species $A$ is proportional to the fraction of the surface covered by $A$, $\vartheta_a$.

For instance, for the simple irreversible reaction $A + B \Rightarrow C + D$, the postulated mechanism is

$$\begin{gathered} A + \sigma \Leftrightarrow A\sigma \\ B + \sigma \Leftrightarrow B\sigma \\ A\sigma + B\sigma \Rightarrow C\sigma + D\sigma \\ C\sigma \Leftrightarrow C + \sigma \\ D\sigma \Leftrightarrow D + \sigma \end{gathered} \tag{7-74}$$

$A\sigma$, $B\sigma$, $C\sigma$, and $D\sigma$ above are adsorbed species on the catalyst surface, and $\sigma$ is an available active site. We will consider a variety of possible scenarios for this simple solid-catalyzed system. Note that the reaction rate for such systems is often expressed on a unit mass catalyst basis ($r_m$) instead of unit reaction volume basis ($r_v$), and the latter is related to the former through the catalyst loading (mass catalyst/reaction volume) or bed density:

$$r_v = \frac{r_m M_{\text{cat}}}{V} = r_m \rho_B \tag{7-75}$$

## ADSORPTION EQUILIBRIUM

Assuming equilibrium for all adsorption steps (e.g., the surface reaction is rate-limiting), the net rates of adsorption of reactants and product are all zero.

$$r_i = k_i p_i \vartheta_v - k_{-i}\vartheta_i = 0 \qquad i = a, b, c, d \tag{7-76}$$

A material balance on all sites (using the fraction of sites $\vartheta_v$ and $\vartheta_i$ versus total number of sites) yields

$$\vartheta_v = 1 - \vartheta_a - \vartheta_b - \vartheta_c - \vartheta_d \tag{7-77}$$

and solving for the surface coverages gives

$$\begin{aligned} \vartheta_a &= \left(\frac{k_a}{k_{-a}}\right) p_a \vartheta_v = K_a p_a \vartheta_v \qquad \vartheta_b = \left(\frac{k_b}{k_{-b}}\right) p_b \vartheta_v = K_b p_b \vartheta_v \\ \vartheta_c &= \left(\frac{k_c}{k_{-c}}\right) p_c \vartheta_v = K_c p_c \vartheta_v \qquad \vartheta_d = \left(\frac{k_d}{k_{-d}}\right) p_d \vartheta_v = K_d p_d \vartheta_v \end{aligned} \tag{7-78}$$

The fraction of surface not covered is

$$\vartheta_v = \frac{1}{1 + K_a p_a + K_b p_b + K_c p_c + K_d p_d} \tag{7-79}$$

In the denominator, terms may be added for adsorbed inerts (say, $K_I p_I$) or other species that may be present. The rate of reaction or the rate-determining step is that between adsorbed reactant species:

$$r = kp_a p_b \vartheta_v^2 = \frac{kp_a p_b}{(1 + K_a p_a + K_b p_b + K_c p_c + K_d P_d)^2} \tag{7-80}$$

## DISSOCIATION

A diatomic molecule $A_2$ may adsorb dissociatively as atoms

$$A_2 + 2\sigma \Rightarrow 2A\sigma \tag{7-81}$$

with the result

$$\vartheta_a = \sqrt{K_a p_a}\,\vartheta_v = \frac{\sqrt{K_a p_a}}{1 + \sqrt{K_a p_a} + K_b p_b + \cdots} \tag{7-82}$$

and the rate-determining step and its rate are

$$2A\sigma + B\sigma \Rightarrow \text{products} + 3\sigma \qquad r = k'\vartheta_a^2 \vartheta_b = kp_a p_b \vartheta_v^3 \tag{7-83}$$

## DIFFERENT SITES

When $A$ and $B$ adsorb on chemically different sites $\sigma_1$ and $\sigma_2$, the rate of the reaction

$$A + B \Rightarrow \text{nonadsorbed products} \tag{7-84}$$

with surface reaction controlling is

$$r = \frac{kp_a p_b}{(1 + K_a p_a)(1 + K_b p_b)} \tag{7-85}$$

## CHANGE IN NUMBER OF MOLES

When the number of moles of product is larger than that of the reactants, extra sites are required:

$$A \Leftrightarrow M + N \tag{7-86}$$

$$A\sigma + \sigma \Rightarrow M\sigma + N\sigma \tag{7-87}$$

and the rate is

$$r = k'\left(\vartheta_a\vartheta_v - \frac{\vartheta_m\vartheta_n}{K}\right) = k\left(p_a - \frac{p_m p_n}{K}\right)\vartheta_v^2 = \frac{k(p_a - p_m p_n/K)}{(1 + K_a p_a + K_m p_m + K_n p_n)^2} \quad (7\text{-}88)$$

## REACTANT IN THE GAS PHASE

When $A$ in the gas phase reacts directly with adsorbed $B$,

$$A + B\sigma \Rightarrow \text{products}$$

$$r = k' p_a \vartheta_b = k p_a p_b \vartheta_v = \frac{k p_a p_b}{1 + \sum K_i p_i} \quad (7\text{-}89)$$

This mechanism is called *Ely-Rideal kinetics*.

## CHEMICAL EQUILIBRIUM IN GAS PHASE

When $A$ is not in adsorptive equilibrium but is in chemical equilibrium in the gas phase according to

$$A + B \Leftrightarrow M + N \quad p_a = \frac{p_m p_n}{K_e p_b} \quad (7\text{-}90)$$

this expression is substituted for $p_a$ wherever it appears in the rate equation. If the rate-determining step is the surface reaction between adsorbed species, then

$$r = k p_a p_b \vartheta_v^2 = \frac{k p_m p_n / K_e}{1 + K_a(p_m p_n / K_e p_b) + K_b p_b + K_m p_m + K_n p_n} \quad (7\text{-}91)$$

Table 7-4 summarizes some examples of reactions where all substances are in adsorptive equilibrium and the surface reaction controls the rate. In Table 7-5, substance $A$ is not in adsorptive equilibrium, and its rate of adsorption is controlling. Details of the derivations of these and some other equations are presented by Yang and Hougen [*Chem. Eng. Prog.* **46:** 146 (1950)], Walas (*Reaction Kinetics for Chemical Engineers,* McGraw-Hill, 1959; Butterworths, 1989, pp. 153–164), and Rase (*Chemical Reactor Design for Process Plants,* vol. 1, Wiley, 1977, pp. 178–191).

## NO RATE-CONTROLLING STEP

All the relations developed above assume that only one step is controlling. In a reaction system, changing the operating conditions may shift the control from one step to another. At certain conditions, there may be no single step controlling. In that case all the reactions and their respective rates have to be considered, and the adsorbed species cannot be eliminated from the rate expressions to obtain a single closed-form kinetic rate.

## LIQUID-SOLID CATALYTIC REACTIONS

A treatment analogous to that for fluid-solid catalysis can be derived for liquid-solid catalysis, with partial pressures replaced by liquid concentrations.

## BIOCATALYSIS

Biochemical reactions such as *aerobic* and *anaerobic fermentations* occur in the presence of living organisms or *cells*, such as bacteria, algae, and yeast. These reactions can be considered as *biocatalyzed* by the organism. Thus in a typical bioreactor a *substrate* (such as glucose) is fed into the *fermenter* or *bioreactor* in the presence of an initial amount of cells. The desired product can be the cells themselves or one of the chemicals produced by the cell, called *metabolites*. In either case the cells multiply in the presence of the substrate, and the rate of production of cells is proportional to the concentration of the cells—hence this process is autocatalytic. In a batch reactor with an ample supply of substrate, this results in *exponential growth* of the culture. A typical cell or biomass growth rate function, called the *Monod kinetics*, is identical in form to the Michaelis-Menten enzyme kinetics in Eq. (7-70):

$$\mu = \frac{\mu_{\max} C_s}{K_s + C_s} \quad (7\text{-}92)$$

In Eq. (7-92) $\mu$ is the *specific growth rate* of the culture. It is measured in units of reciprocal time ($h^{-1}$) and it is related to the *volumetric growth rate* $r_x$ of the culture: $r_x = C_x\mu$. This means that the true unit of $\mu$ is, e.g., (g biomass formed/h)/(g biomass present), where *g biomass* is the *dry weight* (DW) of the biomass, obtained after evaporation of the water content of the cell (which constitutes about 80 percent of the *wet biomass* weight). Similarly $C_x$ has the unit, e.g., (g biomass)/(L medium volume). The variable $C_s$ in Eq. (7-92) is the concentration of the *limiting substrate* in the medium (g/L). There are many substrates (including micronutrients) in the medium, but there is usually just one that determines the specific growth rate. This substrate is often a sugar (e.g., glucose), but it could also be $O_2$, a metal ion ($Mg^{2+}$ etc.), or $PO_4^{3-}$, $NH_4^+$, …, or perhaps a hormone. The limiting substrate may easily change during a batch fermentation, and then the rate expression will change.

The two parameters in Eq. (7-92) are the *maximum specific growth rate* $\mu_{\max}$ ($h^{-1}$) and the *saturation constant* $K_s$ (g substrate/L). The value of $K_s$ is obtained as the substrate concentration at which $\mu = \frac{1}{2}\mu_{\max}$. The growth rate versus limiting substrate concentration is shown in Fig. 7-6. The form of

**TABLE 7-4 Surface-Reaction Controlling Table 7-3**

Adsorptive equilibrium maintained for all participants.

| | Reaction | Special condition | Basic rate equation | Driving force | Adsorption term |
|---|---|---|---|---|---|
| 1. | $A \rightarrow M + N$ | General case | $r = k\theta_a$ | $p_a$ | $1 + K_a p_a + K_m p_m + K_n p_n$ |
| | $A \rightarrow M + N$ | Sparsely covered surface | $r = k\theta_a$ | $p_a$ | 1 |
| | $A \rightarrow M + N$ | Fully covered surface | $r = k\theta_a$ | 1 | 1 |
| 2. | $A \rightleftharpoons M$ | | $r = k_1\theta_a - k_{-1}\theta_m$ | $p_a - \frac{p_m}{K}$ | $1 + K_a p_a + K_m p_m$ |
| 3. | $A \rightleftharpoons M + N$ | Adsorbed $A$ reacts with vacant site | $r = k_1\theta_a\theta_v - k_{-1}\theta_m\theta_n$ | $p_a - \frac{p_m p_n}{K}$ | $(1 + K_a p_a + K_m p_m + K_n p_n)^2$ |
| 4. | $A_2 \rightleftharpoons M$ | Dissociation of $A_2$ upon adsorption | $r = k_1\theta_a^2 - k_{-1}\theta_m\theta_v$ | $p_a - \frac{p_m}{K}$ | $(1 + \sqrt{K_a p_a} + K_m p_m)^2$ |
| 5. | $A + B \rightarrow M + N$ | Adsorbed $B$ reacts with $A$ in gas but | $r = k\theta_a\theta_b$ | $p_a p_b$ | $(1 + K_a p_a + K_b p_b + K_m p_m + K_n p_n)^2$ |
| | $A + B \rightarrow \text{M} + \text{N}$ | not with adsorbed $A$ | $r = k p_a \theta_b$ | $p_a p_b$ | $1 + K_a p_a + K_b p_b + K_m p_m + K_n p_n$ |
| 6. | $A + B \rightleftharpoons M$ | | $r = k_1\theta_a\theta_b - k_{-1}\theta_m\theta_v$ | $p_a p_b - \frac{p_m}{K}$ | $(1 + K_a p_a + K_b p_b + K_m p_m)^2$ |
| 7. | $A + B \rightleftharpoons M + N$ | | $r = k_1\theta_a\theta_b - k_{-1}\theta_m\theta_n$ | $p_a p_b - \frac{p_m p_n}{K}$ | $(1 + K_a p_a + K_b p_b + K_m p_m + K_n p_n)^2$ |
| 8. | $A_2 + B \rightleftharpoons M + N$ | Dissociation of $A_2$ upon adsorption | $r = k_1\theta_a^2\theta_b - k_{-1}\theta_m\theta_n\theta_v$ | $p_a p_b - \frac{p_m p_n}{K}$ | $(1 + \sqrt{K_a p_a} + K_b p_b + K_m p_m + K_n p_n)^3$ |

NOTE: The rate equation is:

$$r = \frac{k(\text{driving force})}{\text{adsorption term}}$$

When an inert substance $I$ is adsorbed, the term $K_I p_I$ is to be added to the adsorption term.

SOURCE: From Walas, *Reaction Kinetics for Chemical Engineers*, McGraw-Hill, 1959; Butterworths, 1989, Table 7-3.

**TABLE 7-5 Adsorption-Rate of Species A Controlling (Rapid Surface Reaction)**

| Reaction | Special condition | Basic rate equation | Driving force | Adsorption term |
|---|---|---|---|---|
| 1. $A \rightarrow M+N$ | | $r=kp_a\theta_v$ | $p_a$ | $1+\frac{K_a p_m p_n}{K}+K_m p_m+K_n p_n$ |
| 2. $A \rightleftharpoons M$ | | $r=k\left(p_a\theta_v-\frac{\theta_a}{K_a}\right)$ | $p_a-\frac{p_m}{K}$ | $1+\frac{K_a p_m}{K}+K_m p_m$ |
| 3. $A \rightleftharpoons M+N$ | | $r=k\left(p_a\theta_v-\frac{\theta_a}{K_a}\right)$ | $p_a-\frac{p_m p_n}{K}$ | $1+\frac{K_a p_m p_n}{K}+K_m p_m+K_n p_n$ |
| 4. $A_2 \rightleftharpoons M$ | Dissociation of $A_2$ upon adsorption | $r=k\left(p_a\theta_v^2-\frac{\theta_a^2}{K_a}\right)$ | $p_a-\frac{p_m}{K}$ | $\left(1+\sqrt{\frac{K_a p_m}{K}}+K_m p_m\right)^2$ |
| 5. $A+B \rightarrow M+N$ | Unadsorbed $A$ reacts with adsorbed $B$ | $r=kp_a\theta_v$ | $p_a$ | $1+\frac{K_a p_m p_n}{Kp_b}+K_b p_b+K_m p_m+K_n p_n$ |
| 6. $A+B \rightleftharpoons M$ | | $r=k\left(p_a\theta_v-\frac{\theta_a}{K_a}\right)$ | $p_a-\frac{p_m}{Kp_b}$ | $1+\frac{K_a p_m}{Kp_b}+K_b p_b+K_m p_m$ |
| 7. $A+B \rightleftharpoons M+N$ | | $r=k\left(p_a\theta_v-\frac{\theta_a}{K_a}\right)$ | $p_a-\frac{p_m p_n}{Kp_b}$ | $1+\frac{K_a p_m p_n}{Kp_b}+K_b p_b+K_m p_m+K_n p_n$ |
| 8. $A_2+B \rightleftharpoons M+N$ | Dissociation of $A_2$ upon adsorption | $r=k\left(p_a\theta_v^2-\frac{\theta_a^2}{K_a}\right)$ | $p_a-\frac{p_m p_n}{Kp_b}$ | $\left(1+\sqrt{\frac{K_a p_m p_n}{Kp_b}}+K_b p_b+K_m p_m+K_n p_n\right)^2$ |

NOTES: The rate equation is:

$$r=\frac{k(\text{driving force})}{\text{adsorption term}}$$

Adsorption rate of substance $A$ is controlling in each case. When an inert substance $I$ is adsorbed, the term $K_I p_I$ is to be added to the adsorption term.
SOURCE: From Walas, *Reaction Kinetics for Chemical Engineers,* McGraw-Hill, 1959; Butterworths, 1989, Table 7-4.

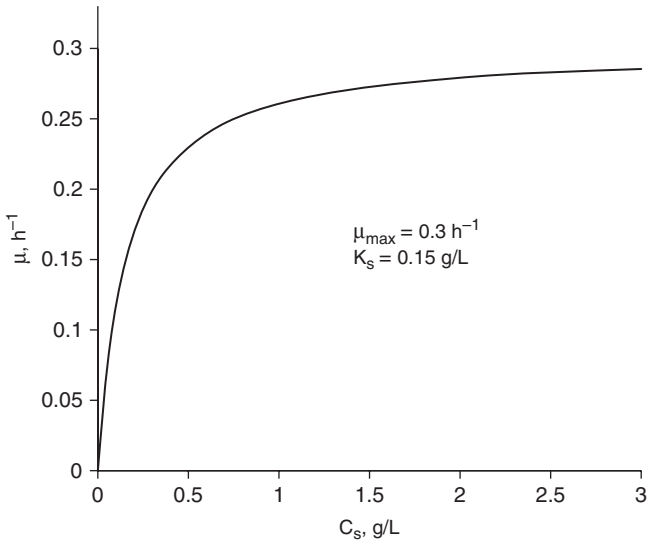

**FIG. 7-6** The effect of substrate concentration on specific growth rate.

Eq. (7-92) is entirely empirical, but it incorporates two important features: (1) At high substrate concentration the whole cell machinery is involved in cell synthesis, and the specific growth rate reaches a maximum $\mu_{max}$; (2) at low substrate concentration, formation of biomass is a first-order rate process (as in any other chemical reaction) and $\mu \rightarrow (\mu_{max}/K_s)C_s$. Note that for many commonly used microorganisms $K_s$ is much smaller than the typical substrate concentration $C_s$. In batch cultivations $K_s$ is several orders of magnitude smaller than $C_s$ until the very end of the batch, and this is what gives the well-known *exponential growth* where $\mu = \mu_{max}$. Equation (7-93) shows the cell's material balance and its integral for a batch cultivation, and it applies after an initial *lag phase* when cell machinery is synthesized. Some typical glucose substrate values for $K_s$ are 150 mg/L (*Saccharomyces cerevisiae*), 5 to 10 mg/L (lactic bacteria and *E. coli*), and less than 1 mg/L (filamentous fungi).

$$\frac{dC_x}{dt}=\mu C_x \qquad \mu=\mu_{max} \quad \text{for} \quad C_s \gg K_s \Rightarrow C_x=C_{x0}e^{-\mu_{max}t} \tag{7-93}$$

Equation (7-93) may have to be modified by subtraction of a *death-rate* term $\mu_d C_x$. Further, $\mu_d$ may well increase during the batch fermentation in which case the net growth rate of (viable) cells eventually becomes negative, and the concentration of (viable) cells will start to decrease.

# FLUID-SOLID REACTIONS WITH MASS AND HEAT TRANSFER

## GAS-SOLID CATALYTIC REACTIONS

The Langmuir-Hinshelwood mechanism of adsorption and reaction described above allowed us to relate the gas concentrations and partial pressures in the vicinity of the catalyst surface to the adsorbed species concentration at the active sites, which in turn determined the surface reaction rates. In practice, two additional mass transfer processes may need to be considered:

1. Diffusion to and from the bulk gas to the external catalyst surface, represented as an external mass transfer process across a film or boundary layer concentration gradient. For nonporous catalyst this is the only mass-transfer step.

2. Diffusion to and from the catalyst external surface through pores in a porous catalyst particle to active sites inside the catalyst particle where the adsorption and reaction occur, represented as intraparticle diffusion and modeled as a diffusion-reaction process.

**External Mass Transfer** In a reactor, the solid catalyst is deposited on the surface of narrow tubes (such as monolith), is packed as particles in a tube, or is suspended in slurry or in a fluidized bed as fine particles. For these systems, the bulk concentration of the gas phase approaches that on the catalyst surface if the mass transfer rate from bulk to surface is substantially faster than the reaction rates on the surface. This, however, is often not the case. The mechanism of mass transfer and reaction on the external catalyst surface includes the following consecutive steps:

1. Mass transfer of gas reactants from the bulk gas to the solid catalyst surface, also called *external mass transfer*
2. Adsorption, reaction on the surface, and desorption of products, e.g., Langmuir-Hinshelwood kinetics
3. Mass transfer of products from the catalyst surface to the bulk gas

At steady state all these rates are equal.

For example, for a first-order irreversible reaction $A \Rightarrow B$, the rate of mass transfer equals the rate of intrinsic reaction:

$$k_s a_s (C_a - C_{as}) = kC_{as} \tag{7-94}$$

Here $a_s$ is the external particle surface area/volume of reactor. Eliminating the surface concentration $C_{as}$ in terms of the observable bulk gas concentration $C_a$ yields the overall specific rate of consumption of $A$:

$$r_{\text{obs}} = k_{\text{obs}} C_a = \frac{C_a}{1/(k_s a_s) + 1/k}$$

$$k_{\text{obs}} = \frac{1}{1/(k_s a_s) + 1/k} \tag{7-95}$$

Hence the observable overall rate constant $k_{\text{obs}}$ is actually a combination of the mass transfer coefficient and the intrinsic rate coefficient; or in terms of resistances (in units of time) the overall resistance is the sum of the mass transfer and intrinsic kinetic resistances. For this first-order rate case, the overall behavior remains first-order in bulk gas concentration. The two limiting cases are mass transfer and kinetic (reaction) control, respectively:

$$k_{\text{obs}} = k_s a_s \quad \text{and} \quad r_{\text{obs}} = k_s a_s C_a \quad \text{for} \quad k_s a_s << k \quad \text{for mass transfer control} \tag{7-96}$$

$$k_{\text{obs}} = k \quad \text{and} \quad r_{\text{obs}} = kC_a \quad \text{for} \quad k_s a_s >> k \quad \text{for kinetic control}$$

The mass transfer coefficient depends on the geometry of the solid surface, on the hydrodynamic conditions in the vicinity of the catalyst (which are a function, e.g., of the reactor type, geometry, operating conditions, and flow regime), and it also depends on the diffusivity of the gas species. Correlations for the mass transfer coefficient are a large topic and outside the scope of this section. For more details see Bird, Stewart, and Lightfoot, *Transport Phenomena,* 2d ed., Wiley, New York, 2002, and relevant sections in this handbook. For non-first-order kinetics, a closed-form relationship (such as resistances in series description) cannot always be derived, but the steady-state assumption of the consecutive mass and reaction steps still applies.

**Intraparticle Diffusion** As indicated above, the larger the catalyst surface area per unit reactor volume $a_s$, the larger the overall reaction rate. For a fixed mass of catalyst, decreasing the particle size increases the total external surface area available for the reaction. Another way to increase the surface area is by providing a porous catalyst with lots of internal surface area. The internal structure of the catalyst determines how accessible these internal sites are to the gas-phase reactant and how easily the products can escape back to the bulk gas. The analysis is based on the pseudohomogeneous reaction-diffusion equation, with the gas reactant diffusing through the pores and reacting at active sites inside the catalyst particle. For a first-order irreversible reaction of species $A$ in an infinite slab geometry, the diffusion-reaction equation describes the reactant concentration profile from the external surface to the center of the slab ($y = 0$) as follows:

$$D_{ea}\frac{d^2 C_{ay}}{dy^2} - kC_{ay} = 0 \qquad C_{ay}(L) = C_{as}$$

$$\frac{dC_{ay}}{dy}(0) = 0 \tag{7-97}$$

where $D_{ea}$ is the effective diffusivity and $L$ is the characteristic length, in this case half the thickness of the slab. The solution of the second-order ordinary differential equation provides $C_a(y)$ and can be used to calculate the reaction rate in the pellet under intraparticle diffusion conditions

$$r = \eta k C_{as} \tag{7-98}$$

The *effectiveness factor* $\eta$ is defined as the ratio of the actual rate to that if the reaction occurred at the external surface concentration in the absence of intraparticle diffusion resistance $C_{as}$:

$$\eta = \frac{(1/L)\int_0^L r(C_{ay})\,dy}{r(C_{as})} = \frac{\text{observed rate with pore diffusion resistances}}{\text{rate at catalyst external surface condition}} \tag{7-99}$$

The effectiveness factor can be obtained as a function of a dimensionless parameter called the *Thiele modulus,* representing the ratio of the rate of reaction to the rate of intraparticle diffusion. For a first-order reaction, the Thiele modulus and the effectiveness factor derived by integration of Eq. (7-97) are shown below:

$$\eta = \frac{\tanh \varphi_{\text{slab}}}{\varphi_{\text{slab}}} \qquad \varphi_{\text{slab}} = L\sqrt{\frac{k}{D_{ea}}} \tag{7-100}$$

The effective diffusivity accounts for the decrease in gas diffusivity on account of the solid parts of the catalyst. The diffusion path is tortuous as gas molecules follow the pores. The simplest expression used to explain the effective gas diffusivity is

$$D_{ea} = \frac{\varepsilon_s}{\tau} D_a \tag{7-101}$$

where the porosity $\varepsilon_s$ accounts for the fact that diffusion only occurs through the gas-filled part of the particle, and the tortuosity $\tau$ accounts for the effect of diffusion path length and contraction/expansion of pores along the diffusion path. The diffusion regime depends on the diffusing molecule, pore size, and operating conditions (concentration, temperature, pressure), and this can be visualized in Fig. 7-7. As indicated, the effective diffusion coefficient ranges over many orders of magnitude from very low values in the configuration regime (e.g., in zeolites) to high values approaching molecular diffusivity where the pores are large.

There is a large body of literature that deals with the proper definition of the diffusivity used in the intraparticle diffusion-reaction model, especially in multicomponent mixtures found in many practical reaction systems. The reader should consult references, e.g., Bird, Stewart, and Lightfoot, *Transport Phenomena,* 2d ed., Wiley, New York, 2002; Taylor and Krishna, *Multicomponent Mass Transfer,* Wiley, 1993; and Cussler, *Diffusion Mass Transfer in Fluid Systems,* Cambridge University Press, Cambridge, UK, 1997.

The larger the *characteristic length L,* the larger the Thiele modulus, the smaller the effectiveness factor, and the steeper the reactant concentration profile in the catalyst particle. A generalized characteristic length definition $V_p/S_{px}$ (particle volume/external particle surface area) brings together the $\eta$-$\phi$ curves for a variety of particle shapes, as illustrated in Table 7-6 and Fig. 7-8 for slabs, cylinders, and spheres. Here $I_0$ and $I_1$ are the corresponding modified Bessel functions of the first kind.

Further generalization of the Thiele modulus and effectiveness factor for a general global reaction and various shapes is

$$\varphi = \frac{(V_p/S_{px}) r_a(C_{as})}{\sqrt{2\int_{C_{ae}}^{C_{as}} D_{ea} r_a(C_{ay})\,dC_{ay}}} \tag{7-102}$$

In Eq. (7-102) component $A$ is the limiting reactant. For example, for an $n$th-order irreversible reaction

$$\varphi = \frac{V_p}{S_{px}}\sqrt{\frac{(n+1)}{2}\frac{kC_{as}^{n-1}}{D_{ea}}} \tag{7-103}$$

This generalized Thiele modulus works well with the effectiveness factors for low and high values of the Thiele modulus, but it is not as accurate for intermediate values. However, these differences are not significant, given the uncertainties associated with measuring some of the other key parameters that go into the calculation of the Thiele modulus, e.g., the effective diffusivity and the intrinsic rate constant.

***Effect of Intraparticle Diffusion on Observed Order and Activation Energy*** For an $n$th-order reaction in the limit of intraparticle diffusion control, i.e., large Thiele modulus, the effectiveness factor is

$$\eta = \frac{1}{\varphi} \tag{7-104}$$

the observed rate is

$$r_{\text{obs}} = \eta r = \frac{S_{px}}{V_p}\sqrt{\frac{2D_{ea}k}{n+1}}\, C_{as}^{(n+1)/2} \tag{7-105}$$

and the observed rate constant is

$$k_{\text{obs}} = \eta k = \frac{S_{px}}{V_p}\sqrt{\frac{2}{n+1} D_{ea0} e^{-(E_D/RT)} k_0 e^{-(E/RT)}} \tag{7-106}$$

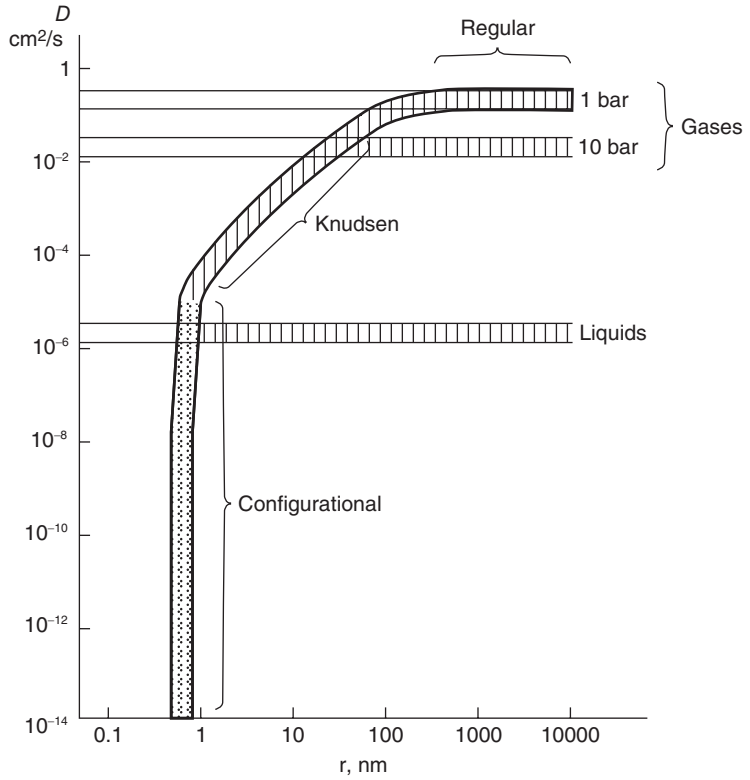

**FIG. 7-7** Diffusion regimes in heterogeneous catalysts [From Weisz, *Trans. Fara. Soc.* **69:** 1696–1705 (1973); Froment and Bischoff, *Chemical Reactor Analysis and Design,* Wiley, 1990, Fig. 3.5.1-1.]

Hence, the observed order and activation energy differ from those of the intrinsic *n*th-order kinetics:

$$n_{\text{obs}} = \frac{n+1}{2} \qquad E_{\text{obs}} = \frac{E+E_D}{2} \simeq \frac{E}{2} \tag{7-107}$$

Here $E_D$ is the activation energy for diffusion; therefore, the intraparticle diffusion limitation lowers the apparent activation energy.

Note that the observed and intrinsic reaction order is the same under intraparticle diffusion control only for a first-order reaction.

Weisz and Prater ["Interpretation of Measurements in Experimental Catalysis," *Adv. Catal.* **6:** 144 (1954)] developed general estimates for the observed order and activation energy over the entire range of $\phi$ for an irreversible *n*th-order reaction:

$$n_{\text{obs}} = n + \frac{n-1}{2}\frac{d\ln\eta}{d\ln\varphi} \qquad E_{\text{obs}} = E + \frac{E-E_D}{2}\frac{d\ln\eta}{d\ln\varphi} \tag{7-108}$$

Weisz and Prater ["Interpretation of Measurements in Experimental Catalysis," *Adv. Catal.* **6:** 144 (1954)] also developed a general criterion for diffusion limitations, which can guide the lab analysis of rate data:

$$\begin{cases} \text{If} \quad \Phi = \left(\dfrac{3V_p}{S_{px}}\right)^2 \dfrac{r_{\text{obs}}}{D_{ea}C_{as}} \gg 1, & \text{then diffusion-limited} \\ \ll 1, & \text{then no intraparticle diffusion resistance} \end{cases} \tag{7-109}$$

**TABLE 7-6 Effectiveness Factors versus Thiele Modulus for Different Shapes for a First-Order Reaction**

| Shape | $V_p/S_{px}$ | Effectiveness factor $\eta$ |
|---|---|---|
| Infinite slab | $R$ | $\dfrac{\tanh\varphi}{\varphi}$ |
| Infinite cylinder | $R/2$ | $\dfrac{I_1(2\varphi)}{\varphi I_0(2\varphi)}$ |
| Sphere | $R/3$ | $\dfrac{1}{\varphi}\left(\dfrac{3}{\tanh 3\varphi} - \dfrac{1}{\varphi}\right)$ |

***Effect of Intraparticle Diffusion for Reaction Networks*** For multiple reactions, intraparticle diffusion resistance can also affect the observed selectivity and yield. For example, for consecutive reactions, intraparticle diffusion resistance reduces the yield of the intermediate (often desired) product if both reactions have the same order. For parallel reactions, diffusion resistance reduces the selectivity for the higher-order reaction. For more details see, e.g., Carberry, *Chemical and Catalytic Reaction Engineering,* McGraw-Hill, 1976; and Levenspiel, *Chemical Reaction Engineering,* 3d ed., Wiley, 1999.

For more complex reactions, the effect of the intraparticle diffusion resistance on rate, selectivity, and yield depends on the particulars of the network. Also the use of the Thiele modulus–effectiveness factor relationships is not as easily applicable, and numerical solution of the diffusion-reaction equations may be required.

**Intraparticle Diffusion and External Mass Transfer Resistance** For typical industrial conditions, external mass transfer is important only if there is substantial intraparticle diffusion resistance. This subject has been discussed by Luss, "Diffusion-Reaction Interactions in Catalyst Pellets," in Carberry and Varma (eds.), *Chemical Reaction and Reactor Engineering,* Marcel Dekker, 1987. This, however, may not be the case for laboratory conditions, and care must be taken to include the proper data interpretation. For instance, for a spherical particle with both external and internal mass-transfer limitations and first-order reaction, an overall effectiveness factor $\eta_t$ can be derived, indicating the series-of-resistances nature of external mass transfer followed by intraparticle diffusion reaction:

$$\frac{1}{\eta_t} = \frac{1}{\eta} + \frac{\varphi^2}{3Sh'} \tag{7-110}$$

$$Sh' = \frac{\varepsilon_s k_s R}{D_{ea}} \tag{7-111}$$

As indicated above, intraparticle diffusion lowers the apparent activation energy. The apparent activation energy is even further lowered under external mass transfer control. Figure 7-9 illustrates how the rate-controlling step changes with temperature, and as a result the dependence of the apparent first-order rate constant on temperature also changes, from a very strong dependence under kinetic control to being virtually independent of temperature under external mass transfer control.

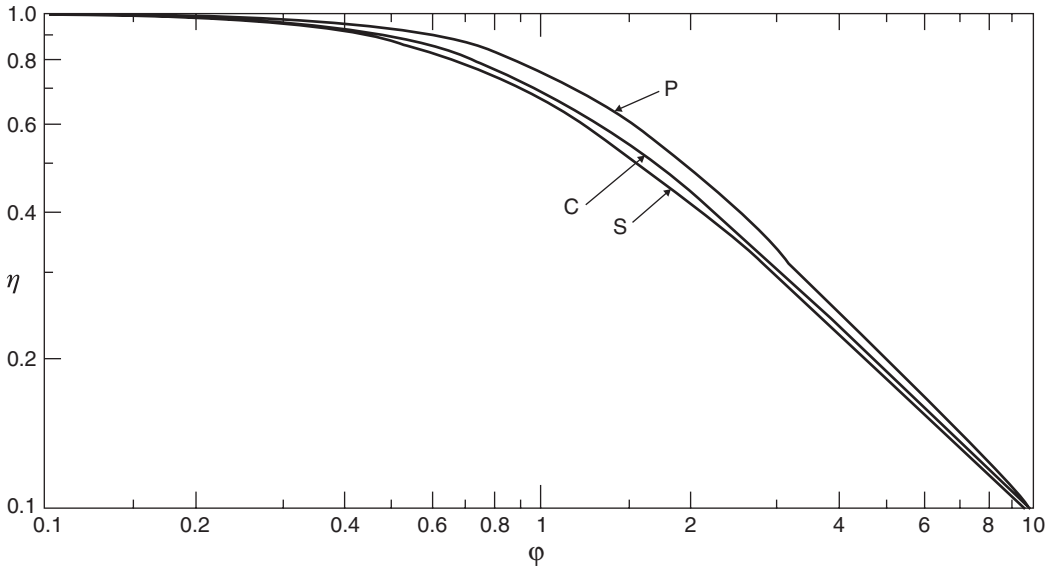

**FIG. 7-8** Effectiveness factors versus Thiele modulus for a first order reaction in a slab (P), a cylinder (C), and a sphere (S). [Adapted from Fig. 1 in Aris and Rester, "The Effect of Shape on the Effectiveness Factor," *Chem. Eng. Sci.* **24:** 793 (1969).]

Note that in the limit of external mass transfer control, the activation energy $E_{obs} \to 0$, as can be shown when substituting Eq. (7-110) in Eq. (7-108). For more details on how to represent the combined effect of external and intraparticle diffusion on the effectiveness factor for more complex systems, see Luss, "Diffusion-Reaction Interactions in Catalyst Pellets," in Carberry and Varma (eds.), *Chemical Reaction and Reactor Engineering,* Marcel Dekker, 1987.

**Heat Transfer Resistance** A similar analysis regarding external and intraparticle heat transfer limitations leads to temperature gradients which add further complexity to the behavior of heterogeneous catalytic systems, including steady-state multiplicity. More details are given in Sec. 19.

**Catalyst Deactivation** The catalyst life may range from seconds to minutes to a few days to several years, as the active surface of a catalyst is degraded by chemical, thermal, or mechanical factors. *Chemical deactivation* occurs due to feed or product *poisoning* or *masking*. Poisoning may be due to compounds such as P, S, As, Na, and Bi and is generally considered irreversible. In some cases a reduced life is simply accepted, as in the case of slow accumulation of trace metals from feed to catalytic cracking; but in other cases the deactivation is too rapid. Sulfur and water are removed from feed to ammonia synthesis, sulfur from feed to platinum reforming, and arsenic from feed to $SO_2$ oxidation with platinum. Masking may be due to covering of the active sites by contaminants in either the feed or products. Examples of feed masking agents can include Si ( from organic silicones) and rust. An example of product masking is coking. Catalysts may be regenerated depending on the cost-effectiveness of the regeneration process.

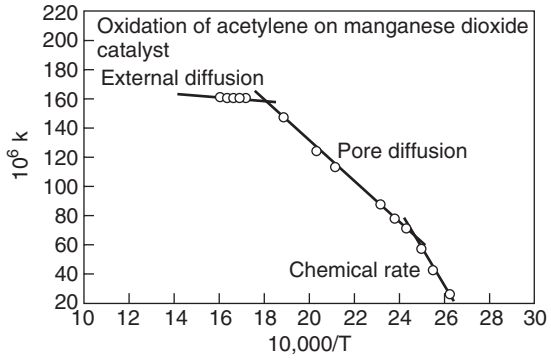

**FIG. 7-9** Dependence of the rate-controlling step on temperature.

Catalyst regeneration sometimes is done in place; for instance, coke is burned off cracking catalyst or off nickel and nickel-molybdenum catalysts in a fluidized reactor/regenerator system. *Thermal deactivation* is primarily due to rearrangement of the active sites at high temperature due to *sintering*. Sintering results in agglomeration of active ingredients (lower dispersion). In most cases sintering is irreversible; however, $Pt/Al_2O_3$ catalysts have been regenerated in place by $Cl_2$ treatment. The catalyst also can be modified by additives, for instance, chromia to nickel to prevent sintering, and rhenium to platinum to reduce coking. *Mechanical deactivation* may be caused by attrition or erosion and subsequent loss of catalyst as fines. The attrition resistance of catalysts is related to the nature of the support and its porosity.

For additional references, see, e.g., Thomas, *Catalytic Processes and Proven Catalysts,* Academic, 1970; Butt and Petersen, *Activation, Deactivation and Poisoning of Catalysts,* Academic, 1988; and Delmon and Froment, *Catalyst Deactivation,* Elsevier, 1980.

The *activity* $\alpha$ at any time on stream may be simply defined as the ratio of the rate at time $t$ to the rate with fresh catalyst

$$\alpha = \frac{r(t)}{r(t=0)} \tag{7-112}$$

The rate of destruction of active sites and pore structure can be expressed as a kinetic relation that can be generally first- or second-order. For instance, for a second-order dependence,

$$\frac{d\alpha}{dt} = -k_d \alpha^2 \tag{7-113}$$

and the corresponding integral is

$$\alpha = \frac{1}{1 + k_d t} \tag{7-114}$$

This type of deactivation mechanism often applies to catalyst sintering and coke deactivation. The deactivation rate constant is expected to have an Arrhenius dependence on temperature.

When the feedstock contains constant proportions of reactive impurities, the rate of decline may also depend on the concentration of the main reactant, e.g., for a power law rate

$$\frac{d\alpha}{dt} = -k_d \alpha^p C^q \tag{7-115}$$

This differential equation now must be solved simultaneously with a rate equation for the main reactant.

The deactivation rate constants are estimated by methods similar to those for finding constants of any rate equation, given suitable ($\alpha$, $t$) data. There are different chemical deactivation mechanisms for catalyst pellets and two of the most common are described below. For more details see Butt and Petersen, *Activation, Deactivation and Poisoning of Catalysts,* Academic, 1988; and Froment and Bischoff, *Chemical Reactor Analysis and Design,* Wiley, 1990. In *uniform deactivation*, the poison is distributed uniformly throughout the pellet and degrades it gradually. In *pore mouth* (*shell progressive*) *poisoning*, the poison is so effective that it kills the active site as it enters the pore; hence complete deactivation begins at the mouth and moves gradually inward.

***Uniform Deactivation*** When uniform deactivation occurs, the specific rate declines by a factor $1-\beta$, where $\beta$ is the fractional poisoning. Factor $\beta$ is calculated from the poisoning rate, and it is often assumed to be proportional to the concentration of the poison in the bulk fluid. Then a power law rate equation becomes

$$r = k(1-\beta)\eta C_s^n \tag{7-116}$$

The effectiveness factor depends on $\beta$ through the Thiele modulus

$$\varphi = \frac{V_p}{S_{px}}\sqrt{\frac{n+1}{2}\,\frac{k(1-\beta)C_s^{n-1}}{D_e}} \tag{7-117}$$

To find the effectiveness under poisoned conditions, this form of the Thiele modulus is substituted into the appropriate relation for the effectiveness factor. For example, for a first-order reaction in slab geometry, with $V_p/S_{px} = L$, the effectiveness factor is

$$\eta = \frac{\tanh\phi}{\phi} = \frac{\tanh\left(L\sqrt{k(1-\beta)/D_e}\right)}{L\sqrt{k(1-\beta)/D_e}} \tag{7-118}$$

Figure 7-10*a* shows the ratio of the effectiveness factor with fresh catalyst to that with uniform poisoning for the above case of first-order reaction in a slab. Hence for the same value of the Thiele modulus, the effectiveness factor is larger for the poisoned catalyst, or alternatively the poisoned catalyst Thiele modulus is smaller, resulting in a larger effectiveness factor than that of the fresh catalyst.

***Pore Mouth (or Shell Progressive) Poisoning*** This mechanism occurs when the poisoning of a pore surface begins at the mouth of the pore and moves gradually inward. This is a moving boundary problem, and the pseudo-steady-state assumption is made that the boundary moves slowly compared with diffusion of poison and reactants to the active surface. Here $\beta$ is the fraction of the pore that is deactivated. The poison diffuses through the dead zone and deposits at the interface between the dead and active zones. The reactants diffuse across the dead zone without reaction, followed by diffusion reaction in the active zone.

Figure 7-10*b* shows simulation results for the ratio of the effectiveness factor with no poisoning to that with pore mouth poisoning for the same first-order reaction in a slab shown above. Here as well the effectiveness factor of the poisoned catalyst is larger than that of the fresh catalyst.

## GAS-SOLID NONCATALYTIC REACTIONS

Examples of gas-solid noncatalytic reactions include production of iron from iron ores, roasting of sulfide oxides, combustion of solid fuels, chlorination of Ti ores to make $TiCl_4$ in the production of $TiO_2$ pigments, incineration of waste, gasification of coal and biomass to produce syngas, and decomposition of solids to produce gases, e.g., solid propellants and explosives. The kinetic treatment of these reactions has to take into consideration external mass transfer and intraparticle diffusion just as in the case of gas-solid catalytic reactions. However, there are major differences, the primary one being consumption of the solid reactant, making the conditions inside the solid particle transient in nature, including change in unreacted particle size, particle density, porosity, etc. For more details see, e.g., Wen ["Noncatalytic Heterogeneous Solid-Fluid Reaction Models," *Ind. Eng. Chem.* **60**(9): 34–54 (1968)], Szekely [in Lapidus and Amundson (eds.), *Chemical Reactor Theory—A Review*, Prentice-Hall, 1977], Doraiswamy and Kulkarni [in Carberry and Varma (eds.), *Chemical Reaction and Reactor Engineering,* Marcel Dekker, 1987], and Levenspiel (*Chemical Reaction Engineering*, 3d ed., Wiley, 1999).

The basic steps are identical to those of catalytic gas-solid reactions. However, as indicated above, the process is transient (non-steady-state) due to change in particle size and properties as the reaction progresses.

Several models that describe gas-solid noncatalytic reactions are summarized in Table 7-7. The first two, the sharp interface and volume reaction models, are pseudohomogeneous, part of the class of shrinking core models, and can be treated by using the Thiele modulus and effectiveness factor concept. The last three are heterogeneous models. The following discussion is restricted to spherical particles.

**Sharp Interface Model** For a first-order reaction in gas and solid reactants,

$$A(g) + bB(s) \Rightarrow \text{products} \tag{7-119}$$

the rate of conversion of the solid $B$ per unit area at the solid surface is

$$r_b = kC_{as}C_s \tag{7-120}$$

Assuming pseudo-steady state for the gas reactant $A$, and constant solid reactant $B$ concentration $C_{s0}$, it can be shown that the observed rate per particle external surface area at any time $t$ is

$$r_{a,\text{obs}} = \frac{C_{a0}}{\dfrac{1}{k_p} + \dfrac{R_p}{D_{ea}}\left(\dfrac{R_p}{R_s} - 1\right) + \dfrac{b}{kC_{s0}}\left(\dfrac{R_p}{R_s}\right)^2} \tag{7-121}$$

where $R_p$ and $R_s$ are the particle and solid core radii. Equation (7-121) represents three resistances in series for the gaseous reactant: external mass transfer $R_{am}$, diffusion in the reacted (ash) zone $R_{ad}$, and reaction at the unreacted solid-ash interface $R_{ar}$ as indicated below (for details see Doraiswamy and Kulkarni [in Carberry and Varma (eds.), *Chemical Reaction and Reactor Engineering,* Marcel Dekker, 1987]):

$$R_{am} = 4\pi R_p^2 k_p (C_{a0} - C_{ap})$$

$$\frac{1}{r^2}\frac{\partial}{\partial r}\left(D_{ea} r^2 \frac{\partial C_a}{\partial r}\right) = 0 \qquad R_s \le r \le R_p \Rightarrow R_{ad} = \frac{4\pi R_p R_s D_{ea}}{R_p - R_s}(C_{ap} - C_{as}) \tag{7-122}$$

$$R_{ar} = 4\pi R_s^2 \frac{kC_{as}C_{s0}}{b} \qquad C_{s0} = \frac{\rho_s}{MW_s}$$

The moving boundary radius $R_s$ is determined from a material balance that relates the unreacted solid volume to the observed reaction rate. Integration gives the time $\tau$ required to achieve a given conversion of the solid $B$, $X_s$:

$$\tau = \frac{R_p C_{s0}}{bC_{a0}}\left\{\frac{1}{3}\left(\frac{1}{k_p} - \frac{R_p}{D_{ea}}\right)X_s + \frac{R_p}{2D_{ea}}\left[1-(1-X_s)^{2/3}\right] + \frac{b}{C_{s0}k}\left[1-(1-X_s)^{1/3}\right]\right\}$$

$$-\frac{d}{dt}\left(\frac{4\pi R_s^3 C_{s0}}{3}\right) = 4\pi R_p^2 b r_{a,\text{obs}} \qquad X_s = 1 - \left(\frac{R_s}{R_p}\right)^3 \tag{7-123}$$

Similar solutions can be obtained for other shapes [Doraiswamy and Kulkarni, in Carberry and Varma (eds.), *Chemical Reaction and Reactor Engineering,* Dekker, 1987]. Figure 7-11 shows typical concentration profiles for this case.

**Volume Reaction Model** A typical concentration profile for the volume reaction model is shown in Fig. 7-12.

A general transient model of diffusion reaction that uses the effective diffusivity concept described for gas-solid catalytic reactions can be derived here as well, e.g., for a spherical particle:

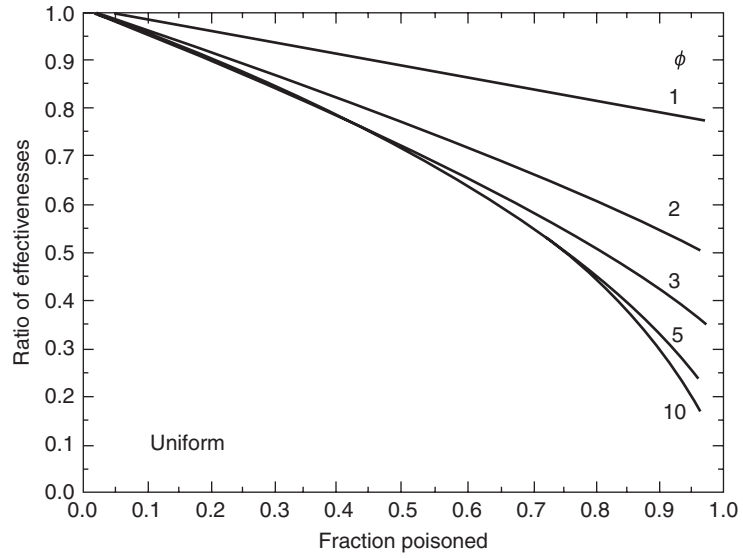
$$\frac{\partial(\varepsilon_s C_{as})}{\partial t} = \frac{1}{r^2}\frac{\partial}{\partial r}\left(D_{ea} r^2 \frac{\partial C_{as}}{\partial r}\right) - r_a \qquad \frac{\partial C_s}{\partial t} = -r_s$$

$$C_{as} = C_{as0} \quad C_s = C_{s0} \qquad \text{at} \quad t = 0 \tag{7-124}$$

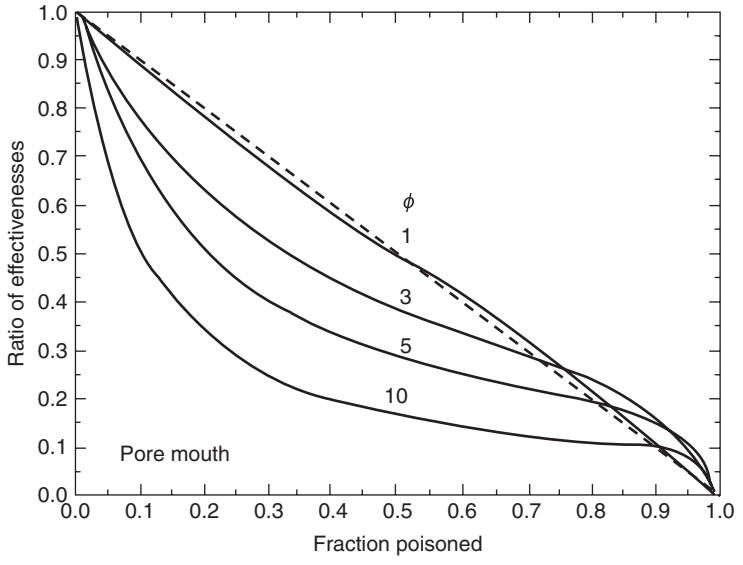
$$\frac{\partial C_{as}}{\partial r} = 0 \qquad \text{at} \qquad r = 0 \qquad D_{ea}\frac{\partial C_{as}}{\partial r}\Big|_{r=R_p} = k_p(C_a - C_{as}|_{r=R_p})$$

$$\varepsilon_s = \varepsilon_{s0} + C_{s0}(\upsilon_s - \upsilon_p)\left(1 - \frac{C_s}{C_{s0}}\right) \qquad \frac{D_{ea}}{D_{ea0}} = \left(\frac{\varepsilon_s}{\varepsilon_{s0}}\right)^\beta \qquad \beta = 2-3 \tag{7-125}$$

Here the porosity and the effective diffusivity vary with conversion of solid; $\upsilon_s$ and $\upsilon_p$ are the reactant and product molar volumes. A Thiele modulus $\varphi$



(*a*)



(*b*)

**FIG. 7-10** Poisoning for a first-order reaction. (*a*) Uniform poisoning. (*b*) Pore mouth poisoning.

**TABLE 7-7 Noncatalytic Gas-Solid Reaction-Diffusion Models**

| Model | Main features |
|---|---|
| Sharp interface model (SIM) | Reacting solid is nonporous.<br>Reacted solid ash is porous.<br>Reaction occurs at the ash-unreacted solid interface. |
| Volume reaction model | Reacting solid is also porous.<br>Reaction occurs everywhere in the particle. |
| Grain model | Particle is divided into identical solid spherical grains.<br>Each grain reacts according to the sharp interface model. |
| Crackling core model | Combination of SIM and grain model. |
| Nucleation model | Nucleation of metals in metal reduction reactions. |

and dimensionless time θ can be defined, e.g., for a rate second-order in $A$ and first-order in $B$:

$$r = kC_{as}^2 C_s \tag{7-126}$$

$$\varphi = R_p \sqrt{\frac{kC_{as}(R_p)C_{s0}}{D_{ea0}}} \quad \theta = bkC_{as0}^2 t \tag{7-127}$$

For the given rate expression, Eqs. (7-124) to (7-127) can be numerically integrated, e.g., in Fig. 7-13 for reaction control and Fig. 7-14 for intraparticle diffusion control, both with negligible external mass transfer resistance; $x$ is the fractional conversion.

## GAS-LIQUID REACTIONS

Many industrial processes employ gas-liquid reactions that can be either noncatalytic or homogeneously catalyzed. These include, for instance, absorption of acid gases ($SO_3$, $NO_2$, $CO_2$), chlorinations (benzene, dodecane, toluene), oxidations (P-xylene to terephthalic acid, cyclohexane to cyclohexanone and cyclohexanol, acetaldehyde to acetic acid), hydrogenations (olefins, esters to fatty acids), and hydroformylation of olefins to alcohols, to name a few. See also Sec. 19 and Shah (*Gas-Liquid-Solid Reactor Design,* McGraw-Hill, 1979). These reactions include gas reactants dissolving in a liquid and reacting there with a liquid reactant. When determining the kinetics of such reactions from lab data, one needs to understand the mechanism and the controlling steps, just as in the case for heterogeneous gas-solid reactions. The simplest model is the two-film model. It involves the following consecutive steps for the gaseous reactant:

1. Mass transfer of the gas reactant from bulk gas to the gas-liquid interface across the gas film.
2. Mass transfer of the dissolved gas reactant to the bulk liquid across the liquid film—if the reaction is fast, the reaction will occur in the liquid film (in parallel with diffusion).
3. Reaction in the bulk liquid.

At the gas-liquid interface, the liquid and gas concentrations of the gaseous reactant are assumed to be at thermodynamic equilibrium.

For a volatile liquid reactant or a volatile product, these steps are essentially reversed. For a nonvolatile liquid reactant or product, only the reaction and diffusion in the liquid take place. Figure 7-15 describes the absorbing gas concentration profiles in a gas-liquid system (excluding the solid catalyst in this case).

For a general gas-liquid reaction:

$$A(g) + bB(\text{l}) \rightarrow \text{products} \tag{7-128}$$

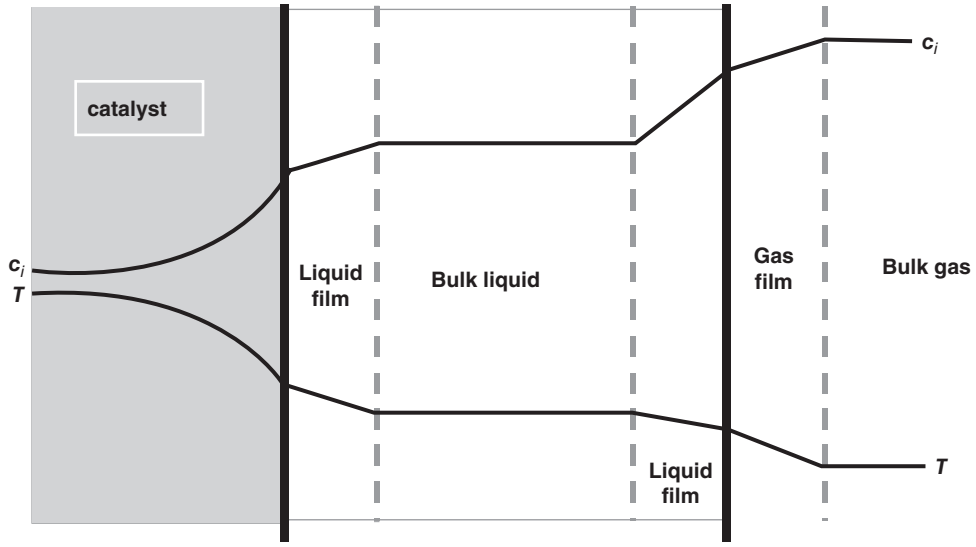

**FIG. 7-15** Absorbing gas concentration and temperature profiles (exothermic reaction) in gas-liquid and gas-liquid-solid reactions.

the two-film pseudo-steady-state model is described by the following fluxes across the interface for the gaseous reactant *A*:

$$N_{aG} = \frac{D_{aG}}{\delta_G}(P_a - P_{ai}) = k_G(P_a - P_{ai}) = N_{aL} = \frac{D_{aL}}{\delta_L}(C_{Lai} - C_{La}) = k_L(C_{Lai} - C_{La}) \tag{7-129}$$

Here the subscript *L* denotes liquid, *G* denotes gas, *i* denotes the gas-liquid interface (where the gas and liquid concentrations are in equilibrium). The thickness of the liquid and gas films is not a directly measurable quantity, and instead mass transfer coefficients are defined as indicated above. These depend on the diffusivity of the molecule, geometry, flow patterns and rates, and operating conditions; typical values of mass transfer coefficients can be viewed in Sec. 19. In addition to the two-film steady-state model, other more accurate, non-steady-state models have also been developed such as the surface renewal and penetration models (see, e.g., Astarita, *Mass Transfer with Chemical Reaction*, Elsevier, 1967). In many cases of industrial interest, mass-transfer resistance in the gas-film is negligible, especially considering that gas-phase diffusivities are 2 to 3 orders of magnitude larger for the same species than those in the liquid. Hence we drop the subscripts *L* and *G* from the concentrations since the concentrations considered are in the liquid phase only.

## REACTION-DIFFUSION REGIMES

Depending on the relative rates of diffusion and reaction, the following diffusion-reaction regimes occur:

$$\begin{aligned} &t_D \ll t_r && \text{slow reaction regime with reaction control} \\ &t_D \gg t_r && \text{fast reaction regime with diffusion control} \\ &t_D \simeq t_r && \text{both reaction and diffusion are important} \\ &t_D = \frac{D_a}{k_L^2} && t_r = \frac{C_{ai} - C_{ae}}{r(C_{ai})} \end{aligned} \tag{7-130}$$

Here $t_D$ and $t_r$ are the diffusion and reaction times, respectively, $C_{ai}$ is the concentration at the liquid side of the interface and $C_{ae}$ is the reaction equilibrium concentration of the gaseous reactant *A*, and $k_L$ is the mass transfer coefficient. For the *fast reaction regime*, diffusion and reaction occur simultaneously in the liquid film, while for the *slow reaction regime*, there is no reaction in the liquid film and the mass transfer can be considered to occur independently of reaction in a consecutive manner. For the slow reaction regime, the following subregimes can be defined:

$$\begin{aligned} &t_m \ll t_r && \text{slow reaction kinetic control} \\ &t_m \gg t_r && \text{slow reaction mass transfer control} \\ &t_m \simeq t_r && \text{both reaction and mass transfer are important} \\ &t_m = \frac{1}{k_L a} \end{aligned} \tag{7-131}$$

Here $t_m$ is the mass transfer time, and *a* is the *gas-liquid interfacial area per unit volume of reactor*. Only under *slow reaction kinetic control regime* can intrinsic kinetics be derived directly from lab data. Otherwise the intrinsic kinetics have to be extracted from the observed rate by using the mass transfer and diffusion-reaction equations, in a manner similar to those defined for catalytic gas-solid reactions. For instance, in the *slow reaction regime* for a first-order reaction,

$$r_{a,\text{obs}} = \frac{C_{ai}}{\text{He}_a/(k_G a) + 1/(k_L a) + 1/k} \tag{7-132}$$

$$k_{\text{obs}} = \frac{1}{\text{He}_a/(k_G a) + 1(k_L a) + 1/k} \tag{7-133}$$

Here $\text{He}_a$ is the Henry constant for the gaseous solute *A*. For the fast reaction regime, instead of the effectiveness factor adjustment for the intrinsic reaction rate, it is customary to define an *enhancement factor* to describe the observed mass transfer enhancement by the reaction, defined as the ratio of mass transfer in the presence of reaction in the liquid to mass transfer in the absence of reaction:

$$E = k_L/k_{L0} \tag{7-134}$$

Solving the diffusion-reaction equation in the liquid, the enhancement factor can be related to the *Hatta number* Ha, which is similar to the Thiele modulus defined for heterogeneous gas-solid catalysts. Thus, the Hatta number and its relation to the controlling regime are

$$\text{Ha} = \sqrt{\frac{t_D}{t_R}} = \sqrt{\frac{\text{reaction rate in the film}}{\text{diffusion rate through the film}}}$$

$$\begin{aligned} &\text{Ha} \ll 1 && \text{slow reaction regime} \\ &\text{Ha} \gg 1 && \text{fast reaction regime} \end{aligned} \tag{7-135}$$

For instance, for a first-order reaction in the gaseous reactant *A* (e.g., with large excess of liquid reactant *B*), using the film model, the following relates the enhancement factor to the Hatta number:

$$\text{Ha} = \delta_L\sqrt{\frac{k}{D_a}} = \sqrt{\frac{kD_a}{k_{L0}^2}} \qquad \text{for } C_b \gg C_{ai} \tag{7-136}$$

$$E = \frac{\text{Ha}}{\tanh \text{Ha}}\left(1 - \frac{C_a}{C_{ai}}\frac{1}{\cosh \text{Ha}}\right) > 1 \tag{7-137}$$

When both *A* and *B* have comparable concentrations, then the enhancement factor is an increasing function of an additional parameter:

$$\lambda = \frac{D_b C_b}{bD_a C_{ai}} \tag{7-138}$$

In the limit of an irreversible instantaneous reaction, the reaction occurs at a plane in the liquid where the concentration of both reactants *A* and *B* is zero and the flux of *A* equals the flux of *B*. The criterion for an instantaneous reaction is

$$\text{Ha} \gg \lambda \qquad E_\infty = 1 + \lambda \gg 1 \tag{7-139}$$

Figure 7-16 illustrates typical concentration profiles of *A* and *B* for the various diffusion-reaction regimes.

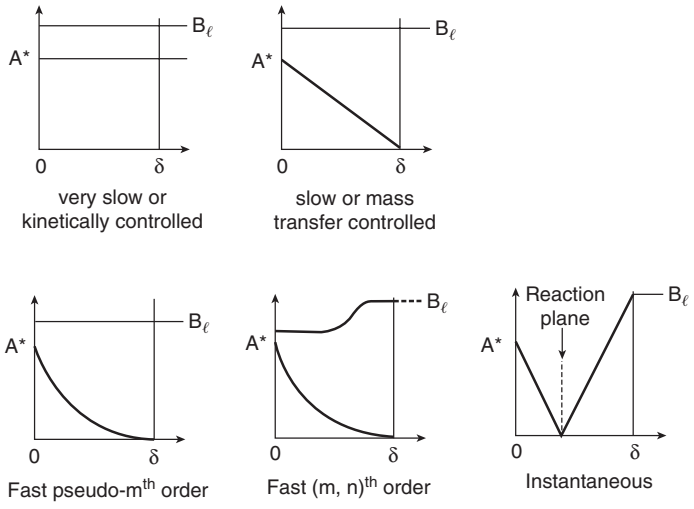

**FIG. 7-16** Concentration profiles for the general reaction $A(g) + bB(l) \rightarrow$ products with the rate $r = kC_a^m C_b^n$. [Adapted from Mills, Ramachandran, and Chaudhari, "Multiphase Reaction Engineering for Fine Chemicals and Pharmaceuticals," in Amundson and Luss (eds.), *Rev. Chem. Eng.* **8**(1–2):1 (1992), Figs. 19 and 20.]

# GAS-LIQUID-SOLID REACTIONS

## GAS-LIQUID-SOLID CATALYTIC REACTIONS

Many solid catalyzed reactions take place with one of the reactants absorbing from the gas phase into the liquid and reacting with a liquid reactant on the surface or inside the pores of a solid catalyst (see Fig. 7-15). Examples include the Fischer-Tropsch synthesis of hydrocarbons from synthesis gas (CO and $H_2$) in the presence of Fe or Co-based heterogeneous catalysts, methanol synthesis from synthesis gas ($H_2 + CO$) in the presence of heterogeneous CuO/ZnO catalyst, and a large number of noble metal catalyzed hydrogenations among others. For a slow first-order reaction of a gaseous reactant, the concept of resistances in series can be expanded as follows, e.g., for a slurry reactor with fine catalyst powder:

$$r_{a,\text{obs}} = \frac{C_{ai}}{\dfrac{\text{He}_a}{k_G a} + \dfrac{1}{k_L a} + \dfrac{1}{k_s a_s} + \dfrac{1}{k}} \qquad k_{\text{obs}} = \frac{1}{\dfrac{\text{He}_a}{k_G a} + \dfrac{1}{k_L a} + \dfrac{1}{k_s a_s} + \dfrac{1}{k}} \tag{7-140}$$

Intraparticle diffusion resistance may become important when the particles are larger than the powders used in slurry reactors, such as for catalytic packed beds operating in trickle flow mode (downflow gas and liquid), in packed bubble column mode (upflow gas and liquid), or countercurrent mode (gas upflow and liquid downflow). For these the effectiveness factor concept for intraparticle diffusion resistance has to be considered in addition to the other resistances present. See more details in Sec. 19.

## POLYMERIZATION REACTIONS

Polymers are high-molecular-weight compounds assembled by the linking of small molecules called *monomers*. Most polymerization reactions involve two or three phases, as indicated below. There are several excellent references dealing with *polymerization kinetics* and reactors, including Ray, *J. Macromol. Sci.-Revs. Macromol. Chem.* **C8:** 1 (1972); Ray in Lapidus and Amundson (eds.), *Chemical Reactor Theory—A Review*, Prentice-Hall, 1977; Tirrel et al. in Carberry and Varma (eds.), *Chemical Reaction and Reactor Engineering*, Marcel Dekker, 1987; Dotson et al., *Polymerization Process Modeling*, Wiley, 1995; and Meyer and Keurentjes (eds.), *Handbook of Polymer Reaction Engineering*, Wiley, 2005. An overview of polymerization modeling in industry can be found in Mueller et al., *Macromol. Reaction Eng.* **5:** 261 (2011). A general reference for polymers is Rodriguez et al., *Principles of Polymer Systems*, 6th ed., CRC Press, 2014.

Polymerization can be classified according to the main phase in which the reaction occurs as liquid (most polymerizations), vapor (e.g., Ziegler Natta polymerization of olefins), and solid phase (e.g., finishing of melt polymerization). Polymerization reactions can be further classified into

1. Bulk mass polymerization
   *a.* Polymer soluble in monomer
   *b.* Polymer insoluble in monomer
   *c.* Polymer swollen by monomer
2. Solution polymerization
   *a.* Polymer soluble in solvent
   *b.* Polymer insoluble in solvent
3. Suspension polymerization with initiator dissolved in monomer
4. Emulsion polymerization with initiator dissolved in dispersing medium

Polymerization can be catalytic or noncatalytic, and it can be homogeneously or heterogeneously catalyzed. Polymers that form from the liquid phase may remain dissolved in the remaining monomer or solvent, or they may precipitate. Sometimes beads are formed and remain in suspension; sometimes emulsions form. In some processes, solid polymers precipitate from a fluidized gas phase. Polymerization processes are also characterized by extremes in temperature, viscosity, and reaction times. For instance, many industrial polymers are mixtures with molecular weights of $10^4$ to $10^7$. In polymerization of styrene the viscosity increases by a factor of $10^6$ as conversion increases from 0 to 60 percent. The adiabatic reaction temperature for complete polymerization of ethylene is 1800 K (3240°R). Initiators of the chain reactions have concentration as low as $10^{-8}$ g-mol/L, so they are highly sensitive to small concentrations of poisons and impurities.

Polymerization mechanism and kinetics require special treatment and special mathematical tools due to the very large number of similar reaction steps. Some polymerization types are briefly described next. In this subsection species names and concentrations are denoted by the same capital letters.

**Bulk Polymerization** The monomer and initiators are reacted with or without mixing (e.g., without mixing to make useful shapes directly, such as in poly(methyl methacrylate) acrylic glass sheet). Because of viscosity limitations, stirred bulk polymerization is not carried to completion. For instance, for addition polymerization, conversions as low as 30 to 60 percent are achieved, with the remaining monomer stripped out and recycled (e.g., in the case of polystyrene).

**Suspension or Bead Polymerization** Bulk reaction proceeds in droplets of 10 μm to 1000 μm diameter suspended in water or another medium and insulated from one another by some colloid. A typical suspending agent is polyvinyl alcohol dissolved in water. The polymerization can be done to high conversion. Temperature control is easy because of the moderating thermal effect of the water and its low viscosity. The suspensions sometimes are unstable, and agitation may be critical. Examples are polyvinyl acetate in methanol, copolymers of acrylates and methacrylates, and polyacrylonitrile in aqueous $ZnCl_2$ solution.

**Emulsion Polymerization** Emulsions have particles of 0.05 to 5.0 μm in diameter. The product is a stable latex, rather than a filterable suspension. Some latexes are usable directly, as in paints, or they may be coagulated by various means to produce very high-molecular-weight polymers. Examples are polyvinyl chloride and butadiene-styrene rubber.

**Solution Polymerization** These processes may retain the polymer in solution or precipitate it. Examples include polyethylene, the copolymerization of styrene and acrylonitrile in methanol, and the aqueous solution of acrylonitrile to precipitate polyacrylonitrile.

**Polymer Characterization** The physical properties of polymers depend largely on the *molecular weight distribution* (MWD), which can cover a wide range. Since it is impractical to fractionate the products and reformulate them into desirable ranges of molecular weights, immediate attainment of desired properties must be achieved through the correct choice of reactor type and operating conditions, notably of distributions of residence time and temperature. High viscosities influence those factors. For instance, high viscosities prevalent in bulk and melt polymerizations can be avoided by using solutions, suspensions, or emulsions. The interaction between the flow pattern in the reactor and the type of reaction affects the MWD. If the period during which the molecule is growing is short compared with the residence time in the reactor, the MWD in a batch reactor is broader than in a CSTR. This situation holds for many free radical and ionic polymerization processes where the reaction intermediates are very short lived. In cases where the growth period is the same as the residence time in the reactor, the MWD is narrower in batch than in CSTR. Polymerizations that have no termination step—for instance, polycondensations—are of this type. This topic is treated by Denbigh [*J. Applied Chem.* **1:** 227 (1951)] and Schork et al. [*Control of Polymerization Reactors*, Marcel Dekker, 1993].

Four types of MWD which are encountered in practice can be defined: (1) The *number chain length distribution* (NCLD), relating the chain length distribution to the number of molecules per unit volume; (2) the *weight chain length distribution* (WCLD) relating the chain length distribution to the weight of molecules per unit volume; (3) the *number molecular weight distribution* (NMWD) relating the chain length distribution to molecular weight; and (4) the *weight molecular weight distribution* (WMWD) relating the weight distribution to molecular weight. It is often not necessary to know the entire molecular weight distribution, and it is enough to know the first few averages. Two average molecular weights and corresponding average chain lengths are typically defined: the *number average molecular weight* $M_n$ and the corresponding *number average chain length* $\mu_n$; and the *weight average molecular weight* $M_w$ and the corresponding *weight average chain length* $\mu_w$. The ratio of the weight to the number average molecular weights or chain lengths is called *polydispersity* (PD) and describes the width of the molecular weight distribution.

$$M_n = \frac{\sum_{j=1}^{\infty} (jw) P_j}{\sum_{j=1}^{\infty} P_j} \qquad \mu_n = \frac{\sum_{j=1}^{\infty} j P_j}{\sum_{j=1}^{\infty} P_j} \qquad M_w = \frac{\sum_{j=1}^{\infty} (jw)^2 P_j}{\sum_{j=1}^{\infty} (jw) P_j} \qquad \mu_w = \frac{\sum_{j=1}^{\infty} j^2 P_j}{\sum_{j=1}^{\infty} j P_j} \tag{7-141}$$

$$\text{PD} = \frac{M_w}{M_n} = \frac{\mu_w}{\mu_n}$$

The average chain lengths can be related to the $k$th moments $\lambda_k$ of the distribution as follows:

$$\mu_n = \frac{\lambda_1}{\lambda_0} \quad \mu_w = \frac{\lambda_2}{\lambda_1} \quad \text{PD} = \frac{\lambda_0 \lambda_2}{\lambda_1^2} \quad \text{where} \quad \lambda_k = \sum_{j=1}^{\infty} j^k P_j \tag{7-142}$$

Here $P_j$ is the concentration of the polymer with chain length $j$—the same symbol is also used for representing the polymer species $P_j$; $w$ is the molecular weight of the repeating unit in the chain.

A factor in addition to the residence time distribution and temperature distribution that affects the molecular weight distribution is the type of chemical reaction (e.g., step or chain addition growth polymerization).

Two major polymerization mechanisms are considered: *chain growth* and *step growth*. In addition, polymerization can be *homopolymerization*—a single monomer is used—and *copolymerization* usually with two or more monomers with complementary functional groups.

**Chain Growth Homopolymerization Mechanism and Kinetics** Free radical and ionic polymerizations proceed through this type of mechanism, such as styrene polymerization. Here one monomer molecule is added to the chain in each step. The general reaction steps and corresponding rates can be written as follows:

$$\begin{aligned}
&I\cdot \xrightarrow{f\,k_d} 2R\cdot && && \text{initiation}\\
&R\cdot + M \xrightarrow{k_i} P_1\cdot && &&\\
&P_n\cdot + M \xrightarrow{k_p} P_{n+1}\cdot && n,m=1,2,\ldots && \text{propagation}\\
&P_n\cdot + M \xrightarrow{k_{fm}} M_n + P_1\cdot && && \text{chain transfer to monomer}\\
&P_n\cdot + P_m\cdot \xrightarrow{k_{tc}} M_{n+m} && && \text{termination by coupling}\\
&P_n\cdot + P_m\cdot \xrightarrow{k_{td}} M_n + M_m && && \text{termination by disproportionation}
\end{aligned} \tag{7-143}$$

Here $M$, $I$, and $R$ are the monomer, initiator, and initiator radical concentrations, $P_n$ is the *growing* or *live polymer* concentration of chain length $n$, $P$ is the *total live polymer concentration*, $P=\sum_{n=1}^{\infty} P_n$, and $M_n$ is the *dead* or *product polymer* of chain length $n$. Considering a well-stirred batch polymerization, the mass balances with initial conditions are

$$\begin{aligned}
\frac{dI}{dt} &= -k_d I \quad I(0)=I_0\\
\frac{dR}{dt} &= 2fk_d I - k_i MR \quad R(0)=0\\
\frac{dM}{dt} &= -k_i MR - k_{fm} MP - k_p MP \quad M(0)=M_0\\
\frac{dP_1}{dt} &= k_i MR - k_p MP_1 + k_{fm} M\left(P-P_1\right) - \left(k_{tc}+k_{td}\right)PP_1 \quad P_1(0)=0\\
\frac{dP_n}{dt} &= k_p M\left(P_{n-1}-P_n\right) - k_{fm} MP_n - \left(k_{tc}+k_{td}\right)PP_n \quad P_n(0)=0 \quad n>1\\
\frac{dM_n}{dt} &= k_{fm} MP_n + k_{td} PP_n + \frac{k_{tc}}{2}\sum_{m=1}^{n-1} P_m P_{n-m} \quad M_n(0)=0 \quad n>1
\end{aligned}$$

Assuming reaction steps are independent of chain length and the pseudo-steady-state approximation for the radicals and the long chain hypothesis, that is, propagation terms are much larger than initiation or termination terms, using the *z transform* or *generating function* methods, leads to the following rates for monomer and initiator conversion and live polymer distribution and the instantaneous dead polymer degree of polymerization. The growing chains distribution is the *Flory-Schulz, geometric, or most probable distribution* [see, e.g., Ray, *J. Macromol. Sci.-Revs. Macromol. Chem.* **C8:** 1 (1972); Ray in Lapidus and Amundson (eds.), *Chemical Reactor Theory—A Review*, Prentice-Hall, 1977; Tirrel et al. in Carberry and Varma (eds.), *Chemical Reaction and Reactor Engineering*, Marcel Dekker, 1987; Schork et al., *Control of Polymerization Reactors*, Marcel Dekker, 1993; and Dotson et al., *Polymerization Process Modeling*, Wiley, 1995]:

$$P_n = P(1-\alpha)\alpha^{n-1} \qquad \alpha = \frac{k_p M}{(k_p+k_{fm})M+(k_{tc}+k_{td})P}$$

$$P = \left(\frac{2fk_d I}{k_{tc}+k_{td}}\right)^{1/2} \qquad I = I_0 e^{-k_d t} \tag{7-144}$$

$$r_p = -\frac{dM}{dt} = k_p\left(\frac{2fk_d}{k_{tc}+k_{td}}\right)^{1/2} M\, I^{1/2} \qquad \mu_n^{\text{inst}} = \frac{k_p M}{k_{fm}M+(k_{td}+\frac{1}{2}k_{tc})P}$$

Here $r_p$ is the rate of polymerization, $\alpha$ is the probability of propagation, $\mu_n^{\text{inst}}$ is the number average instantaneous degree of polymerization, i.e., the number of monomer units in the dead polymer, and $f$ is the initiator efficiency. Compare $r_p$ in Eq. (7-144) with the simpler mechanism represented by Eq. (7-68). When chain transfer is the primary termination mechanism or when disproportionation is the primary termination method, then the *instantaneous polydispersity* $\text{PD}^{\text{inst}}=2$. When coupling is the primary termination mechanism, then the instantaneous polydispersity $\text{PD}^{\text{inst}}=1.5$. These are lower bounds on the *cumulative polydispersity* of the dead polymer MWD since polydispersities greater than these bounds occur due to variations in monomer, initiator, or temperature during the batch.

Mathematically, the infinite set of equations describing the rate of each chain length can be solved by using the *z transform* or the *generating function methods* (which are discrete methods), *continuous variable approximation method*, or the *method of moments* [see, e.g., Ray, *J. Macromol. Sci.-Revs. Macromol. Chem.* **C8:** 1 (1972); and Ray in Lapidus and Amundson (eds.), *Chemical Reactor Theory—A Review*, Prentice-Hall, 1977]. In general, the infinite set of equations must be solved numerically to obtain the full *cumulative molecular weight distribution* of dead chains due to changing initiator and monomer during the batch [see, e.g., Butté et al., *Macromol. Theory Simul.* **11**(1): 22, 2002]. The effect of compartmentalization on emulsion polymerization kinetics can be found in Wulkow and Richards, *Ind. Eng. Chem. Res.* **53**(18): 7275, 2014.

Typical ranges of the kinetic parameters for low conversion homopolymerization are given in Table 7-8. For more details, see Hutchinson in Meyer and Keurentjes (eds.), *Handbook of Polymer Reaction Engineering*, Wiley, 2005.

**Step Growth Homopolymerization Mechanism and Kinetics** Here any two growing chains can react with each other. The propagation mechanism is an infinite set of reactions

$$P_n + P_m \underset{k_p'}{\overset{k_p}{\rightleftarrows}} P_{n+m} + W \qquad n,m=1,2,\ldots \tag{7-145}$$

Here $P_n$ is the *growing polymer* concentration of chain length $n$, and $W$ is the condensation product concentration, e.g., water for polyesters. Some nylons are also produced through this mechanism. This is usually modeled under the simplifying assumption that the rate constants are independent of chain length which has proved fairly accurate. Assuming a well-stirred batch reactor, pure monomer with concentration that is charged initially, and that the condensation product is removed continuously, the reaction may be considered irreversible. The polymer chain balances and initial conditions are

$$\begin{aligned}
\frac{dP_1}{dt} &= -2k_p P_1 P, \quad P_1(0)=P_{10}\\
\frac{dP_n}{dt} &= k_p\sum_{r=1}^{n-1} P_r P_{n-r} - 2k_p P_n P, \quad P_n(0)=0, \quad n>1
\end{aligned}$$

By using the $z$ transform or generating function methods, the polymer has a Flory-Schulz distribution:

$$\begin{aligned}
&P_n = P_{10}(1-\alpha)^2\alpha^{n-1},\ n\geq 1 \qquad k_{p,n,m}=k_p \qquad \alpha=\frac{P_{10}k_p t}{P_{10}k_p t+1}\\
&\mu_n = \frac{1}{1-\alpha} \qquad \mu_w = \frac{1+\alpha}{1-\alpha} \qquad \text{PD}=\frac{\mu_w}{\mu_n}=1+\alpha
\end{aligned} \tag{7-146}$$

As the conditions approach complete conversion of functional groups ($\alpha$ approaches 1), the polydispersity approaches a value of PD = 2. For further details, see Gupta and Kumar, *Reaction Engineering of Step Growth Polymerization*, Springer, 1987; and Dotson et al., *Polymerization Process Modeling*, Wiley, 1995.

**Chain Growth Copolymerization** Copolymerization involves more than one monomer, usually two comonomers, as opposed to the single monomer involved in the chain growth and step homopolymerization schemes above. Examples are styrene and ethylene copolymers, some nylons, polyesters, and aramids. Here as well there are step growth and chain growth mechanisms, and these are much more complex [see, e.g., Ray, *J. Macromol.*

**TABLE 7-8 Typical Ranges of Kinetic Parameters**

| Coefficient/concentration | Typical range |
|---|---|
| $k_d$, 1/s | $10^{-6}$–$10^{-4}$ |
| $f$ | 0.4–0.9 |
| $k_p$, L/(mol/s) | $10^{2}$–$10^{4}$ |
| $k_t$, L/(mol/s) | $10^{6}$–$10^{8}$ |
| $k_{fm}/k_p$ | $10^{-6}$–$10^{-4}$ |
| $I$, mol/L | $10^{-4}$–$10^{-2}$ |
| $M$, mol/L | 1–10 |

SOURCE: Hutchenson, "Typical Ranges of Kinetic Parameters," in *Handbook of Polymer Reaction Engineering*, Wiley, 2005, Table 4.1.

*Sci.-Revs. Macromol. Chem.* **C8:** 1 (1972); Ray in Lapidus and Amundson (eds.), *Chemical Reactor Theory—A Review*, Prentice-Hall, 1977; Schork, *Control of Polymerization Reactors*, Marcel Dekker, 1993].

Consider a free radical polymerization of two monomers *A* and *B*. The propagation reactions are

$$P_{n,m}\cdot + A \xrightarrow{k_{paa}} P_{n+1,m}\cdot$$
$$P_{n,m}\cdot + B \xrightarrow{k_{pab}} Q_{n,m+1}\cdot$$
$$Q_{n,m}\cdot + A \xrightarrow{k_{pba}} P_{n+1,m}\cdot$$
$$Q_{n,m}\cdot + B \xrightarrow{k_{pbb}} Q_{n,m+1}\cdot$$

Here $P_{n,m}$ and $Q_{n,m}$ are live chain concentrations with $n$ monomer $A$ units and $m$ monomer $B$ units having $A$ and $B$ units at the radical ends, respectively. Assuming the long chain hypothesis, that is, propagation terms are much larger than initiation or termination terms, the monomer and radical mass balances are

$$-\frac{dA}{dt} = k_{paa}PA + k_{pba}QA$$
$$-\frac{dB}{dt} = k_{pab}PB + k_{pbb}QB$$
$$\frac{dP}{dt} = k_{pba}QA - k_{pab}PB$$
$$\frac{dQ}{dt} = k_{pab}PB - k_{pba}QA$$

Here $P$ and $Q$ are total radical concentrations. Assuming pseudo-steady state radical concentrations results in the *copolymer equation* or *Mayo-Lewis equation*:

$$r_1 = \frac{k_{paa}}{k_{pab}} \qquad r_2 = \frac{k_{pbb}}{k_{pba}} \qquad F_1 = \frac{r_1(f_1)^2 + f_1 f_2}{r_1(f_1)^2 + 2f_1 f_2 + r_2(f_2)^2}$$

where $r_1$ and $r_2$ are the *reactivity ratios*, $F_1$ is the *instantaneous monomer mole fraction composition of A* in the polymer being formed, and $f_1$ and $f_2$ are the *instantaneous monomer mole fractions of A and B* in the reactor. The reactivity ratios can be used to understand the copolymer structure. If $r_1 = r_2 = 0$, then $F_1 = 1/2$, and the copolymer has an *alternating sequence distribution*. If $r_1 = r_2 = 1$, then $F_1 = f_1$ and the copolymer has a *random sequence distribution*.

## BIOCHEMICAL REACTIONS

Mechanism and kinetics in biochemical systems describe the reactions that occur in living cells. Biochemical reactions involve two or three phases. For example, aerobic fermentation involves gas (air), liquid (water and dissolved nutrients), and solid (cells), as described in the Biocatalysis subsection above. Bioreactions convert feeds called *substrates* into more *cells* or *biomass* (cell growth), proteins, and *metabolic* products. Any of these can be the desired product in a commercial *fermentation*. For instance, methane is converted to biomass in a commercial process to supply fish meal to the fish farming industry. Ethanol, a metabolic product used in transportation fuels, is obtained by fermentation of corn-based or sugar cane–based sugars. There is a substantial effort to develop genetically modified biocatalysts that produce a desired metabolite at high rate and yield.

Bioreactions follow the same general laws that govern conventional chemical reactions, but the complexity of the mechanism is higher due to the close coupling of bioreactions and *enzymes* that are turned on (*expressed*) or turned off (*repressed*) by the cell depending on the conditions in the fermenter and in the cell. Thus the Monod rate expression in Eq. (7-92) can be used mainly to design bioreaction processes when the culture is in *balanced growth,* i.e., for steady-state cultivations or batch growth (in the exponential growth phase). After a sudden process upset (e.g., a sudden change in substrate concentration or pH), the *control network* of the cell that lies under the *mass flow network* is activated, and dramatic changes in the kinetics of product formation can occur. Table 7-9 summarizes key differences between biochemical and conventional chemical systems [see, e.g., Leib, Pereira, and Villadsen, "Bioreactors, A Chemical Engineering Perspective," *Chem. Eng. Sci.* **56:** 5485–5497 (2001)].

The network of bioreactions is called the *metabolic network*; the parallel and consecutive steps between key intermediates in the network are called *metabolic pathways*, and the determination of the mechanism and kinetics is called *metabolic flux analysis*. As for chemical systems, there are several levels of mechanistic and kinetic representation and analysis, listed in order of increasing complexity in Table 7-10.

**TABLE 7-9 Biological versus Chemical Systems**

- There is tighter control on conditions (e.g., pH, temperature, substrate and product concentrations, dissolved $O_2$ concentration, avoidance of contamination by foreign organisms).
- Pathways can be turned on/off by the microorganism through expression of certain enzymes depending on the substrate type and concentration and operating conditions, leading to a richness of behavior unparalleled in chemical systems.
- The global stoichiometry changes with operating conditions and feed composition; kinetics and stoichiometry obtained from steady-state (chemostat) data cannot be used reliably over a wide range of conditions, unless fundamental models are employed.
- Long-term adaptations (mutations) may occur in response to environment changes that can alter completely the product distribution.
- Only the substrates that maximize biomass growth are utilized even in the presence of multiple substrates.
- Cell energy balance requirements pose additional constraints on the stoichiometry that can make it very difficult to predict flux limitations.

Additional complexity can be included through cell population balances that account for the distribution of cell generations present in the fermenter through use of stochastic models. In this section we limit the discussion to simple black box and unstructured models. For more details on bioreaction systems, see, e.g., Villadsen, Nielsen, and Liden, *Bioreaction Engineering Principles*, 3d ed., Springer, 2011; Bailey and Ollis, *Biochemical Engineering Fundamentals*, 2d ed., McGraw-Hill, 1986; Blanch and Clark, *Biochemical Engineering*, Marcel Dekker, 1997; and Sec. 19.

**Mechanism** Stoichiometric balances are done on a C atom basis called *C-moles,* e.g., relative to the substrate (denoted by subscript *s*), and the corresponding stoichiometric coefficients $Y_{si}$ (based on C-mole of the primary substrate) are called *yield coefficients*. For instance,

$$\begin{aligned} &CH_2O + Y_{so}\,O_2 + Y_{sn}\,NH_3 + Y_{ss1}S_1 + \cdots \\ &\Rightarrow Y_{sx}X + Y_{sc}\,CO_2 + Y_{sp1}\,P_1 + \cdots + Y_{sw}\,H_2O \end{aligned} \tag{7-147}$$

Here the reactants (substrates) are glucose ($CH_2O$), $O_2$, $NH_3$, and a sulfur-providing nutrient $S_1$, and the products are biomass X, $CO_2$, metabolic products $P_i$, and $H_2O$.

The products of bioreactions can be reduced or oxidized, and all feasible pathways have to be *redox neutral*. There are several cofactors that transfer redox power in a pathway or between pathways, each equivalent to the reducing power of a molecule of $H_2$, e.g., nicotinamide adenine dinucleotide (NADH), and these have to be included in the stoichiometric balances as H equivalents through redox balancing. For instance, for the reaction of glucose to glycerol ($CH_{8/3}O$), $\frac{1}{3}$NADH equivalent is consumed:

$$CH_2O + \frac{1}{3}NADH \Rightarrow CH_{8/3}O \tag{7-148}$$

The stoichiometry in the biochemical literature often does not show $H_2O$ produced by the reaction; however, for complete elemental balance, and for fermenter design, water has to be included, and this is easily done once an $O_2$ requirement has been determined based on a redox balance.

**TABLE 7-10 Heirarchy of Kinetic Models in Biological Systems**

- Stoichiometric black box models (similar to a single global chemical reaction) represent the biochemistry by a single global reaction with fixed stoichiometric or *yield coefficients* (limited to a narrow range of conditions). Black box models can be used over a wider range of conditions by establishing different sets of yield coefficient for different conditions. These are also needed to establish the quantitative amounts of various nutrients needed for the completion of the bioreaction.
- Unstructured models view the cell as a single component interacting with the fermentation medium, and each bioreaction is considered to be a global reaction, with a corresponding empirical rate expression.
- Structured models include information on individual reactions or groups of reactions occurring in the cell, and cell components such as DNA, RNA, and proteins are included in addition to the primary metabolites and substrates (see, e.g., the active cell model of Nielsen and Villadsen, *Bioreaction Engineering Principles*, 2d ed., Kluwer Academic/Plenum Press, 2003).
- Fundamental models include cell dimensions, transport of substrates and metabolites across the cell membrane, and the elementary cell bioreaction steps and their corresponding enzyme induction mechanism. In recent years further kinetic steps have been added to the above models which are based on the conversion of substrates to metabolites. Thus the kinetics of protein synthesis by *transcription* and *translation* from the *genome* add much further complexity to cell kinetics.

Likewise for simplicity, the other form of the cofactor [e.g., the oxidized form of the cofactor NADH in Eq. (7-148)] is usually left out. In addition to C balances, for aerobic systems cell respiration has to be accounted for as well through a stoichiometric equation:

$$\text{NADH} + 0.5\text{O}_2 \Rightarrow \text{H}_2\text{O} + (\text{P/O})\text{ATP} \tag{7-149}$$

where P/O is the stoichiometric yield factor of adenosine triphosphate (ATP) on NaDH, $Y_{\text{NaDH, ATP}}$. The associated free energy produced or consumed in each reaction is measured in ATP units. To obtain the stoichiometric coefficient of ATP for a given reaction in a pathway, one has to consult tables (or charts) of biochemical reactions. The ATP produced in one part of the metabolic network (for example, in catabolism) has to be consumed in another part of the network (for example, in anabolism, the cell building reactions). Thus for Eq. (7-148) the stoichiometric ATP requirement to convert one C-mole of glucose to one C-mole of glycerol is $\frac{1}{3}$. In calculations of the carbon flux distribution in different pathways this ATP requirement has to be added on the left-hand side of the equation. Again the other form of the cofactor ATP is usually left out to simplify the reaction equation.

Several metabolic pathways are repeated for many living cells, and these are split into two: *catabolic,* or energy-producing, and *anabolic,* or energy-consuming, the later producing building blocks such as amino acids and the resulting macromolecules such as proteins. Of course, the energy produced in catabolic steps has to be balanced by the energy consumed in anabolic steps. Catabolic pathways include the well-studied *glycolysis*, *TCA cycle*, *oxidative phosphorylation,* and *fermentative pathways*. For more details see Stephanopoulos, Aristidou, and Nielsen, *Metabolic Engineering: Principles and Methodologies*, Academic, 1998; and Villadsen, Nielsen, and Liden, *Bioreaction Engineering Principles*, 3d ed., Springer, 2011; Bailey and Ollis, *Biochemical Engineering Fundamentals*, 2d ed., McGraw-Hill, 1986.

**Monod-Type Empirical Kinetics** Many bioreactions show increased biomass growth rate with increasing substrate concentration at low substrate concentration for the limiting substrate, but no effect of substrate concentration at high concentrations. This behavior can be represented by the Monod equation, Eq. (7-92). Additional variations on the Monod equation are briefly illustrated below. For two essential substrates, the Monod equation can be modified as

$$\mu = \frac{\mu_{\max} C_{s1} C_{s2}}{(K_{s1} + C_{s1})(K_{s2} + C_{s2})} \tag{7-150}$$

This type of rate expression is often used in models for water treatment, and many environmental factors can be included (the effect of phosphate, ammonia, volatile fatty acids, etc.). The correlation between parameters in such complicated models is, however, severe, and very often a simple Monod model such as Eq. (7-92) with only one limiting substrate is sufficient.

When *substrate inhibition* occurs,

$$\mu = \frac{\mu_{\max} C_s}{K_s + C_s + K_i / C_s^2} \tag{7-151}$$

Typically $O_2$ is a substrate that in high concentrations leads to substrate inhibition, but a high concentration of the carbon source can also be inhibiting (e.g., in bioremediation of toxic waste a high concentration of the organic substrate can lead to severe inhibition or death of the microorganism).

When *product inhibition* is present,

$$\mu = \frac{\mu_{\max} C_s}{K_s + C_s}\left(1 - \frac{C_p}{C_{p\max}}\right) \tag{7-152}$$

Here the typical example is the inhibitor effect of ethanol on yeast growth. Considerable efforts are made by the biotech companies to develop yeast strains that are tolerant to high ethanol concentrations since this will give considerable savings in, e.g., production of biofuel ethanol by fermentation.

The various component reaction rates for a single reaction can be related to the growth rate by using the stoichiometric (yield) coefficients, e.g., from Eq. (7-147):

$$r_i = Y_{xi}\mu C_x = \frac{Y_{si}}{Y_{sx}}\mu C_x \tag{7-153}$$

**Chemostat with Empirical Kinetics** Using the CSTR equation, Eq. (7-54), for a constant-volume single reaction [e.g. Eq. (7-147)], the substrate, biomass, and product material balances are

$$\begin{gathered} \frac{1}{Y_{sx}}\mu C_x + D(C_{s0} - C_s) = 0 \\ \mu C_x - DC_p = 0 \rightarrow D = \mu \\ \frac{Y_{sp}}{Y_{sx}}\mu C_x - DC_p = 0 \end{gathered} \tag{7-154}$$

Here $C_{s0}$ is the feed substrate concentration, and $D$ is the *dilution rate* which at steady state is equal to both the feed and effluent volumetric flow rates and to the specific growth rate. The effluent concentrations of substrate, biomass, and products can be calculated by using a suitable expression for the specific growth rate μ such as one of the relevant variants of the Monod kinetics described above.

## ELECTROCHEMICAL REACTIONS

Electrochemical reactions involve coupling between chemical reactions and electric charge transfer. These reactions often include two or three phases, for instance, a gas (e.g., $H_2$ or $O_2$ evolved at the electrodes or fed as reactants), a liquid (the electrolyte solution), and solids (electrodes). Electrocatalysts may be employed to enhance the reaction for a particular desired product. Also an electrode material may be selected to retard an undesired reaction. Electrochemical reactions are heterogeneous reactions that occur at the surface of electrodes and involve the transfer of charge in the form of electrons as part of a chemical reaction. The electrochemical reaction can produce a chemical change by passing an electric current through the system (e.g., electrolysis), or reversely a chemical change can produce electric energy (e.g., using a battery or fuel cell to power an appliance). There are a variety of practical electrochemical reactions, some occurring naturally, such as corrosion, and others used in production of chemicals (e.g., the decomposition of HCl to produce $Cl_2$ and $H_2$, the production of caustic soda and chlorine from NaCl brine, the smelting of aluminum), electroplating, and energy generation or storage (e.g., fuel cells, batteries, flow cells, and photovoltaics). Electrochemical reactions are typically reversible and can be generally written as a *reduction-oxidation* (*redox*) couple:

$$O + ne^- \Leftrightarrow R$$

where $O$ is an oxidized species and $R$ is a reduced species. For instance, the corrosion process includes oxidation at the *anode*:

$$\text{Fe} \Leftrightarrow \text{Fe}^{2+} + 2e^-$$

and reduction at the *cathode*:

$$\text{O}_2 + 2\text{H}_2\text{O} + 4e^- \Leftrightarrow 4\text{OH}^-$$

The overall electrochemical reaction is the stoichiometric sum of the anode and cathode reactions:

$$2\text{Fe} + \text{O}_2 + 2\text{H}_2\text{O} \Leftrightarrow 2\text{Fe}^{2+} + 4\text{OH}^- \quad \text{(four-electron transfer process, } n = 4\text{)}$$

The anode and cathode reactions are closely coupled in that the electric charge is conserved; therefore, the overall production rate is a direct function of the electric charge passed per unit time, the electric current $I$.

*Faraday's law* relates the charge transferred by ions in the electrolyte and electrons in the external circuit to the moles of chemical species reacted (Newman and Thomas-Alvea, *Electrochemical Systems*, 3d ed., Wiley Interscience, 2004):

$$\begin{gathered} Q = nmF \qquad F = 96{,}485\ \text{C/equiv} \\ I = \frac{Q}{t} = \frac{\text{charge}}{\text{time}}\ \text{A} \end{gathered} \tag{7-155}$$

where $n$ is the number of equivalents per mole, $m$ is the number of moles, $F$ is the Faraday constant, $Q$ is the charge, and $t$ is time. The total current passed may represent several parallel electrochemical reactions; therefore, we designate a current efficiency for each chemical species. The *current efficiency* is the ratio of the theoretical electric charge (Coulombs) required for the amount of product obtained to the total amount of electrical charge passed through the electrochemical cell. The chemical species production rate (mass/time), $w_i$, is related to the total current passed $I$, the species *current efficiency* $\varepsilon_{\text{current},i}$, and the molecular weight of the chemical species $\text{MW}_i$:

$$\begin{gathered} w_i = \frac{I \times \varepsilon_{\text{current},i} \times \text{MW}_i}{nF} = \frac{\text{mass}}{\text{time}} \\ j = \frac{\text{current}}{\text{area}} = \frac{I}{A_{\text{projected}}} \end{gathered} \tag{7-156}$$

Since electrochemical reactions are heterogeneous at electrode surfaces, the current $I$ is generally normalized by dividing it by the geometric or projected area of the electrode, resulting in the quantity known as the *current density j*, in units of $\text{kA/m}^2$.

The overall electrochemical cell *equilibrium potential* $E^o_{\text{cell}}$, as measured between the cathode and the anode, is related to the Gibbs free energy change for the overall electrochemical reaction:

$$\Delta G^o = \Delta H^o - T\Delta S^o = -nFE^o_{\text{cell}}$$
$$E^o_{\text{cell}} = -\frac{\Delta G^o}{nF} = E^o_{\text{cathode}} - E^o_{\text{anode}} \tag{7-157}$$

Each anode and cathode electrode reaction, or half-cell reaction, has an associated energy level or electric potential (volts) associated with it. Values of the standard equilibrium electrode reduction potentials $E^o$ at unit activity and 25°C may be obtained from the literature (de Bethune and Swendeman, "Table of Electrode Potentials and Temperature Coefficients," *Encyclopedia of Electrochemistry*, Van Nostrand Reinhold, 1964; and de Bethune and Swendeman, *Standard Aqueous Electrode Potentials and Temperature Coefficients*, Hampel, 1964). The overall electrochemical cell *equilibrium potential* either can be obtained from $\Delta G$ values or is equal to the cathode half-cell potential minus the anode half-cell potential, as shown above.

The *Nernst equation* allows one to calculate the *equilibrium potential* $E^{\text{eq}}$ when the activity of the reactants or products is not at unity:

$$\sum_i \nu_i M_i^{n_i} \rightarrow ne^-$$
$$E^{\text{eq}} = E^0 - \frac{RT}{nF}\ln(\prod a_i^{\nu_i}) \tag{7-158}$$
$$\left(\frac{\partial E}{\partial T}\right)_P = \frac{\Delta S}{nF}$$

where $\nu_i$ is the stoichiometric coefficient of chemical species $i$ (positive for products; negative for reactants), $M_i$ is the symbol for species $i$, $n_i$ is the charge number of the species, $a_i$ is the activity of the species, $E^o$ is the *formal potential*, and $\prod$ represents the product of all respective activities raised to their stoichiometric powers as required by the reaction. Please note that if the value of the equilibrium potential is desired at another temperature, $E^o$ must also be evaluated at the new temperature as indicated above.

**Kinetic Control** In 1905, Julius Tafel experimentally observed that when mass transport was not limiting, the *current density j* of electrochemical reactions exhibited the following behavior:

$$j = a' e^{\eta_{\text{act}}/b'} \quad \text{or} \quad \eta_{\text{act}} = a + b\log j$$

where the quantity $\eta_{\text{act}}$ is known as the *activation overpotential* $(E - E^{\text{eq}})$ and is the difference between the actual electrode potential $E$ and the reversible equilibrium potential of the electrochemical reaction $E^{\text{eq}}$. Thus the driving force for the electrochemical reaction is not the absolute potential; it is the activation overpotential $\eta_{\text{act}}$.

This relationship between the current density and activation overpotential has been further developed and resulted in the Butler-Volmer equation

$$r = \frac{j}{nF} = k_f C_o - k_r C_r \quad j = j_0(e^{-(\alpha nF/RT)\eta_{\text{act}}} - e^{[(1-\alpha)nF/RT]\eta_{\text{act}}})$$
$$\eta_{\text{act}} = E - E^{\text{eq}} \tag{7-159}$$

Here the reaction rate $r$ is defined per unit electrode area, moles per area per time, $j_0$ is the *equilibrium exchange current* when $E = E^{\text{eq}}$, $\eta_{\text{act}}$ is the *activation overpotential*, $\alpha$ is the *transfer coefficient* for the cathode, and $1-\alpha$ for the anode. For large activation overpotentials, the *Tafel empirical equation* applies as indicated above:

$$\eta_{\text{act}} = a + b\log j \quad \text{for } \eta_{\text{act}} > 100 \text{ mV}, \; b = \text{Tafel slope} \tag{7-160}$$

For small activation overpotentials, linearization gives

$$j = j_0 \frac{nF}{RT}\eta_{\text{act}} \tag{7-161}$$

**Mass Transfer Control** In this case, the surface concentration at the electrodes differs significantly from the bulk electrolyte concentration. The Nernst equation applies to the surface concentrations (or activities in case of nonideal solutions):

$$E^{\text{eq}} = E^o - \frac{RT}{nF}\ln(\prod a_{i,\text{surf}}^{\nu_i}) \tag{7-162}$$

If mass transfer is limiting, then a *limiting current* is obtained for each chemical species $i$:

$$j_{i,\text{lim}} = \frac{nFD_iC_i}{\delta} = nFk_{L,i}C_i \tag{7-163}$$

where $D_i$ is the diffusion coefficient, $\delta$ is the boundary layer thickness, and $k_{L,i}$ is the mass transfer coefficient of species $i$. The effect of mass transfer is included as follows:

$$j = j_0\left[\left(1 - \frac{j}{j_{c,\text{lim}}}\right)e^{-(\alpha nF/RT)\eta_{\text{act}}} - \left(1 - \frac{j}{j_{a,\text{lim}}}\right)e^{[(1-\alpha)nF/RT]\eta_{\text{act}}}\right]$$
$$\frac{C_{i,\text{surf}}}{C_i} = \left(1 - \frac{j}{j_{i,\text{lim}}}\right) \; i = o, r \tag{7-164}$$

**Ohmic Control** The overall electrochemical reactor cell voltage may be dependent on the kinetic and mass transfer aspects of the electrochemical reactions; however, a third factor is the potential lost within the electrolyte as current is passing through this phase. The potential drops may become dominant and limit the electrochemical reactions, requiring an external potential to be applied to drive the reactions or significantly lower the delivered electric potential in power generation applications such as batteries and fuel cells.

**Multiple Reactions** With multiple reactions, the total current is the sum of the currents from the individual reactions with anodic currents positive and cathodic currents negative. This is called the *mixed potential principle*. For more details see Bard and Faulkner, *Electrochemical Methods: Fundamentals and Applications*, 2d ed., Wiley, 2001.

Additional references on electrochemical reaction kinetics and mechanism include Newman and Thomas-Alvea, *Electrochemical Systems*, 3d ed., Wiley Interscience, 2004; Bard and Faulkner, *Electrochemical Methods: Fundamentals and Applications*, 2d ed., Wiley, 2001; Bethune and Swendeman, "Table of Electrode Potentials and Temperature Coefficients," *Encyclopedia of Electrochemistry*, Van Nostrand Reinhold, New York, 1964, pp. 414–424; and Bethune and Swendeman, *Standard Aqueous Electrode Potentials and Temperature Coefficients*, C. A. Hampel Publisher, 1964. Discussion on electrochemical reactors is in Sec. 19.

# DETERMINATION OF MECHANISM AND KINETICS

Laboratory data are the predominant source for reaction mechanism and kinetics in industrial practice. However, laboratory data intended for scoping and demonstration studies rather than for kinetic evaluation often have to be used, thus reducing the effectiveness and accuracy of the resulting kinetic model. The following are the steps required to obtain kinetics from laboratory data:

1. Develop initial guesses on mechanism, reaction time scale, and potential kinetic models from the literature, scoping experiments, similar chemistries, and computational chemistry calculations, when possible.
2. Select a suitable laboratory reactor type and scale, and analytical tools for kinetic measurements.
3. Develop a priori factorial experimental design or sequential experimental design.
4. When possible, provide ideal reactor conditions, e.g., good mechanical agitation in batch and CSTR, high-velocity flow in PFR.
5. Estimate the limiting diffusion-reaction regimes under the prevailing lab reactor conditions for heterogeneous reactions, and use the appropriate lab reactor model to interpret the data. When possible, operate the reactor under kinetic control.
6. Discriminate between competing mechanisms and kinetic rates by forcing maximum differentiation between competing hypotheses regarding mechanism and rates through the experimental design, and by obtaining the best fit of the kinetic data to the proposed kinetic forms.

## LABORATORY REACTORS

Selection of the laboratory reactor type and size, and associated feed and product handling, control, and analytical schemes depends on the type of reaction, reaction time scales, and type of analytical methods required. The criteria for selection include equipment cost, ease of operation, ease of data

analysis, accuracy, versatility, temperature uniformity and controllability, suitability for mixed phases, and to a lesser extent scale-up feasibility. Many configurations of laboratory reactors have been employed. Rase (*Chemical Reactor Design for Process Plants,* Wiley, 1977) and Shah (*Gas-Liquid-Solid Reactor Design,* McGraw-Hill, 1979) each have about 25 sketches, and Shah's bibliography has 145 items classified into 22 categories of reactor types. Jankowski et al. [*Chemische Technik* **30:** 441–446 (1978)] illustrate 25 different kinds of gradientless laboratory reactors for use with solid catalysts.

Laboratory reactors are of two main types:

1. Reactors used to obtain fundamental data on intrinsic chemical rates free of mass transfer resistances or other complications. Some of the gas-liquid lab reactors, for instance, employ known interfacial areas, thus avoiding the uncertainty regarding the area for gas to liquid mass transfer. When ideal behavior cannot be achieved, intrinsic kinetic estimates need to account for mass and heat transfer effects using the appropriate lab reactor model.
2. Reactors used to obtain scale-up data due to their similarity to the reactor intended for the pilot or commercial plant scale. How to scale down from the conceptual commercial or pilot scale to lab scale is a difficult problem in itself, and it is not possible to maintain all key features while scaling down.

The first type is often the preferred one—once the intrinsic kinetics are obtained at "ideal" lab conditions, scale-up is done by using models or correlations that describe large-scale reactor hydrodynamics coupled with the intrinsic kinetics. However, in some cases ideal conditions cannot be achieved, and the laboratory reactor has to be adequately modeled to account for mass and heat transfer and nonideal mixing effects to enable extraction of intrinsic kinetics. In addition, with homogeneous reactions, attention must be given to prevent wall-catalyzed reactions, which can result in observed kinetics that are fundamentally different from intrinsic homogeneous kinetics. This is a problem for scale-up, due to the high surface/volume ratio in small reactors versus the low surface/volume ratio in large-scale systems, resulting in widely different contributions of wall effects at different scales. Similar issues arise in bioreactors with the potential of undesirable wall growth of the biocatalyst cells masking the homogeneous growth kinetics. In catalytic reactions, certain reactor configurations may enhance undesirable homogeneous reactions, and the importance of these reactions may be different at larger scale, causing potential scale-up pitfalls.

The reaction rate is expressed in terms of chemical compositions of the reacting species, so ultimately the variation of composition with time or space must be found. The composition is determined in terms of a property that is measured by some instrument and calibrated. Among the measures that have been used are titration, pressure, refractive index, density, chromatography, spectrometry, polarimetry, conductimetry, absorbance, and magnetic resonance. Therefore, batch or semibatch data are converted to composition as a function of time ($C, t$), or to composition and temperature as functions of time ($C, T, t$), to prepare for kinetic analysis. In a CSTR and PFR at steady state, the rate and compositions in the effluent are observed as a function of residence time and operating conditions, e.g., temperature and pressure. In addition, for a PFR it is desirable to also obtain composition and temperature along the reactor.

**TABLE 7-11 Laboratory Reactors**

| Reaction | Reactor |
|---|---|
| Homogeneous gas | Isothermal U-tube in temperature-controlled batch |
| Homogeneous liquid | Mechanically agitated batch or CSTR with jacketed cooling/heating |
| Catalytic gas-solid | Packed tube in furnace |
| | Isothermal U-tube in temperature-controlled bath |
| | Rotating basket with jacketed cooling/heating |
| | Internal recirculation (Berty) reactor with jacketed cooling/heating |
| Noncatalytic gas-solid | Packed tube in furnace |
| Liquid-solid | Packed tube in furnace |
| Gas-liquid | CSTR with jacketed cooling/heating |
| | Fixed interface CSTR |
| | Wetted wall |
| | Laminar jet |
| Gas-liquid-solid | Slurry CSTR with jacketed cooling/heating |
| | Packed bed with downflow, upflow, or countercurrent |
| Solid-solid | Packed tube in furnace |

When a reaction has many reactive species (which may be the case even for apparently simple processes such as pyrolysis of ethane or synthesis of methanol), a factorial or sequential experimental design should be developed, and the data can be subjected to a *response surface analysis* (Box, Hunter, and Hunter, *Statistics for Experimenters,* 2d ed., Wiley Interscience, 2005; Davies, *Design and Analysis of Industrial Experiments,* Oliver & Boyd, 1954). This can result in a black box correlation or statistical model, such as a quadratic (limited to first- and second-order effects) expression for the variables $x_1$, $x_2$, and $x_3$:

$$r = k_1x_1 + k_2x_2 + k_3x_3 + k_{12}x_1x_2 + k_{13}x_1x_3 + k_{23}x_2x_3$$

Analysis of such statistical correlations may reveal the significant variables and interactions and may suggest potential mechanisms and kinetic models, say, of the Langmuir-Hinshelwood type, that could be analyzed in greater detail by a regression process. The variables $x_i$ could be various parameters of heterogeneous processes as well as concentrations. An application of this method to isomerization of *n*-pentane is given by Kittrel and Erjavec [*Ind. Eng. Chem. Proc. Des. Dev.* **7:** 321 (1968)].

Table 7-11 summarizes laboratory reactor types that approach the three ideal concepts BR, CSTR, and PFR, classified according to reaction types.

For instance, Fig. 7-17 summarizes laboratory reactor types and typical hydrodynamic parameters for gas-liquid reactions.

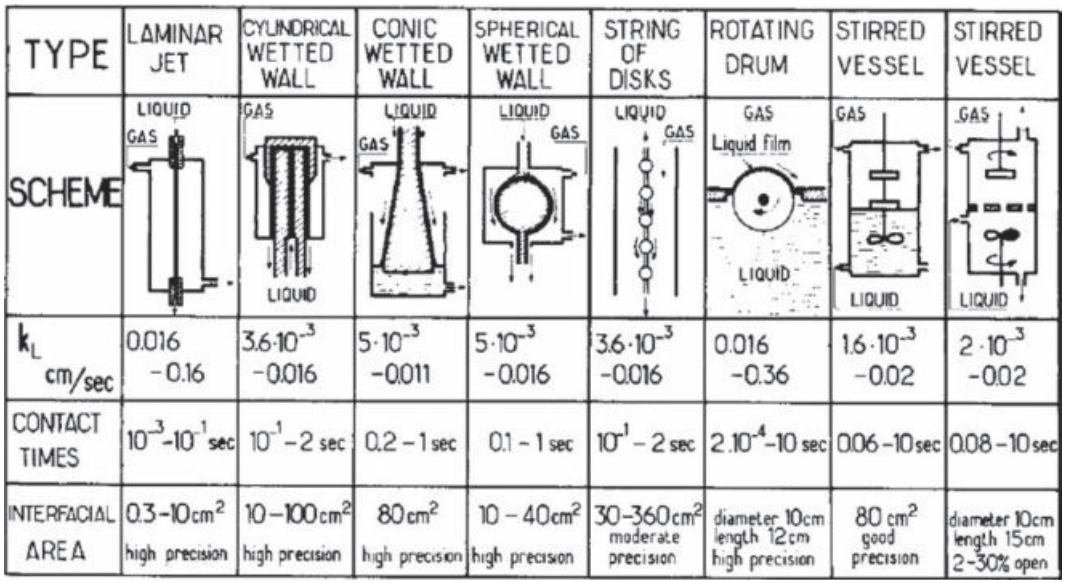

**FIG. 7-17** Principal types of laboratory reactors for gas-liquid reactions. [From Fig. 8 in Charpentier, "Mass Transfer Rates in Gas-Liquid Absorbers and Reactors," in Drew et al. (eds.), *Advances in Chemical Engineering,* vol. 11, Academic Press, 1981.]

**Batch Reactors** In the simplest kind of investigation, reactants can be loaded into a number of sealed tubes, kept in a constant temperature bath for various periods, shaken mechanically to maintain uniform composition, and analyzed. In terms of cost and versatility, the stirred batch reactor is the unit of choice for homogeneous reactions or heterogeneous slurry reactions including liquid-phase, gas-solid, gas-liquid, and gas-liquid-solid systems. For multiphase systems, some of the reactants can be semibatch or continuous. The batch reactor is especially suited to reactions with half-lives in excess of 10 min. Samples are taken at time intervals, and the reaction is stopped by cooling, by dilution, or by neutralizing a residual reactant such as an acid or base; analysis can then be made at a later time. Analytical methods that do not necessitate termination of reaction include nonintrusive measurements, e.g., (1) the amount of gas produced, (2) the gas pressure in a constant-volume vessel, (3) absorption of light, (4) electric or thermal conductivity, (5) polarography, (6) viscosity in polymerization, (7) pH and dissolved oxygen probes, and so on. The reactor may be operated under isothermal conditions, with the important effect of temperature determined from several isothermal runs, or the composition and temperature may be recorded simultaneously and the data regressed. On the laboratory scale, it is essential to ensure that a batch reactor is stirred to uniform composition, and for critical cases such as high viscosities this should be checked with tracer tests.

**Flow Reactors** CSTRs and other devices that require flow control are more expensive and difficult to operate. However, CSTRs and PFRs are the preferred laboratory reactors for steady-state operation. One of the benefits of CSTRs is their ability to operate isothermally and the fact that their mathematical representation is an algebraic equation thus making data analysis simpler. For laboratory research purposes, CSTRs are considered feasible for holding times of 1 to 4000 s, reactor volumes of 2 to 1000 $cm^3$ (0.122 to 61 $in^3$), and flow rates of 0.1 to 2.0 $cm^3/s$. Fast reactions and those in the gas phase are generally done in tubular flow reactors, just as they are often done on the commercial scale. Often it is not possible to measure compositions along a PFR, although temperatures can be measured using a thermowell with fixed or mobile thermocouple bundle. PFRs can be kept at nearly constant temperatures; small-diameter tubes immersed in a fluidized sand bed or molten salt can hold quite constant temperatures up to a maximum temperature of a few hundred degrees. PFRs may also be operated at near adiabatic conditions by providing dual radial temperature control to minimize the radial heat flux, with multiple axial zones. A recycle unit can be operated as a differential reactor with arbitrarily small conversion and temperature change. Test work in a tubular flow unit may be desirable if the intended commercial unit is of that type.

**Multiphase Reactors** Reactions between gas-liquid, liquid-liquid, and gas-liquid-solid phases are often tested in CSTRs. Other laboratory types are suggested by the commercial units depicted in appropriate sketches in Sec. 19 and in Fig. 7-17 [Charpentier, *Mass Transfer Rates in Gas-Liquid Absorbers and Reactors*, in Drew et al. (eds.), *Advances in Chemical Engineering*, vol. 11, Academic, 1981]. Liquids can be reacted with gases of low solubilities in stirred vessels, with the liquid charged first and the gas fed continuously at the rate of reaction or dissolution. Some of these reactors are designed to have known interfacial areas. Most equipment for gas absorption without reaction is adaptable to absorption with reaction. The many types of equipment for liquid-liquid extraction also are adaptable to reactions of immiscible liquid phases.

**Solid Catalysts** Processes with solid catalysts are affected by diffusion of heat and mass (1) within the pores of the pellet, (2) between the fluid and the particle, and (3) axially and radially within the packed bed. Criteria in terms of various dimensionless groups have been developed to tell when these effects are appreciable, and some of these were discussed above. For more details see Mears [*Ind. Eng. Chem. Proc. Des. Devel.* **10:** 541–547 (1971); *Ind. Eng. Chem. Fund.* **15:** 20–23 (1976)] and Satterfield (*Heterogeneous Catalysis in Practice,* McGraw-Hill, 1991, p. 491). For catalytic investigations, the rotating basket or fixed basket with internal recirculation is the standard device, usually more convenient and less expensive than equipment with external recirculation. In the fixed-basket type, an internal recirculation rate of 10 to 15 or so times the feed rate effectively eliminates external diffusional resistance and temperature gradients (see, e.g., Berty, *Experiments in Catalytic Reaction Engineering*, Elsevier, 1999). A unit holding 50 $cm^3$ (3.05 $in^3$) of catalyst can operate up to 800 K (1440°R) and 50 bar (725 psi). When deactivation occurs rapidly (in a few seconds during catalytic cracking, for instance), the fresh activity can be maintained with a transport reactor through which both reactants and fresh catalyst flow without slip and with short contact time. Since catalysts often are sensitive to traces of impurities, the time deactivation of the catalyst usually can be evaluated only with commercial feedstock. Physical properties of catalysts also may need to be checked periodically, including pellet size, specific surface, porosity, pore size and size distribution, effective diffusivity, and active metals content and dispersion. The effectiveness factor of a porous catalyst is found by measuring conversions with successively smaller pellets until no further change occurs. These topics are touched on by Satterfield (*Heterogeneous Catalysis in Industrial Practice,* McGraw-Hill, 1991).

**TABLE 7-12 Calorimetric Methods**

| Adiabatic | Nonadiabatic |
|---|---|
| Accelerating rate calorimeter (ARC) | Reaction calorimeter (RC1) + IR |
| Vent sizing package (VSP) calorimeter | Differential scaning calorimeter (DSC) |
| | Thermal gravitometry (TG) |
| PHI-TEC | Isothermal calorimetry |
| Dewar | Differential thermal analysis (DTA) |
| Automatic pressure tracking adiabatic calorimeter (APTAC) | Differential microcalorimeters |
| | Advanced reaction system screening tool (ARSST) |

To determine the deactivation kinetics, long-term deactivation studies at constant conditions and at different temperatures are required. In some cases, accelerated aging can be used to reduce the time required for the experimental work, by either increasing the feed flow rate (if the deactivation is a result of feed or product poisoning) or increasing the temperature above the standard reaction temperature. These approaches for accelerated aging require a good understanding of how the higher-temperature or rate-accelerated deactivation correlates with deactivation at commercial operating conditions.

**Bioreactors** There are several types of laboratory bioreactors:

1. Mechanically agitated batch/semibatch with pH control and nutrients or other species either fed at the start or added continuously based on a recipe or protocol.
2. CSTR to maintain a controlled *dilution rate* ( feed rate). These require some means to separate the biocatalyst from the product and recycle to the reactor, such as centrifuge or microfiltration:
   a. *Chemostat* controls the flow or dilution rate to maintain a constant fermentation volume.
   b. *Turbidostat* controls the biomass or cell concentration.
   c. *pH-auxostat* controls pH in the effluent (same as pH in reactor).
   d. *Productostat* controls the effluent concentration of one of the metabolic products.

The preferred reactor for kinetics is the chemostat, but semibatch reactors are more often used owing to their simpler operation and wide use for process and biocatalyst development.

**Calorimetry** Another category of laboratory systems that can be used for kinetics includes *calorimeters*. These are primarily used to establish temperature effects and thermal runaway conditions, but can also be employed to determine reaction kinetics. Types of calorimeters are summarized in Table 7-12; for more details see Reid, "Differential Microcalorimeters," *J. Physics E: Scientific Instruments*, **9** (1976).

Additional methods of laboratory data acquisition are described in Masel, *Chemical Kinetics and Catalysis*, Wiley, 2001.

## KINETIC PARAMETERS

The kinetic parameters are constants that appear in the intrinsic kinetic rate expressions and are required to describe the rate of a reaction or rates of a reaction network. For instance, for the simple global *n*th-order reaction with Arrhenius temperature dependence:

$$A \Rightarrow B \qquad r = kC_a^n \qquad k = k_0 e^{-E/RT} \tag{7-165}$$

The kinetic parameters are $k_0$, $E$, and $n$, and knowledge of these parameters and the prevailing concentration of $A$ and temperature fully determines the reaction rate.

For a more complex expression such as the Langmuir-Hinshelwood rate for gas reaction on heterogeneous catalyst surface with equilibrium adsorption of reactants $A$ and $B$ on two different sites and nonadsorbing products, Eq. (7-85) can be rewritten as

$$r = \frac{k_0 e^{-E/RT} p_a p_b}{(1 + K_{a0} e^{-E_{aa}/RT})(1 + K_{b0} e^{-E_{ab}/RT})} \tag{7-166}$$

and the kinetic parameters are $k_0$, $E$, $K_{a0}$, $E_{aa}$, $K_{b0}$, and $E_{ab}$.

A number of factors limit the accuracy with which parameters needed for the design of commercial equipment can be determined. The kinetic parameters may be affected by inaccurate accounting for laboratory reactor heat and mass transport and hydrodynamics; correlations for these are typically determined under nonreacting conditions at ambient temperature and pressure and with nonreactive model fluids and may not be applicable or accurate at reaction conditions. Experimental uncertainty including errors in analysis, measurement, and control is also a contributing factor

**TABLE 7-13 Comparison of Direct and Indirect Methods**

| Direct method | Indirect method |
|---|---|
| Advantages | Disadvantages |
| Get rate equation directly | Must infer rate equation |
| Easy to fit data to a rate law | Hard to analyze rate data |
| High confidence on final rate equation | Low confidence on final rate equation |
| Disadvantages | Advantages |
| Difficult experiment | Easier experiment |
| Need many runs | Can do a few runs and get important information |
| Not suitable for very fast or very slow reactions | Suitable for all reactions including very fast or very slow ones |

## DATA ANALYSIS METHODS

In this subsection we focus on the three main types of ideal reactors: BR, CSTR, and PFR. Laboratory data are usually in the form of concentrations or partial pressures versus batch time (batch reactors), concentrations or partial pressures versus distance from reactor inlet or residence time (PFR), or rates versus residence time (CSTR). Rates can also be calculated from batch and PFR data by differentiating the concentration versus time or distance data, respectively, usually by first smoothing the data to reduce noise in the calculated rates. It follows that a general classification of experimental methods is based on whether the data measure rates directly (differential or direct method) or indirectly (integral of indirect method). Table 7-13 shows the pros and cons of these methods.

Some simple reaction kinetics are amenable to analytical solutions and graphical linearized analysis to calculate the kinetic parameters from rate data. More complex systems require numerical solution of nonlinear systems of differential and algebraic equations coupled with nonlinear parameter estimation or regression methods.

**Differential Data Analysis** As indicated above, the rates can be obtained either directly from differential CSTR data or by differentiation of integral data. A common way of evaluating the kinetic parameters is by rearrangement of the rate equation, to make it linear in parameters (or some transformation of parameters) where possible. For example, in the case of the simple *n*th-order reaction in Eq. (7-165) , taking the natural logarithm of both sides of the equation results in a linear relationship between the variables $\ln r$, $1/T$, and $\ln C_a$:

$$\ln r = \ln k_0 - \frac{E}{RT} + n \ln C_a \tag{7-167}$$

Multilinear regression can be used to find the constants $k_0$, $E$, and $n$. For constant-temperature (isothermal) data, Eq. (7-167) can be simplified by using the Arrhenius form as

$$\ln r = \ln k + n \ln C_a \tag{7-168}$$

and the kinetic parameters $n$ and $k$ can be determined as the intercept and slope of the best straight-line fit to the data, respectively, as shown in Fig. 7-18.

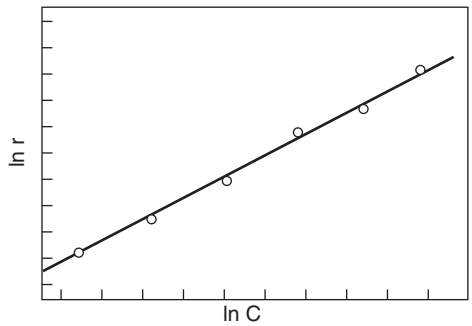

**FIG. 7-18** Determination of the rate constant and reaction order.

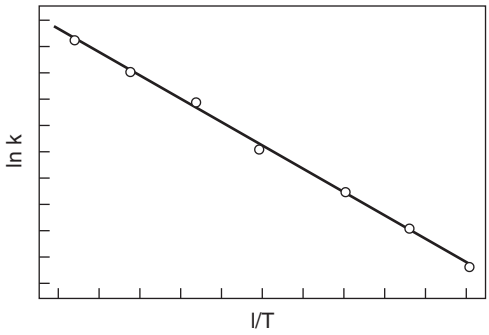

**FIG. 7-19** Determination of the preexponential and activation energy.

The preexponential $k_0$ and activation energy $E$ can be obtained from multiple isothermal data sets at different temperatures by using the linearized form of the Arrhenius equation

$$\ln k = \ln k_0 - \frac{E}{RT} \tag{7-169}$$

as shown in Fig. 7-19.

**Integral Data Analysis** Integral data such as from batch and PFR relate concentration to time or distance. Integration of the BR equation for an *n*th-order homogeneous constant-volume reaction yields

$$\begin{aligned} \ln \frac{C_{a0}}{C_a} &= k\tau \quad \text{for} \quad n = 1 \\ \left(\frac{C_{a0}}{C_a}\right)^{n-1} &= 1 + k\tau (n-1) C_{a0}^{n-1} \quad \text{for } n \neq 1 \end{aligned} \tag{7-170}$$

For the first-order case, the rate constant $k$ can be obtained directly from the slope of the graph of the left-hand side of Eq. (7-170) versus batch time, as shown in Fig. 7-20.

For orders other than first, plotting the natural log of Eq. (7-170) can at least indicate if the order is larger or smaller than 1, as shown in Fig. 7-21.

**The Half-Life Method** The half-life is the batch time required to get 50 percent conversion. For an *n*th-order reaction,

$$\begin{aligned} \tau_{1/2} &= \frac{\ln 2}{k} \quad \text{for} \quad n = 1 \\ \tau_{1/2} &= \frac{2^{n-1} - 1}{(n-1) k C_{a0}^{n-1}} \quad \text{for } n \neq 1 \end{aligned} \tag{7-171}$$

Thus for first-order reactions, the *half-life* is constant and independent of the initial reactant concentration and can be used directly to calculate the rate constant $k$. For non-first-order reactions, Eq. (7-171) can be linearized as follows:

$$\ln \tau_{1/2} = \ln \frac{2^{n-1} - 1}{(n-1)k} - (n-1) \ln C_{a0} \quad \text{for } n \neq 1 \tag{7-172}$$

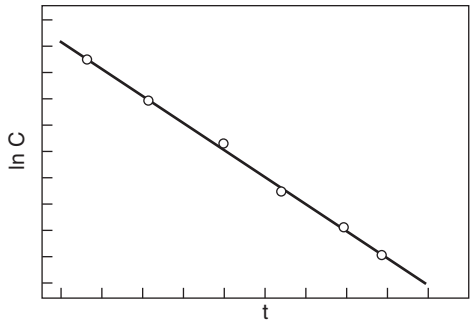

**FIG. 7-20** Determination of first-order rate constant from integral data.

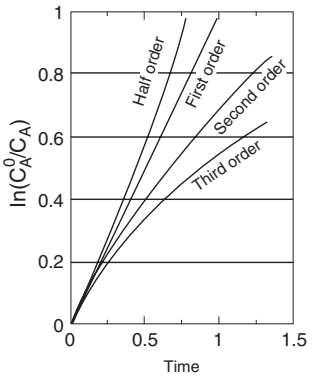

**FIG. 7-21** Reaction behavior for *n*th-order reaction. (Masel, *Chemical Kinetics and Catalysis,* Wiley, 2001, Fig. 3.15.)

The reaction order $n$ can be obtained from the slope and the rate constant $k$ from the intercept of the plot of Eq. (7-172), shown in Fig. 7-22.

**Complex Rate Equations** The examples above are for special cases amenable to simple treatment. Complex rate equations and reaction networks with complex kinetics require individual treatment, which often includes both numerical solvers for the differential and algebraic equations describing the laboratory reactor used to obtain the data and linear or nonlinear parameter estimation.

## PARAMETER ESTIMATION

The straightforward method to obtain kinetic parameters from data is the numerical fitting of the concentration data (e.g., from BR or PFR data) to integral equations, or the rate data (e.g., from a CSTR or from differentiation of BR or PFR data) to rate equations. This is done by parameter estimation methods described here. An excellent reference for experimental design and parameter estimation (illustrated for heterogeneous gas-solid reactions) is the review paper of Froment and Hosten, "Catalytic Kinetics—Modeling," in *Catalysis—Science and Technology,* Springer-Verlag, New York, 1981. Two previous papers devoted to this topic by Hofmann [in *Chemical Reaction Engineering, ACS Advances in Chemistry* **109:** 519–534 (1972); in de Lasa (ed.), *Chemical Reactor Design and Technology,* Martinus Nijhoff, 1985, pp. 69–105] are also very useful. As indicated above, the acquisition of kinetic data and parameter estimation can be a complex endeavor. It includes statistical design of experiments, laboratory equipment, computer-based data acquisition, complex analytical methods, and statistical evaluation of the data.

*Regression* is the procedure used to estimate the kinetic parameters by fitting kinetic model predictions to experimental data. When the parameters can be made to appear linear in the kinetic model (through transformations, grouping of parameters, and rearrangement), the regression is linear, and an accurate fit to data can be obtained, provided the form of the kinetic model represents well the reaction kinetics and the data are obtained over a broad range of temperature, pressure, and composition for statistically significant estimates. Often such linearization is not possible.

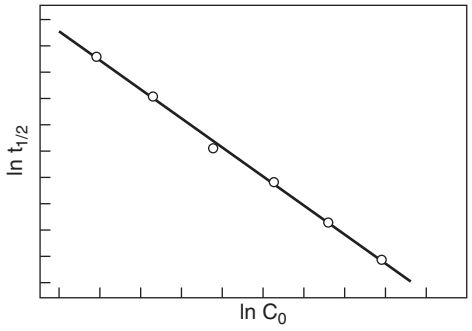

**FIG. 7-22** Determination of reaction order and rate constant from half-life data.

**Linear Models in Parameters, Single Reaction** We adopt the terminology from Froment and Hosten, "Catalytic Kinetics—Modeling," in *Catalysis—Science and Technology,* Springer-Verlag, New York, 1981. For $n$ observations (experiments) of the concentration vector $y$ for a model linear in the parameter vector $\beta$ of length $p < n$, the *residual error* $\varepsilon$ is the difference between the measured data values and kinetic model-predicted values:

$$\varepsilon = y - X\beta = y - \hat{y} \tag{7-173}$$

The linear model is represented as a linear transformation of the parameter vector $\beta$ through the model matrix $X$. Estimates $b$ of the true parameters $\beta$ are obtained by minimizing the *objective function* $S(\beta)$, *the sum of squares of the residual errors*, while varying the values of the parameters:

$$S(\beta) = \varepsilon^T \varepsilon = \sum_{i=1}^{n} (y_i - \hat{y}_i)^2 \xrightarrow{\beta} \text{Min} \tag{7-174}$$

This linear optimization problem, subject to constraints on the possible values of the parameters (e.g., requiring positive preexponentials, activation energies, etc.), can be solved to give the estimated parameters:

$$b = (X^T X)^{-1} X^T y \tag{7-175}$$

When the error is *normally distributed* and has zero *mean* and *variance* $\sigma^2$, then the *variance-covariance matrix* $V(b)$ is defined as

$$V(b) = (X^T X)^{-1} \sigma^2 \tag{7-176}$$

An estimate for $\sigma^2$, denoted $s^2$, is

$$s^2 = \frac{\sum_{i=1}^{n} (y_i - \hat{y}_i)^2}{n - p} \tag{7-177}$$

When $V(b)$ is known from experimental observations, a *weighted objective function* should be used for optimization of the objective function:

$$S(\beta) = \varepsilon^T V^{-1} \varepsilon \xrightarrow{\beta} \text{Min} \tag{7-178}$$

and the estimates $b$ are obtained as

$$b = (X^T V^{-1} X)^{-1} X^T V^{-1} y \tag{7-179}$$

The parameter fit is adequate if the *F test* is satisfied, that is, $F_c$, the calculated $F$, is larger than the tabulated statistical one at the *confidence level* of $1 - \alpha$:

$$F_c = \frac{\dfrac{\text{LFSS}}{n - p - n_e + 1}}{\dfrac{\text{PESS}}{n_e - 1}} \geq F(n - p - n_e + 1, n_e - 1; 1 - \alpha)$$
$$\text{LFSS} = \sum_{i=1}^{n} (y_i - \hat{y}_i)^2 - \sum_{i=1}^{n_e} (y_i - \bar{y}_i)^2 \qquad \text{PESS} = \sum_{i=1}^{n_e} (y_i - \bar{y}_i)^2 \tag{7-180}$$

Here $\bar{y}_i$ are the averaged values of the data for replicates, LFSS is the lack of fit sum of squares, PESS is the pure error sum of squares, and $n_e$ is the number of replicate experiments. Equation (7-180) is valid if there are replicate experiments and PESS is known. Without replicates,

$$F_c = \frac{\dfrac{\text{RgSS}}{p}}{\dfrac{\text{RSS}}{n - p}} \geq F(p, n - p; 1 - \alpha) \quad \text{RgSS} = \sum_{i=1}^{n} \hat{y}_i^2 \quad \text{RSS} = \sum_{i=1}^{n} (y_i - \hat{y}_i)^2 \tag{7-181}$$

Here RgSS is the regression sum of squares and RSS is the residual sum of squares. The *error bounds* on the parameter estimates are given by the *t statistics*:

$$b_i - t\left(n - p; 1 - \frac{\alpha}{2}\right) \leq \beta_i \leq b_i + t\left(n - p; 1 - \frac{\alpha}{2}\right) \tag{7-182}$$

An example of a linear model in parameters is Eq. (7-167), where the parameters are $\ln k_0$, $E$, and $n$, and the linear regression can be used directly to estimate these.

**Nonlinear Models in Parameters, Single Reaction** In practice, the parameters appear often in nonlinear form in the rate expressions, requiring nonlinear regression. Nonlinear regression does not guarantee optimal parameter estimates even if the kinetic model adequately represents the

true kinetics and the data range is adequate. Further, the statistical tests of model adequacy apply rigorously only to models linear in parameters, and can only be considered approximate for nonlinear models.

For a general nonlinear model $f(x_i, \beta)$, where $x$ is the vector of the independent model variables and $\beta$ is the vector of parameters,

$$\varepsilon = y - f(x,\beta) \tag{7-183}$$

An example of a model nonlinear in parameters is Eq. (7-166). Here it is not possible through any number of transformations to obtain a linear form in all the parameters $k_0$, $E$, $K_{a0}$, $E_{aa}$, $K_{b0}$, $E_{ab}$. Note that for some Langmuir-Hinshelwood rate expressions it is possible to linearize the model in parameters at isothermal conditions and obtain the kinetic constants for each temperature, followed by Arrhenius-type plots to obtain activation energies (see, e.g., Churchill, *The Interpretation and Use of Rate Data: The Rate Concept,* McGraw-Hill, 1974).

Minimization of the sum of squares of residuals does not result in a closed form for nonlinear parameter estimates as for the linear case; rather it requires an iterative numerical solution, and having a reasonable initial estimate for the parameter values and their feasible ranges is critical for success. Also, the minima in the residual sum of squares are local and not global. To increase the probability of approach to global minima that better represent the kinetics over a wide range of conditions, parameter estimation has to be repeated with a wide range of initial parameter guesses. The nonlinear regression procedure typically involves a *steepest descent* optimization search combined with *Newton's linearization* method when a minimum is approached, enhancing the convergence speed [e.g., the *Marquardt-Levenberg* or *Newton-Gauss* method; Marquardt, *J. Soc. Ind. Appl. Math.* **2:** 431 (1963)].

An integral part of the parameter estimation methodology is *mechanism discrimination*, i.e., selection of the best mechanism that would result in the best kinetic model. Nonlinear parameter estimation is an extensive topic and will not be further discussed here. For more details see Froment and Hosten, "Catalytic Kinetics—Modeling," in *Catalysis—Science and Technology*, Springer-Verlag, New York, 1981.

**Network of Reactions** The statistical parameter estimation for multiple reactions is more complex than for a single reaction. As indicated before, a single reaction can be represented by a single concentration [e.g., Eq. (7-39)]. With a network of reactions, there are a number of dependent variables equal to the number of stoichiometrically independent reactions, also called *responses*. In this case the objective function has to be modified. For details see Froment and Hosten, "Catalytic Kinetics—Modeling," in *Catalysis—Science and Technology*, Springer-Verlag, New York, 1981.

## THEORETICAL METHODS

**Prediction of Mechanism and Kinetics** Reaction mechanisms for a variety of reaction systems can be predicted to some extent by following a set of heuristic rules derived from experience with a wide range of chemistries. For instance, Masel, *Chemical Kinetics and Catalysis*, Wiley, 2001, chap. 5, enumerates the rules for gas-phase chain and nonchain reactions including limits on activation energies for various elementary steps. Other reaction systems such as ionic reactions, and reactions on metal and acid surfaces, are also discussed by Masel, although these mechanisms are not as well understood. Nevertheless, the rules can lead to computer-generated mechanisms for complex systems such as homogeneous gas-phase combustion and partial oxidation of methane and higher hydrocarbons. Developments in computational chemistry methods allow, in addition to the derivation of most probable elementary mechanisms, prediction of thermodynamic and kinetic parameters for relatively small molecules in homogeneous gas-phase and liquid-phase reactions, and even for some heterogeneous catalytic systems. This is especially useful for complex kinetics where there is no easily discernible rate-determining step, and therefore no simple closed-form global reaction rate can be determined. In particular, estimating a large number of kinetic parameters from laboratory data requires a large number of experiments and use of intermediate reaction components that are not stable or not readily available. The nonlinear parameter estimation with many parameters is difficult, with no assurance that near global minima are actually obtained. For such complex systems, computational chemistry estimates are an attractive starting point, requiring experimental validation.

Computational chemistry includes a wide range of methods of varying accuracy and complexity, summarized in Table 7-14. Many of these methods have been implemented as software packages that require high-speed supercomputers or parallel computers to solve realistic reactions. For more details on computational chemistry, see, e.g., Cramer, *Essentials of Computational Chemistry: Theories and Models*, 2d ed., Wiley, 2004.

**TABLE 7-14 Computational Chemistry Methods**

| |
|---|
| *Ab initio* methods (no empirical parameters) |
| Electronic structure determination (time-independent Schrodinger equation) |
| Hartree-Fock (HF) with corrections |
| Quantum Monte Carlo (QMT) |
| Density functional theory (DFT) |
| Chemical dynamics determination (time-dependent Schrodinger equation) |
| Split operator technique |
| Multiconfigurational time-dependent Hartree-Fock method |
| Semiclassical method |
| Semiempirical methods (approximate parts of HF calculations such as two-electron integrals) |
| Huckel |
| Extended Huckel |

| Empirical methods (group contributions) |
| Polanyi linear approximation of activation energy |

**Lumping and Mechanism Reduction** It is often useful to reduce complex reaction networks to a smaller reaction set that still maintains the key features of the detailed reaction network but with a much smaller number of representative species, reactions, and kinetic parameters. Simple examples were already given above for reducing simple networks into global reactions through assumptions such as pseudo-steady state, rate-limiting step, and equilibrium reactions.

In general, *mechanism reduction* can only be used over a limited range of conditions for which the simplified system simulates the original complete reaction network. This reduces the number of kinetic parameters that have to be either estimated from data or calculated by using computational chemistry. The simplified system also reduces the computation load for reactor scale-up, design, and optimization.

A type of mechanism reduction called *lumping* is typically performed on a reaction network that consists of a large number of similar reactions occurring between similar species, such as homologous series or molecules having similar functional groups. Such situations occur, for instance, in the oil refining industry, examples including catalytic reforming, catalytic cracking, hydrocracking, and hydrotreating. Lumping is done by grouping similar species, or molecules with similar functional groups, into pseudocomponents called *lumped species*. The behavior of the lumped system depends on the initial composition, the distribution of the rate constants in the detailed system, and the form of the rate equation. The two main issues in lumping are

1. Determination of the lump structure that simulates the detailed system over the required range of conditions
2. Determination of the kinetics of the lumped system from general knowledge about the type of kinetics and the overall range of parameters of the detailed system

Lumping has been applied extensively to first-order reaction networks [e.g., Wei and Kuo, "A Lumping Analysis in Monomolecular Reaction Systems," *I&EC Fundamentals* **8**(1): 114–123 (1969); Golikeri and Luss, "Aggregation of Many Coupled Consecutive First Order Reactions," *Chem. Eng. Sci.* **29:** 845–855 (1974)]. For instance, it has been shown that a lumped reaction network of first-order reactions can behave under certain conditions as a global second-order reaction. Where analytical solutions were not available, others, such as Golikeri and Luss, "Aggregation of Many Coupled Consecutive First Order Reactions," *Chem. Eng. Sci.* **29:** 845–855 (1974), developed bounds that bracketed the behavior of the lump for first-order reactions as a function of the initial composition and the rate constant distribution. Lumping has not been applied as successfully to nonlinear or non-first-order kinetics. More recent applications of lumping were published, including structure-oriented lumping that lumps similar structural groups, by Quann and Jaffe, "Building Useful Models of Complex Reaction Systems in Petroleum Refining," *Chem. Eng. Sci.* **51**(10): 1615–1635 (1996).

For other types of systems such as highly branched reaction networks for homogeneous gas-phase combustion and combined homogeneous and catalytic partial oxidation, mechanism reduction involves pruning branches and pathways of the reaction network that do not contribute significantly to the overall reaction. This pruning is done by using *sensitivity analysis*. See, e.g., Bui et al., "Hierarchical Reduced Models for Catalytic Combustion: $H_2$/Air Mixtures near Platinum Surfaces," *Combustion Sci. Technol.* **129**(1–6): 243–275 (1997).

**Multiple Steady States, Oscillations, and Chaotic Behavior** There are reaction systems whose steady-state behavior depends on the initial or starting conditions; i.e., for different starting conditions, different steady states can be reached at the same operating conditions. This behavior is called *steady-state multiplicity* and is often the result of the interaction of kinetic and transport phenomena. For some cases, the cause of the multiplicity is entirely reaction-related, as shown below. Associated with steady-state multiplicity is hysteresis (achieving different steady states depending

on the direction in which a key parameter is varied), and higher-order instabilities such as self-sustained oscillations (repeated oscillations around a steady state) and chaotic behavior. The existence of multiple steady states may be relevant to analysis of laboratory data, since faster or slower rates may be observed at the same conditions depending on how the lab reactor is started up.

For example, CO oxidation on heterogeneous Rh catalyst exhibits hysteresis and multiple steady states, and one of the explained causes is the existence of two crystal structures for Rh, each with a different reactivity (Masel, *Chemical Kinetics and Catalysis*, Wiley, 2001, p. 38).

Another well-known example of chemistry-related instability includes the oscillatory behavior of the Bhelousov-Zhabotinsky reaction of malonic acid and bromate in the presence of homogeneous Ce catalyst having the overall reaction

$$HOOCCH_2COOH + HBrO \overset{Ce^{4+}}{\Rightarrow} \text{products}$$

Ce can be in two oxidation states, $Ce^{3+}$ and $Ce^{4+}$, and there are competing reaction pathways. Complex kinetic models are required to predict the oscillatory behavior, the most well known being that of Noyes [e.g., Showalter, Noyes, and Bar-Eli, *J. Chem. Phys.* **69**(6): 2514–2524 (1978)].

A large body of work has been done to develop criteria that determine the onset of chemistry- and transport-based instabilities. More details and transport-reaction coupling examples are discussed in Sec. 19.

## SOFTWARE TOOLS

There are a number of useful software packages that enable efficient analysis of laboratory data for developing the mechanism and kinetics of reactions and for testing the kinetics by using simple reactor models. The reader is urged to search the Internet as some of these software packages change ownership or name. Worth mentioning are the Aspen Engineering Suite (Aspen), the MATLAB suite (Mathworks), the Chemkin software suite (Reaction Design), the NIST Chemical Kinetics database (NIST), the Thermal Safety Software suite (Cheminform St. Petersburg), and Gepasi for biochemical kinetics (freeware). The user is advised to experiment and validate any software package with known data and kinetics to ensure robustness and reliability.

### Nomenclature

| Symbol | Definition |
|---|---|
| $A$ | Area |
| $A_a$ | Actuator area |
| $A_c$ | Output amplitude limits |
| $A_v$ | Amplitude of controlled variable |
| $A_1$ | Cross-sectional area of tank |
| $b$ | Controller output bias |
| $B$ | Bottoms flow rate |
| $B_i^*$ | Limit on control |
| $c_A$ | Concentration of $A$ |
| $C$ | Cumulative sum |
| $C_d$ | Discharge coefficient |
| $C_i$ | Inlet concentration |
| $C_i^*$ | Limit on control move |
| $C_L$ | Specific heat of liquid |
| $C_0$ | Integration constant |
| $C_p$ | Process capability |
| $C_r$ | Heat capacity of reactants |
| $C_V$ | Valve flow coefficient |
| $D$ | Distillate flow rate, disturbance |
| $D_i^*$ | Limit on output |
| $e$ | Error |
| $E$ | Economy of evaporator |
| $f$ | Function of time |
| $F$,$f$ | Feed flow rate |
| $F_L$ | Pressure recovery factor |
| $g_c$ | Unit conversion constant |
| $g_i$ | Algebraic inequality constraint |
| $G$ | Transfer function |
| $G_c$ | Controller transfer function |
| $G_d$ | Disturbance transfer function |
| $G_f$ | Feedforward controller transfer function |
| $G_m$ | Sensor transfer function |
| $G_p$ | Process transfer function |
| $G_t$ | Transmitter transfer function |
| $G_v$ | Valve transfer function |
| $h_i$ | Algebraic equality constraints |
| $h_1$ | Liquid head in tank |
| $H$ | Latent heat of vaporization, control limit or threshold |
| $i$ | Summation index |
| $I_i$ | Impulse response coefficient |
| $j$ | Time index |
| $J$ | Objective function or performance index |
| $k$ | Time index |
| $k_f$ | Flow coefficient |
| $k_r$ | Kinetic rate constant |
| $K$ | Gain, slack parameter |
| $K_c$ | Controller gain |
| $K_d$ | Disturbance transfer function gain |
| $K_m$ | Measurement gain |
| $K_p$ | Process gain |
| $K_u$ | Ultimate controller gain (stability) |
| $L$ | Load variable |
| $L_p$ | Sound pressure level |
| $M$ | Manipulated variable |
| $m_c$ | Number of constraints |
| $M_v$ | Mass flow |
| $M_r$ | Mass of reactants |
| $M_w$ | Molecular weight |
| $n$ | Number of data points, number of stages or effects |
| $N$ | Number of inputs/outputs, model horizon |
| $p$ | Proportional band (percent) |
| $p_c$ | Vapor pressure |
| $p_d$ | Actuator pressure |
| $p_i$ | Pressure |
| $p_u$ | Proportional band (ultimate) |
| $q$ | Radiated energy flux |
| $q_b$ | Energy flux to a black body |
| $Q$ | Flow rate |
| $r_c$ | Number of constraints |
| $R$ | Equal-percentage valve characteristic |
| $R_T$ | Resistance in temperature sensor |
| $R_1$ | Valve resistance |
| $s$ | Laplace transform variable |
| $s$ | Search direction |
| $S_i$ | Step response coefficient |
| $t$ | Time |
| $T$ | Temperature, target |
| $T(s)$ | Decoupler transfer function |
| $T_b$ | Base temperature |
| $T_f$ | Exhaust temperature |
| $T_R$ | Reset time |
| $U$ | Heat-transfer coefficient |
| $u$, $U$ | Manipulated variable, controller output |
| $V$ | Volume |
| $V_s$ | Product value |
| $w$ | Mass flow rate |
| $w_i$ | Weighting factor |
| $W$ | Steam flow rate |
| $x$ | Mass fraction |
| $\overline{x}$ | Sample mean |
| $x_i$ | Optimization variable |
| $x_T$ | Pressure drop ratio factor |
| $X$ | Transform of deviation variable |
| $y$, $Y$ | Process output, controlled variable, valve travel |
| $Y_{sp}$ | Set point |
| $z$ | Controller tuning law, expansion factor |
| $z_i$ | Feed mole fraction (distillation) |
| $Z$ | Compressibility factor |

| Greek symbols | |
|---|---|
| $\alpha$ | Digital filter coefficient |
| $\alpha_T$ | Temperature coefficient of resistance |
| $\beta$ | Resistance thermometer parameter |
| $\gamma$ | Ratio of specific heats |
| $\delta$ | Move suppression factor, shift in target value |
| $\Delta_q$ | Load step change |
| $\Delta_t$ | Time step |
| $\Delta_T$ | Temperature change |
| $\Delta_u$ | Control move |
| $\varepsilon$ | Spectral emissivity, step size |
| $\zeta$ | Damping factor (second-order system) |
| $\theta$ | Time delay |
| $\lambda$ | Relative gain array parameter, wavelength |
| $\Lambda$ | Relative gain array |
| $\xi$ | Deviation variable |
| $\rho$ | Density |
| $\sigma$ | Stefan-Boltzmann constant, standard deviation |
| $\Sigma_t$ | Total response time |
| $\tau$ | Time constant |
| $\tau_d$ | Natural period of closed loop, disturbance time constant |
| $\tau_D$ | Derivative time (PID controller) |
| $\tau_F$ | Filter time constant |
| $\tau_I$ | Integral time (PID controller) |
| $\tau_P$ | Process time constant |
| $\tau_o$ | Period of oscillation |
| $\phi_{PI}$ | Phase lag |

| Subscripts | |
|---|---|
| $A$ | Species $A$ |
| $b$ | Best |
| $c$ | Controller |
| $d$ | Disturbance |
| eff | Effective |
| $f$ | Feedforward |
| $i$ | Initial, inlet |
| $L$ | Load, disturbance |
| $m$ | Measurement or sensor |
| $p$ | Process |
| $s$ | Steady state |
| sp | Set-point value |
| $t$ | Transmitter |
| $u$ | Ultimate |
| $v$ | Valve |

# FUNDAMENTALS OF PROCESS DYNAMICS AND CONTROL

## GENERAL CONTROL SYSTEM

A process is shown in Fig. 8-1 with a manipulated input $U$, a load or disturbance input $D$, and a controlled output $Y$, which could be flow, pressure, liquid level, temperature, composition, or any other inventory, environmental, or quality variable that is to be held at a desired value identified as the set point $Y_{sp}$. The load may be a single variable or an aggregate of variables either acting independently or manipulated for other purposes, affecting the controlled variable much as the manipulated variable does. Changes in load may occur randomly as caused by changes in weather, diurnally with ambient temperature, manually when operators change production rate, stepwise when equipment is switched into or out of service, or cyclically as the result of oscillations in other control loops. Variations in load will drive the controlled variable away from the set point, requiring a corresponding change in the manipulated variable to bring it back. The manipulated variable must also change to move the controlled variable from one set point to another.

An open-loop system positions the manipulated variable either manually or on a programmed basis, without using any process measurements. This operation is acceptable for well-defined processes without disturbances. An automated transfer switch is provided to allow manual adjustment of the manipulated variable in case the process or the control system is not performing satisfactorily.

A closed-loop system uses the measurement of one or more process variables to move the manipulated variable to achieve control. Closed-loop systems may include feedforward, feedback, or both.

**Feedback Control** In a feedback control loop, the controlled variable is compared to the set point $Y_{sp}$, with the error $E$ acted upon by the controller to move $U$ in such a way as to minimize the error. This action is specifically negative feedback, in that an increase in error moves $U$ so as to decrease the error. (Positive feedback would cause the error to expand rather than diminish and therefore does not regulate.) The action of the controller is selectable to allow use on process gains of both signs.

The controller has tuning parameters related to proportional, integral, derivative, lag, dead time, and sampling functions. A negative feedback loop will oscillate if the controller gain is too high; but if it is too low, control will be ineffective. The controller parameters must be properly related to the process parameters to ensure closed-loop stability while still providing effective control. This relationship is accomplished, first, by the proper selection of control modes to satisfy the requirements of the process and, second, by the appropriate tuning of those modes.

**Feedforward Control** A feedforward system uses measurements of disturbance variables to position the manipulated variable in such a way as to minimize any resulting deviation. The disturbance variables could be either measured loads or the set point, the former being more common. The feedforward gain must be set precisely to reduce the deviation of the controlled variable from the set point.

Feedforward control is usually combined with feedback control to eliminate any offset resulting from inaccurate measurements and calculations and unmeasured load components. The feedback controller can be used as a bias on the feedforward controller or in a multiplicative form.

**Computer Control** Computers have been used to replace analog PID controllers, either by setting set points of lower-level controllers in supervisory control or by driving valves directly in direct digital control. Single-station digital controllers perform PID control in one or two loops, including computing functions such as mathematical operations, characterization, lags, and dead time, with digital logic and alarms. Distributed control systems provide all these functions, with the digital processor shared among many control loops; separate processors may be used for displays, communications, file servers, and the like. A host computer may be added to perform high-level operations such as scheduling, optimization, and multivariable control. More details on computer control are provided later in this section.

## PROCESS DYNAMICS AND MATHEMATICAL MODELS

**Open-Loop versus Closed-Loop Dynamics** It is common in industry to manipulate coolant in a jacketed reactor in order to control conditions in the reactor itself. A simplified schematic diagram of such a reactor control system is shown in Fig. 8-2. Assume that the reactor temperature is adjusted by a controller that increases the coolant flow in proportion to the difference between the desired reactor temperature and the temperature that is measured. The proportionality constant is $K_c$. If a small change in the temperature of the inlet stream occurs, then depending on the value of $K_c$, one might observe the reactor temperature responses shown in Fig. 8-3. The top plot shows the case for no control ($K_c = 0$), which is called the *open loop*, or the normal dynamic response of the process by itself. As $K_c$ increases, several effects can be noted. First, the reactor temperature responds faster and faster. Second, for the initial increases in $K_c$, the maximum deviation in the reactor temperature becomes smaller. Both of these effects are desirable so that disturbances from normal operation have as small an effect as possible on the process under study. As the gain is increased further, eventually a point is reached where the reactor temperature oscillates indefinitely, which is undesirable. This point is called the *stability limit*, where $K_c = K_u$, the ultimate controller gain. Increasing $K_c$ further causes the magnitude of the oscillations to increase, with the result that the control valve will cycle between full open and closed.

The responses shown in Fig. 8-3 are typical of the vast majority of regulatory loops encountered in the process industries. Figure 8-3 shows that there is an optimal choice for $K_c$, somewhere between 0 (no control) and $K_u$ (stability limit). If one has a dynamic model of a process, then this model can be used to calculate controller settings. In Fig. 8-3, no time scale is given, but rather the figure shows relative responses. A well-designed controller might be able to speed up the response of a process by a factor of roughly 2 to 4. Exactly how fast the control system responds is determined by the dynamics of the process itself.

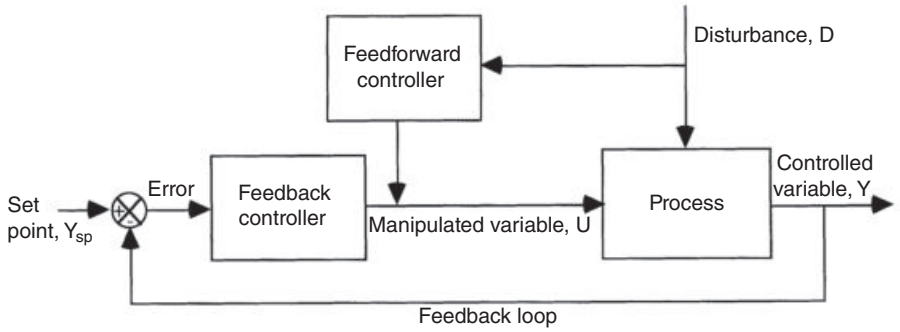

**FIG. 8-1** Block diagram for feedforward and feedback control.

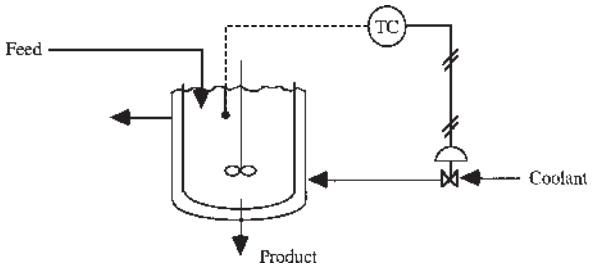

**FIG. 8-2** Reactor control system.

**Physical Models versus Empirical Models** In developing a dynamic process model, two distinct approaches can be taken. The first involves models based on first principles, called *physical* or *first-principles* models, and the second involves empirical models. The conservation laws of mass, energy, and momentum form the basis for developing physical models. The resulting models typically involve sets of differential and algebraic equations that must be solved simultaneously. Empirical models, by contrast, involve postulating the form of a dynamic model, usually as a transfer function (input-output model), which is discussed below. This transfer function contains a number of parameters that need to be estimated from data. For the development of both physical and empirical models, the most expensive step normally involves verification of their accuracy in predicting plant behavior.

To illustrate the development of a physical model, a simplified treatment of the reactor, shown in Fig. 8-2, is used. It is assumed that the reactor is operating isothermally and that the inlet and exit volumetric flows and densities are the same. There are two components, $A$ and $B$, in the reactor, and a single first-order reaction of $A \rightarrow B$ takes place. The inlet concentration of $A$, which we call $c_i$, varies with time. A dynamic mass balance for the concentration of $A$, denoted $c_A$, can be written as follows:

$$V\frac{dc_A}{dt} = Fc_i - Fc_A - kVc_A \tag{8-1}$$

In Eq. (8-1), the flow in of component $A$ is $Fc_i$, the flow out is $Fc_A$, and the loss via reaction is $k_rVc_A$, where $V$ = reactor volume and $k_r$ = kinetic rate constant. In this example, $c_i$ is the input, or forcing, variable and $c_A$ is the output variable. If $V$, $F$, and $k_r$ are constant, Eq. (8-1) can be rearranged by dividing by $F + k_rV$ so that it contains only two groups of parameters. The result is

$$\tau\frac{dc_A}{dt} = Kc_i - c_A \tag{8-2}$$

where $\tau = V/(F + k_rV)$ and $K = F/(F + k_rV)$. For this example, the resulting model is a first-order differential equation in which $\tau$ is called the time constant and $K$ the process gain.

As an alternative to deriving Eq. (8-2) from a dynamic mass balance, one could simply postulate a first-order differential equation to be valid (empirical modeling). Then it would be necessary to estimate values for $\tau$ and $K$ so that the postulated model described the reactor's dynamic response. The advantage of the physical model over the empirical model is that the physical model gives insight into how reactor parameters affect the values of $\tau$ and $K$, which in turn affects the dynamic response of the reactor.

**Nonlinear versus Linear Models** If $V$, $F$, and $k_r$ are constant, then Eq. (8-1) is an example of a linear differential equation model. In a linear equation, the output and input variables and their derivatives appear to only the first power. If the rate of reaction were second-order, then the resulting dynamic mass balance would be

$$V\frac{dc_A}{dt} = Fc_i - Fc_A - k_rVc_A^2 \tag{8-3}$$

Since $c_A$ appears in this equation to the second power, the equation is nonlinear.

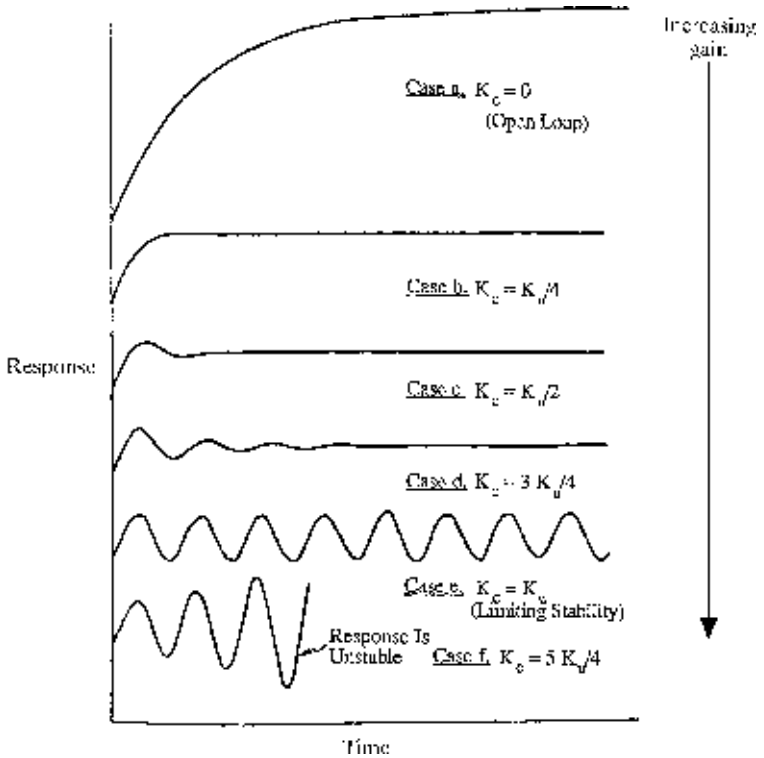

**FIG. 8-3** Typical control system responses.

The difference between linear systems and nonlinear systems can be seen by considering the steady-state behavior of Eq. (8-1) compared to Eq. (8-3) (the left-hand side is zero; that is, $dc_A/dt = 0$). For a given change in $c_i$, $\Delta c_i$, the change in $c_A$ calculated from Eq. (8-1), $\Delta c_A$, is always proportional to $\Delta c_i$, and the proportionality constant is $K$ [see Eq. (8-2)]. The change in the output of a system divided by a change in the input to the system is called the *process gain*. Linear systems have constant process gains for all changes in the input. By contrast, Eq. (8-3) gives a $\Delta c_A$ that varies with $\Delta c_i$, which is a function of the concentration levels in the reactor. Thus, depending on the reactor operating conditions, a change in $c_i$ produces different changes in $c_A$. In this case, the process has a nonlinear gain. Systems with nonlinear gains are more difficult to control than linear systems that have constant gains.

**Simulation of Dynamic Models** Linear dynamic models are particularly useful for analyzing control system behavior. The insight gained through linear analysis is invaluable. However, accurate dynamic process models can involve large sets of nonlinear equations. Analytical solution of these models is not possible. Thus, in these cases, one must turn to simulation approaches to study process dynamics and the effect of process control. Equation (8-3) will be used to illustrate the simulation of nonlinear processes. If $dc_A/dt$ on the left-hand side of Eq. (8-3) is replaced with its finite difference approximation, one gets

$$c_A(t+\Delta t) = \frac{c_A(t) + \Delta t \cdot \left[ Fc_i(t) - Fc_A(t) - k_r V c_A^2(t) \right]}{V} \tag{8-4}$$

Starting with an initial value of $c_A$ and given $c_i(t)$, Eq. (8-4) can be solved for $c_A(t+\Delta t)$. Once $c_A(t+\Delta t)$ is known, the solution process can be repeated to calculate $c_A(t+2\Delta t)$, and so on. This approach is called the *Euler integration method*; while it is simple, it is not necessarily the best approach to numerically integrating nonlinear differential equations. As discussed in Sec. 3, more sophisticated approaches are available that allow much larger step sizes to be taken.

Increasingly sophisticated simulation packages (e.g., MATLAB, gPROMS) are being used to calculate the dynamic behavior of processes and to test control system behavior. These packages have good user interfaces, and they can handle stiff systems where some variables respond on a time scale that is significantly faster or slower than that of other variables. A simple Euler approach cannot effectively handle stiff systems, which frequently occur in chemical process models. See Sec. 3 of this handbook for more details.

**Laplace Transforms** When mathematical models are used to describe process dynamics in conjunction with control system analysis, the models generally involve linear differential equations. Laplace transforms are very effective for solving linear differential equations analytically. The key advantage of using Laplace transforms is that they convert differential equations to algebraic equations. The resulting algebraic equations are easier to solve than the original differential equations. When the Laplace transform is applied to a linear differential equation in time, the result is an algebraic equation in a new variable $s$, called the *Laplace variable*. To get the solution to the original differential equation, one needs to invert the Laplace transform. Details on these procedures are contained in process control textbooks, e.g., Seborg, Edgar, Mellichamp, and Doyle, *Process Dynamics and Control*, 4th ed., Wiley, New York, 2016. The use of Laplace transforms in process control analysis has decreased over the past 40 years, due to ever-improving simulation tools.

**Transfer Functions and Block Diagrams** A very convenient and compact method of representing the process dynamics of linear systems involves the use of transfer functions and block diagrams. A transfer function can be obtained by starting with a physical model, as discussed previously. If the physical model is nonlinear, first it needs to be linearized around an operating point. The resulting linearized model is then approximately valid in a region around this operating point. A transfer function is typically characterized by its process gain $K$ and time constant $s$ ($\tau_1$, $\tau_2$, etc.) to fit the process under study. In fitting the parameters, data can be generated by forcing the process. If step forcing is used, then the resulting response is called the *process reaction curve*. Block diagrams show how changes in an input variable affect an output variable. Block diagrams are a means of concisely representing the dynamics of a process under study. Since linearity is assumed in developing a block diagram, if more than one variable affects an output, the contributions from each can be added (see Seborg, Edgar, Mellichamp, and Doyle, *Process Dynamics and Control*, 4th ed., Wiley, New York, 2016).

**Continuous versus Discrete Models** The preceding discussion has focused on systems where variables change continuously with time. Most real processes have variables that are continuous, such as temperature, pressure, and flow. However, some processes involve discrete events, such as the starting or stopping of a pump. In addition, modern plants are controlled by digital computers, which are discrete. In controlling a process, a digital system samples variables at a fixed rate, and the resulting system is a sampled data system. From one sampling instant until the next, variables are assumed to remain fixed at their sampled values. Similarly, in controlling a process, a digital computer sends out signals to control elements, usually valves, at discrete instants of time. These signals remain fixed until the next sampling instant.

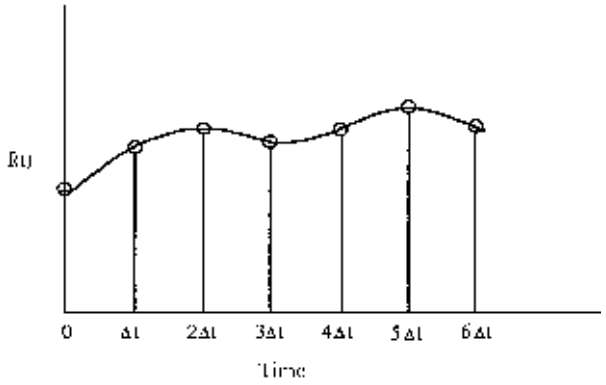

**FIG. 8-4** Sampled data example.

Figure 8-4 illustrates the concept of sampling a continuous function. At integer values of the sampling rate $\Delta t$, the value of the variable to be sampled is measured and held until the next sampling instant. To deal with sampled data systems, the $z$ transform has been developed, which is analogous to the Laplace transform for continuous systems. Utilization of $z$ transforms has been discussed in various textbooks (e.g., Seborg, Edgar, Mellichamp, and Doyle, *Process Dynamics and Control*, Wiley, New York, 2016). Sampling a continuous variable results in a loss of information. However, in practical applications, sampling is fast enough that the loss is typically insignificant and the difference between continuous and discrete modeling is small in terms of its effect on control. Increasingly, model predictive controllers that make use of discrete dynamic models are being used in the process industries. The purpose of these controllers is to guide a process to optimum operating points. These model predictive control algorithms are typically run at much slower sampling rates than are used for basic control loops such as flow control or pressure control. The discrete dynamic models used are normally developed from data generated from plant testing, as discussed hereafter. For a detailed discussion of modeling sampled data systems, the interested reader is referred to textbooks on digital control (Åström and Wittenmark, *Computer Controlled Systems*, Prentice-Hall, Englewood Cliffs, N.J., 1997).

**Process Characteristics in Transfer Functions** Process characteristics can be expressed in the form of transfer functions. Consider a system involving flow out of a tank, shown in Fig. 8-5.

***Proportional Element*** First, consider the outflow through the exit valve on the tank. If the flow through the line is turbulent, then Bernoulli's equation can be used to relate the flow rate through the valve to the pressure drop across the valve as

$$f_1 = k_f A_v \sqrt{2 g_c (h_1 - h_0)} \tag{8-5}$$

where $f_1$ = flow rate, $k_f$ = flow coefficient, $A_v$ = cross-sectional area of the restriction, $g_c$ = constant, $h_1$ = liquid head in tank (pressure at the base of the tank), and $h_0$ = atmospheric pressure. This relationship between flow and

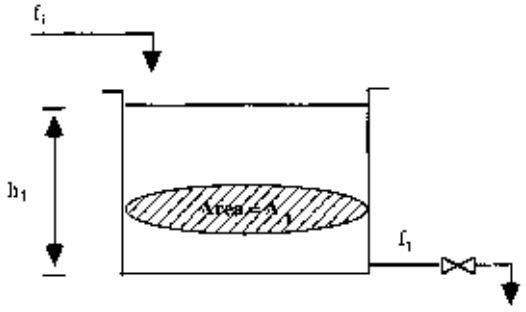

**FIG. 8-5** Single tank with exit valve.

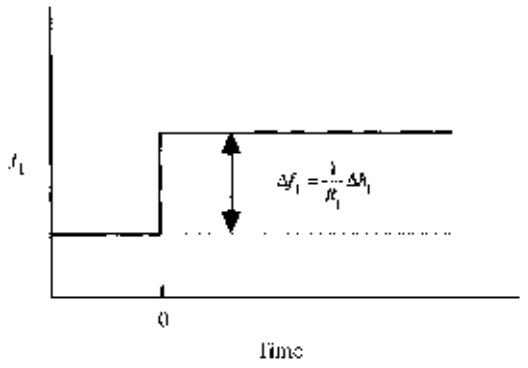

**FIG. 8-6** Response of proportional element.

pressure drop across the valve is nonlinear, and it can be linearized around a particular operating point to give

$$f_1 - \bar{f}_1 = \left(\frac{1}{R_1}\right)(h_1 - \bar{h}_1) \tag{8-6}$$

where $R_1 = \bar{f}_1/(g_c k_f^2 A_v^2)$ is called the *resistance* of the valve in analogy with an electrical resistance. This is an example of a pure gain system with no dynamics. In this case, the process gain is $K = 1/R_1$. Such a system has an instantaneous dynamic response, and for a step change in head, there is an immediate step change in flow, as shown in Fig. 8-6. The exact magnitude of the step in flow depends on the operating flow $\bar{f}_1$ as the definition of $R_1$ shows.

***First-Order Lag (Time Constant Element)*** Next consider the system to be the tank itself. A dynamic mass balance on the tank gives

$$A_1 \frac{dh_1}{dt} = f_i - f_1 \tag{8-7}$$

where $A_1$ is the cross-sectional area of the tank and $f_i$ is the inlet flow. By substituting Eq. (8-6) into Eq. (8-7) one can develop the differential equation relating changes in $h_1$ to changes in $f_i$. The resulting input-output relationship is a first-order system, and it has a gain $K = R_1$ and a time constant $\tau_1 = R_1 A_1$. For a step change in $f_i$, $h_1$ follows a decaying exponential response from its initial value $\bar{h}_1$ to a final value of $\bar{h}_1 + R_1 \Delta f_i$ (Fig. 8-7). At a time equal to $\tau_1$, the transient in $h_1$ is 63 percent finished; and at $3\tau_1$, the response is 95 percent finished. These percentages are the same for all first-order processes. Thus, knowledge of the time constant of a first-order process gives insight into how fast the process responds to sudden input changes.

***Capacity Element*** Now consider the case where the valve in Fig. 8-7 is replaced with a pump. In this case, it is reasonable to assume that the exit flow from the tank is independent of the level in the tank. For such a case, Eq. (8-7) still holds, except that $f_1$ no longer depends on $h_1$. For changes in $f_i$, a differentiated equation relates changes in $h_1$ to changes in $f_i$, which is an example of a pure capacity process, also called an *integrating system*. The cross-sectional area of the tank is the chemical process equivalent of an electrical capacitor. If the inlet flow is step-forced while the outlet is held constant, then the level builds up linearly, as shown in Fig. 8-8. Eventually the liquid will overflow the tank.

***Second-Order Element*** Consider the two-tank system shown in Fig. 8-9. For tank 1, the first-order dynamic model relates changes in $f_1$ to changes in $f_i$.

Since $f_1$ is the inlet flow to tank 2, a first-order dynamic model also relates changes in $h_2$ to changes in $f_1$, which has the same form as tank 1. The overall model is a second-order differential equation, which has a gain $R_2$ and two time constants $A_1R_1$ and $A_2R_2$. For two tanks with equal areas, a step change in $f_i$ produces the S-shaped response in level in the second tank shown in Fig. 8-10.

***General Second-Order Element*** Figure 8-3 illustrates the fact that closed-loop systems can exhibit oscillatory behavior. A general second-order transfer function that can exhibit oscillatory behavior is important for the study of automatic control systems. For a unit step input, the transient responses shown in Fig. 8-11 result. As can be seen, when $\zeta < 1$, the response oscillates; and when $\zeta < 1$, the response is S-shaped. Few open-loop chemical processes exhibit an oscillating response; most exhibit an S-shaped step response.

***Distance-Velocity Lag (Dead-Time Element)*** The dead-time or time-delay element, commonly called a *distance-velocity lag*, is often encountered in process systems. For example, if a temperature-measuring element is located downstream from a heat exchanger, a time delay occurs before the

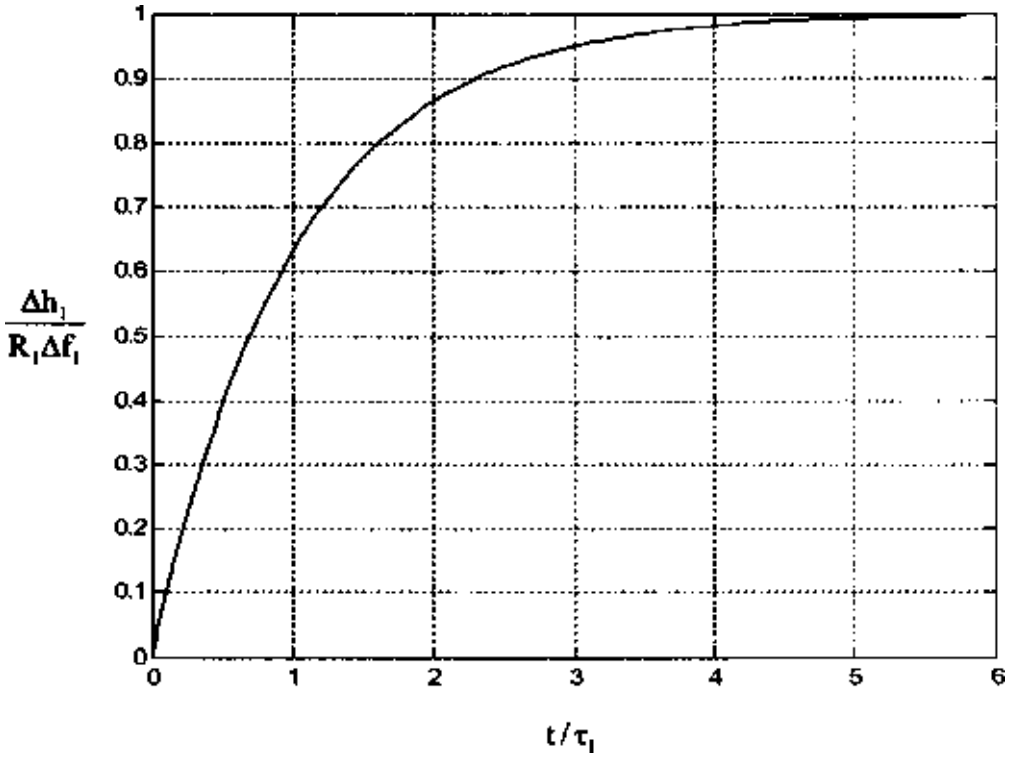

**FIG. 8-7** Response of first-order system.

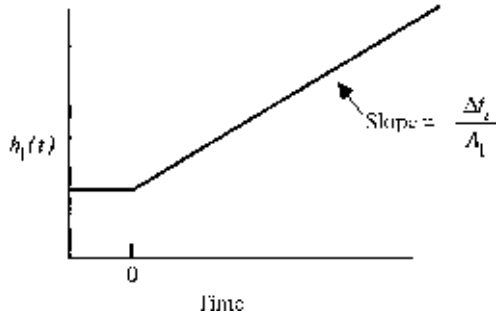

**FIG. 8-8** Response of pure capacity system.

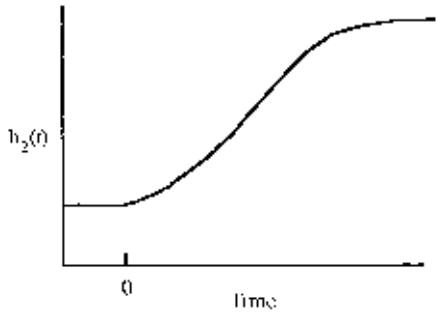

**FIG. 8-10** Response of second-order system.

heated fluid leaving the exchanger arrives at the temperature measurement point. If some element of a system produces a dead time of θ time units, then an input to that unit $f(t)$ will be reproduced at the output as $f(t-\theta)$. The transient response of the element is shown in Fig. 8-12.

***Higher-Order Lags*** If a process is described by a series of $n$ first-order lags, the overall system response becomes proportionally slower with each lag added. The special case of a series of $n$ first-order lags with equal time constants has a transfer function given by

$$G(s)=\frac{K}{(\tau s+1)^n} \tag{8-8}$$

The step response of this transfer function is shown in Fig. 8-13. Note that all curves reach about 60 percent of their final value at $t=n\tau$.

Higher-order systems can be approximated by a first- or second-order plus dead-time system for control system design.

***Multi-input, Multioutput Systems*** The dynamic systems considered up to this point have been examples of single-input, single-output (SISO) systems. In chemical processes, one often encounters systems where one input can affect more than one output. For example, assume that one is studying a distillation tower in which both reflux and boil-up are manipulated for control purposes. If the output variables are the top and bottom product compositions, then each input affects both outputs. For this distillation example, the process is referred to as a $2\times 2$ system to indicate the number of inputs and outputs. In general, *multi-input*, *multi-output* (MIMO) systems can have $n$ inputs and $m$ outputs with $n\neq m$, and they can be nonlinear. Such a system would be called an $n\times m$ *system*. A depiction of a $2\times 2$ linear system is given in Fig. 8-14. Note that since linear systems are involved, the effects of the two inputs on each output are additive. In many process control systems, one input is selected to control one output in a MIMO system. For $m$ outputs there would be $m$ such selections. For this type of control strategy, one needs to consider which inputs and outputs to couple with feedback controllers, and this problem is referred to as *loop pairing*. Another important issue that arises involves interaction between control loops. When one loop makes a change in its manipulated variable, the change affects the other loops in the system. These changes are the direct result of the multivariable nature of the process. In some cases, the interaction can be so severe that overall control system performance is drastically reduced. Finally, some of the modern approaches to process control tackle the MIMO problem directly, and they simultaneously use all manipulated variables to control all output variables rather than pair one input to one output (see later section on multivariable control).

**Fitting Dynamic Models to Experimental Data** In developing empirical transfer functions, it is necessary to identify model parameters from experimental data. A number of approaches to process identification have been published. The simplest approach involves introducing a step test into the process and recording the response of the process, as illustrated in Fig. 8-15. The $x$'s in the figure represent the recorded data. For purposes of illustration, the process under study will be assumed to be first-order with dead time and will have three parameters to characterize the response: gain $K$, time constant τ, and time delay θ.

An experimental response is shown in Fig. 8-15 for a set of model parameters $K$, τ, and θ fitted to the data. These parameters are calculated by using optimization to minimize the squared difference between the model predictions and the data, i.e., a least-squares approach. Let each measured data point be represented by $y_j$ (measured response), $t_j$ (time of measured response), $j=1$ to $n$. Then the least-squares problem can be formulated as

$$\min_{\tau,\theta,K}\sum_{j=1}^{n}[y_j-\hat{y}(t_j)]^2 \tag{8-9}$$

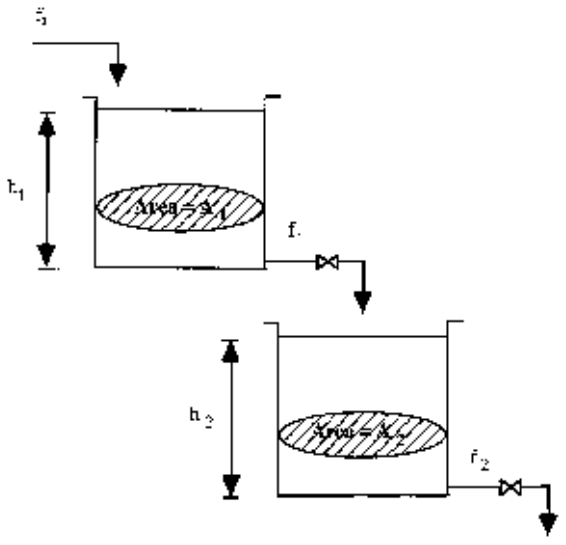

**FIG. 8-9** Two tanks in series.

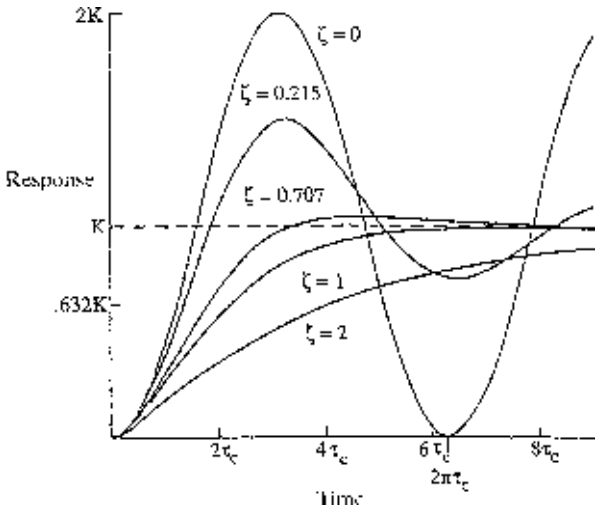

**FIG. 8-11** Response of general second-order system.

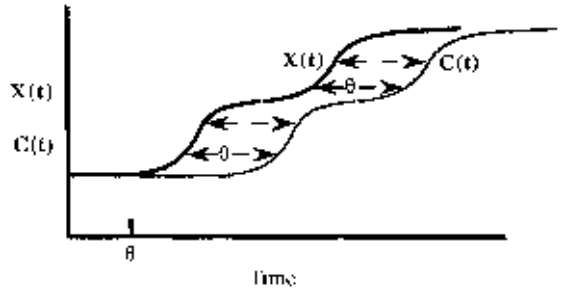

**FIG. 8-12** Response of dead-time system.

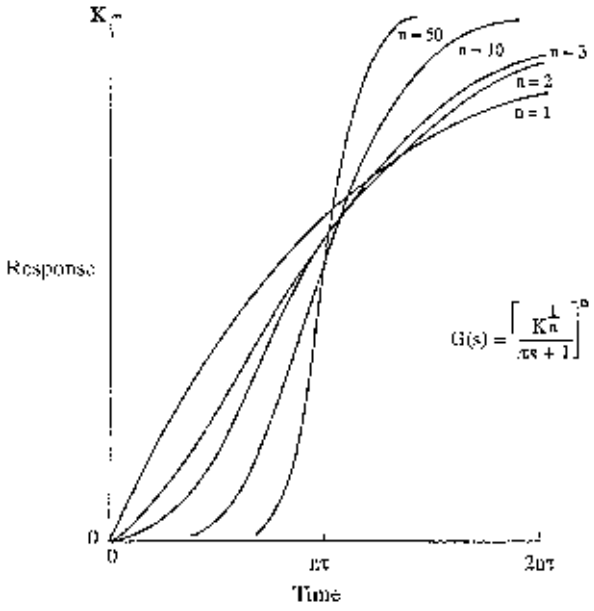

**FIG. 8-13** Response of *n*th-order lags.

where $\hat{y}(t_j)$ is the predicted value of $y$ at time $t_j$ and $n$ is the number of data points. This optimization problem can be solved to calculate the optimal values of $K$, $\tau$, and $\theta$. A number of software packages such as Excel Solver are available for minimizing Eq. (8-9).

One operational problem caused by step forcing is the fact that the process under study is moved away from its steady-state operating point. Plant managers may be reluctant to allow large steady-state changes, since normal production will be disturbed by the changes. As a result, alternative methods of forcing actual processes have been developed, and these included pulse testing and *pseudorandom binary signal* (PRBS) forcing. With pulse forcing, one introduces a step, and then after a period of time the input is returned to its original value. The result is that the process dynamics are excited, but after the forcing the process returns to its original steady state. PRBS forcing involves a series of pulses of fixed height and random duration, as shown in Fig. 8-16. The advantage of PRBS is that forcing can be concentrated on particular frequency ranges that are important for control system design.

Transfer function models assume linear, dynamic models are adequate, but chemical processes are known to exhibit nonlinear behavior. One could use the same type of optimization objective as given in Eq. (8-27) to determine parameters in nonlinear first-principles models, such as Eq. (8-3) presented earlier. Also, nonlinear input-output empirical models, such as neural network models, have recently been proposed for process applications. The key to the use of these nonlinear empirical models is to have high-quality process data, which allows the important nonlinearities to be identified.

## FEEDBACK CONTROL SYSTEM CHARACTERISTICS

**General References:** Shinskey, *Process Control Systems*, 4th ed., McGraw-Hill, New York, 1996; Seborg, Edgar, Mellichamp, and Doyle, *Process Dynamics and Control*, 4th ed., Wiley, New York, 2016; Bequette, *Process Control: Modeling, Design and Simulation*, 2d ed., Prentice-Hall, Upper Saddle River, N.J., 2017. There are two objectives in applying feedback control: (1) regulate the controlled variable at the set point following changes in load and (2) respond to set-point changes, with the latter called *servo operation*. In fluid processes, almost all control loops must contend with variations in load, and therefore regulation is of primary importance. While most loops will operate continuously at fixed set points, frequent changes in set points can occur in flow loops and in batch production. The most common mechanism for achieving both objectives is feedback control, because it is the simplest and most universally applicable approach to the problem.

**Closing the Loop** The simplest representation of the closed feedback loop is shown in Fig. 8-17. Other versions of the block diagram can include a measurement or sensor block in the feedback path rather than including it in $G_p$ (e.g., Seborg et al., 2016). The load is shown entering the process at the same point as the manipulated variable because that is the most common point of entry, and because, lacking better information, the elements in the path of the manipulated variable are the best estimates of those in the load path. The load rarely impacts directly on the controlled variable without passing through the dominant lag in the process. Where the load is unmeasured, its current value can be observed as the controller output required to keep the controlled variable $Y$ at set point $Y_{sp}$.

If the loop is opened—either by placing the controller in manual operation or by setting its gains to zero—the load will have complete influence over the controlled variable, and the set point will have none. Only by closing the loop with controller gain as high as possible will the influence of

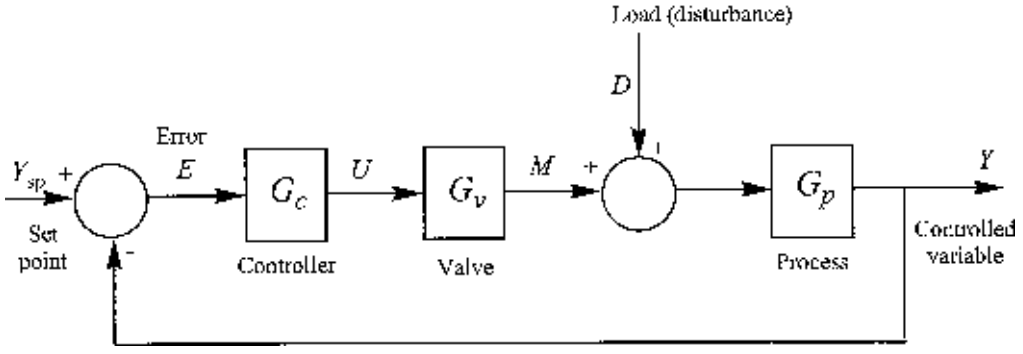

**FIG. 8-17** Both load regulation and set-point response require high gains for the feedback controller.

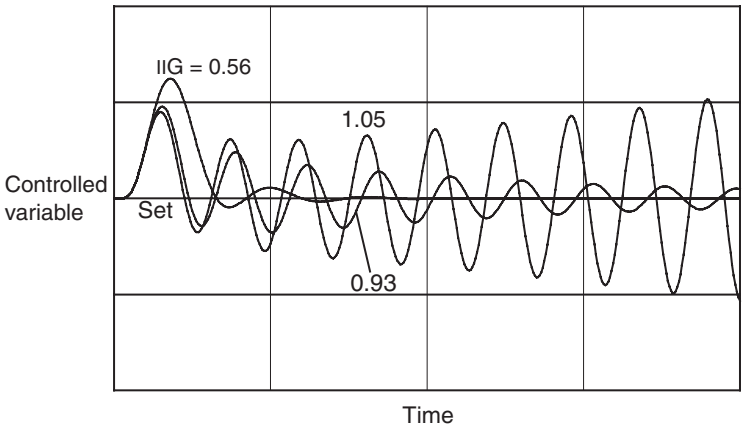

**FIG. 8-18** Transition from well-damped load response to instability develops as loop gain increases.

the load be minimized and that of the set point be maximized. There is a practical limit to the controller gain, however, at the point where the controlled variable develops a uniform oscillation. This is defined as the *limit of stability*, and it is reached when the product of gains in the loop $\Pi G = G_c G_v G_p$ is equal to 1.0 at the period of the oscillation. If the gain of any element in the loop increases from this condition, oscillations will expand, creating a dangerous situation where safe limits of operation could be exceeded in a few cycles. Consequently, control loops should be left in a condition where the loop gain is less than 1.0 by a safe margin that allows for possible variations in process parameters. Figure 8-18 describes a load response under PID (proportional-integral-derivative) control where the loop is well damped at a loop gain of 0.56; loop gain is then increased to 0.93 and to 1.05, creating a lightly damped and then an expanding cycle, respectively.

In controller tuning, a choice must be made between performance and robustness. Performance is a measure of how well a given controller with certain parameter settings regulates a variable, relative to the best response that can be achieved for that particular process. Robustness is a measure of how small a change in a process parameter is required to bring the loop from its current state to the limit of stability ($\Pi G = 1.0$). The well-damped loop in Fig. 8-18 has a robustness of 79 percent, in that increasing the gain of any element in the loop by a factor of 1/0.56, or 1.79, would bring the loop to the limit of stability. Increasing controller performance by raising its gain can therefore be expected to decrease robustness. Both performance and robustness are functions of the dynamics of the process being controlled, the selection of the controller, and the tuning of the controller parameters.

**On/Off Control** An on/off controller is used for manipulated variables having only two states. They commonly control temperatures in homes, electric water heaters and refrigerators, and pressure and liquid level in pumped storage systems. On/off control is satisfactory where slow cycling is acceptable, because it always leads to cycling when the load lies between the two states of the manipulated variable. The cycle will be positioned symmetrically about the set point only if the load happens to be equidistant between the two states of the manipulated variable. The period of the symmetric cycle will be approximately $4\theta$, where $\theta$ is the dead time in the loop. If the load is not centered between the states of the manipulated variable, the period will tend to increase and the cycle will follow a sawtooth pattern.

Every on/off controller has some degree of dead band, also known as *lockup*, or differential gap. Its function is to prevent erratic switching between states, thereby extending the life of contacts and motors. Instead of changing states precisely when the controlled variable crosses the set point, the controller will change states at two different points for increasing and decreasing signals. The difference between these two switching points is the dead band (see Fig. 8-19); it increases the amplitude and period of the cycle, similar to the effects of dead time.

A three-state controller is used to drive either a pair of independent two-state actuators, such as heating and cooling valves, or a bidirectional motorized actuator. The controller is comprised of two on/off controllers, each with dead band, separated by a dead zone. While the controlled variable lies within the dead zone, neither output is energized. This controller can drive a motorized valve to the point where the manipulated variable matches the load, thereby avoiding cycling.

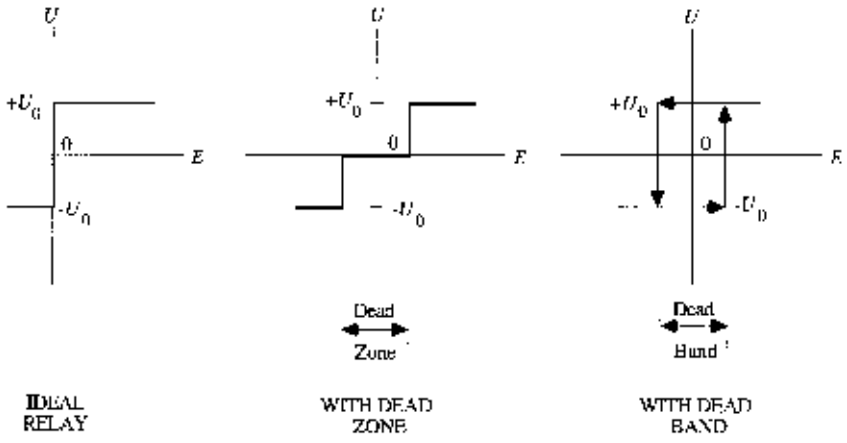

**FIG. 8-19** On/off controller characteristics.

**Proportional Control** A proportional controller moves its output proportional to the deviation $e$ between the controlled variable $y$ and its set point $y_{sp}$:

$$u = K_c e + b = \frac{100}{p} e + b \tag{8-10}$$

where $e = \pm(y - y_{sp})$, the sign selected to produce negative feedback. In some controllers, proportional gain $K_c$ is introduced as a pure number; in others, it is set as $100/P$, where $P$ is the proportional band in percent. The output bias $b$ of the controller is also known as *manual reset*. The proportional controller is not a good regulator, because any change in output required to respond to a change in load results in a corresponding change in the controlled variable. To minimize the resulting offset, the bias should be set at the best estimate of the load, and the proportional band set as low as possible. Processes requiring a proportional band of more than a few percent may control with unacceptably large values of offset.

Proportional control is most often used to regulate liquid level, where variations in the controlled variable carry no economic penalty and where other control modes can easily destabilize the loop. It is actually recommended for controlling the level in a surge tank when manipulating the flow of feed to a critical downstream process. By setting the proportional band just under 100 percent, the level is allowed to vary over the full range of the tank capacity as inflow fluctuates, thereby minimizing the resulting rate of change of manipulated outflow. This technique is called *averaging level control*.

**Proportional-plus-Integral (PI) Control** Integral action eliminates the offset described above by moving the controller output at a rate proportional to the deviation from set point—the output will then not stop moving until the deviation is zero. Although available alone in an integral controller, it is most often combined with proportional action in a PI controller:

$$u = \frac{100}{P}\left( e + \frac{1}{\tau_I}\int e\,dt \right) + C_0 \tag{8-11}$$

where $\tau_I$ is the integral time constant in minutes; in some controllers it is introduced as integral gain or reset rate $1/\tau_I$ in repeats per minute. The last term in the equation is the constant of integration $C_0$, the value of the controller output when integration begins. The PI controller is by far the most commonly used controller in the process industries.

**Proportional-plus-Integral-plus-Derivative (PID) Control** The derivative mode moves the controller output as a function of the rate of change of the controlled variable, which adds phase lead to the controller, increasing its speed of response. It is normally combined with proportional and integral modes. The noninteracting or ideal form of the PID controller appears functionally as

$$u = \frac{100}{p}\left( e + \frac{1}{\tau_I}\int e\,dt \pm \tau_D \frac{dy}{dt} \right) + C_0 \tag{8-12}$$

where $\tau_D$ is the derivative time constant. Note that derivative action is applied to the controlled variable rather than to the deviation, as it should not be applied to the set point; the selection of the sign for the derivative term must be consistent with the action of the controller.

In some PID controllers, the integral and derivative terms are combined serially rather than in parallel, as done in the last equation. This results in interaction between these modes, such that the effective values of the controller parameters differ from their set values as follows:

$$\begin{aligned} \tau_{I,\text{eff}} &= \tau_I + \tau_D \\ \tau_{D,\text{eff}} &= \frac{1}{1/\tau_D + 1/\tau_I} \\ K_c &= \frac{100}{P}\left( 1 + \frac{\tau_D}{\tau_I} \right) \end{aligned} \tag{8-13}$$

The performance of the interacting controller is almost as high as that of the noninteracting controller on most processes, but the tuning rules differ because of the above relationships. Both controllers are in common use in digital systems.

There is always a gain limit placed upon the derivative vector—a value of 10 is typical. However, interaction decreases the derivative gain below this value by the factor $1 + \tau_D/\tau_I$, which is the reason for the decreased performance of the interacting PID controller. Sampling in a digital controller has a similar effect, limiting the derivative gain to the ratio of derivative time to the sample interval of the controller. Noise on the controlled variable is amplified by the derivative gain, preventing its use in controlling flow and liquid level. Derivative action is recommended for control of temperature and composition in multiple-capacity processes with little measurement noise.

**Controller Comparison** Figure 8-20 compares the step load response of a distributed lag without control, and with P, PI, and interacting PID control. A distributed lag is a process whose resistance and capacity are distributed throughout its length—a heat exchanger is characteristic of this class, its heat-transfer surface and heat capacity being uniformly distributed. Other examples include imperfectly stirred tanks and distillation columns—both trayed and packed. The signature of a distributed lag is its open-loop (uncontrolled) step response, featuring a relatively short dead time followed by a dominant lag called $\Sigma\tau$, which is the time required to reach 63.2 percent complete response.

The proportional controller is unable to return the controlled variable to the set point following the step load change, as a deviation is required to sustain its output at a value different from its fixed bias $b$. The amount of proportional offset produced as a fraction of the uncontrolled offset is $1/(1 + KK_c)$, where $K$ is the steady-state process gain—in Fig. 8-20 that fraction is 0.13. Increasing $K_c$ can reduce the offset, but with an accompanying loss in damping.

The PI and PID controller were tuned to produce a minimum *integrated absolute error* (IAE). Their response curves are similar in appearance to a gaussian distribution curve, but with a damped cycle in the trailing edge. The peak deviation of the PID response curve is only 0.12 times the uncontrolled offset, occurring at 0.36 $\Sigma\tau$; the peak deviation of the PI response curve is 0.21 times the uncontrolled offset, occurring at 0.48 $\Sigma\tau$. These values can be used to predict the load response of any distributed lag whose parameters $K$ and $\Sigma\tau$ are known or can be estimated as described below.

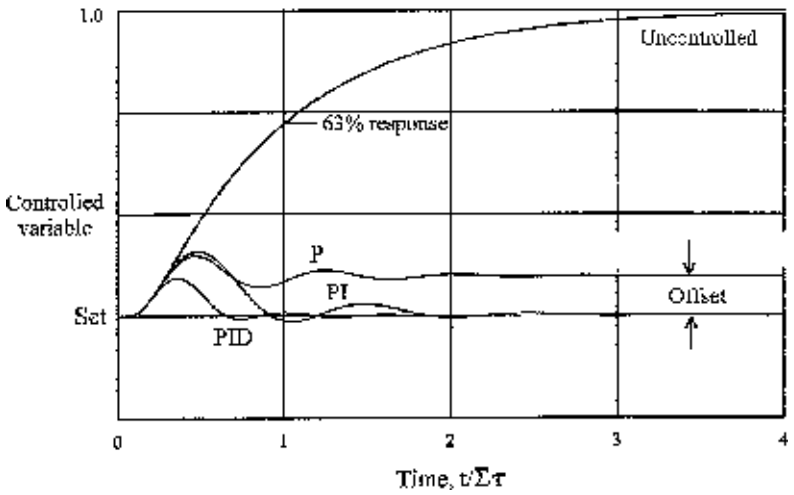

**FIG. 8-20** Minimum-IAE tuning gives very satisfactory load response for a distributed lag.

## CONTROLLER TUNING

The performance of a controller depends as much on its tuning as on its design. Tuning must be applied by the end user to fit the controller to the controlled process. There are many different approaches to controller tuning, based on the particular performance criteria selected, whether load or set-point changes are more important, whether the process is lag- or dead-time-dominant, and the availability of information about the process dynamics. The earliest definitive work in this field was done at Taylor Instrument Company by Ziegler and Nichols (*Trans. ASME*, p. 759, 1942), tuning PI and interacting PID controllers for optimum response to step load changes applied to lag-dominant processes. While these tuning rules are still in use, they do not apply to set-point changes, dead-time-dominant processes, or noninteracting PID controllers (Seborg, Edgar, Mellichamp, and Doyle, *Process Dynamics and Control*, Wiley, New York, 2016).

**Controller Performance Criteria** The most useful measures of controller performance in an industrial setting are the maximum deviation in the controlled variable resulting from a disturbance, and its integral. The disturbance could be to the set point or to the load, depending on the variable being controlled and its context in the process. The size of the deviation and its integral are proportional to the size of the disturbance (if the loop is linear at the operating point). While actual disturbances arising in a plant may appear to be random, the controller needs a reproducible test to determine how well it is tuned. The disturbance of choice for test purposes is the step, because it can be applied manually, and by containing all frequencies including zero it exercises all modes of the controller. (The step actually has the same frequency distribution as integrated white noise, a "random walk.") When tuned optimally for step disturbances, the controller will be optimally tuned for most other disturbances as well.

A step change in set point, however, may be a poor indicator of a loop's load response. For example, a liquid-level controller does not have to integrate to follow a set-point change, as its steady-state output is independent of the set point. Stepping a flow controller's set point is an effective test of its tuning, however, as its steady-state output is proportional to its set point. Other loops should be load-tested: simulate a load change from a steady state at zero deviation by transferring the controller to manual and stepping its output, and then immediately transferring back to automatic before a deviation develops.

Figure 8-21*a* and *b* shows variations in the response of a distributed lag to a step change in load for different combinations of proportional and integral settings of a PI controller. The maximum deviation is the most important criterion for variables that could exceed safe operating levels, such as steam pressure, drum level, and steam temperature in a boiler. The same rule can apply to product quality if violating specifications causes it to be rejected. However, if the product can be accumulated in a downstream storage tank, its average quality is more important, and this is a function of the deviation integrated over the residence time of the tank. Deviation in the other direction, where the product is better than specification, is safe but increases production costs in proportion to the integrated deviation because quality is given away.

For a PI or PID controller, the integrated deviation—better known as *integrated error* IE—is related to the controller settings

$$\mathrm{IE} = \Delta u \frac{P\tau_I}{100} \tag{8-14}$$

where $\Delta u$ is the difference in controller outputs between two steady states, as required by a change in load or set point. The proportional band $P$ and

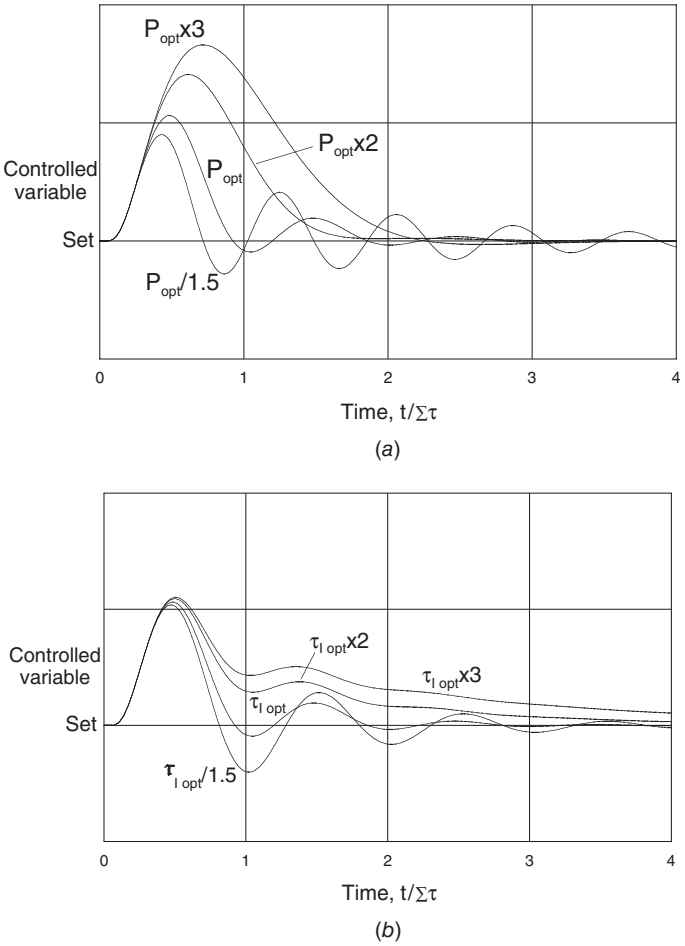

**FIG. 8-21** The optimum settings produce minimum-IAE load response. (*a*) The proportional band primarily affects damping and peak deviation. (*b*) Integral time determines overshoot.

integral time $\tau_I$ are the indicated settings of the controller for PI and both interacting and noninteracting PID controllers. Although the derivative term does not appear in the relationship, its use typically allows a 50 percent reduction in integral time and therefore in IE. The integral time in the IE expression should be augmented by the sample interval if the controller is digital, the time constant of any filter used, and the value of any dead-time compensator.

It would appear, from the above, that minimizing IE is simply a matter of minimizing the $P$ and $\tau_I$ settings of the controller. However, settings will be reached that produce excessive oscillations, such as shown in the lowest two response curves in Fig. 8-21*a* and *b*. It is preferable instead to find a combination of controller settings that minimizes *integrated absolute error* IAE, which for both load and set-point changes is a well-damped response with minimal overshoot. The curves designated $P_{\text{opt}}$ and $\tau_{I,\text{opt}}$ in Fig. 8-21 are the same minimum-IAE response to a step change in load for a distributed-lag process under PI control. Because of the very small overshoot, the IAE will be only slightly larger than the IE. Loops that are tuned to minimize IAE tend to give responses that are close to minimum IE and with minimum peak deviation. The other curves in Fig. 8-21*a* and *b* describe the effects of individual adjustments to $P$ and $\tau_I$, respectively, around those optimum values and can serve as a guide to fine-tuning a PI controller.

The performance of a controller (and its tuning) must be based on what is achievable for a given process. The concept of best practical IE ($\text{IE}_b$) for a step change in load $\Delta L$ to a process consisting of dead time and one or two lags can be estimated (Shinskey, *Process Control Systems*, 4th ed., McGraw-Hill, New York, 1996) as

$$\text{IE}_b = \Delta L K_L \tau_L (1 - e^{-\theta/\tau_L}) \tag{8-15}$$

where $K_L$ is the gain and $\tau_L$ the primary time constant in the load path, and $\theta$ the dead time in the manipulated path to the controlled variable. If the load or its gain is unknown, $\Delta u$ and $K$ ($= K_v K_p$) may be substituted. If the process is non-self-regulating (i.e., an integrator), the relationship is

$$\text{IE}_b = \frac{\Delta L \theta^2}{\tau_1} \tag{8-16}$$

where $\tau_1$ is the time constant of the process integrator. The peak deviation of the best practical response curve is

$$e_b = \frac{\text{IE}_b}{\theta + \tau_2} \tag{8-17}$$

where $\tau_2$ is the time constant of a common secondary lag (e.g., in the measuring device).

The performance of any controller can be measured against this standard by comparing the IE it achieves in responding to a load change with the best practical IE. Maximum performance levels for PI controllers on lag-dominant processes lie in the 20 to 30 percent range, while for PID controllers they fall between 40 and 60 percent, varying with secondary lags.

**Tuning Methods Based on Known Process Models** The most accurate tuning rules for controllers have been based on simulation, where the process parameters can be specified and IAE and IE can be integrated during the simulation as an indication of performance. Controller settings are then iterated until a minimum IAE is reached for a given disturbance. Next these optimum settings are related to the parameters of the simulated process in tables, graphs, or equations, as a guide to tuning controllers for processes whose parameters are known (Seborg, Edgar, Mellichamp, and Doyle, *Process Dynamics and Control*, Wiley, New York, 2016). This is a multidimensional problem, however, in that the relationships change as a function of process type, controller type, and source of disturbance.

Table 8-1 summarizes rules cited by Shinskey for minimum-IAE load response for the most common controllers. The process gain and time constant $\tau_m$ are obtained from the product of $G_v$ and $G_p$ in Fig. 8-17. Derivative action is not effective for dead-time-dominant processes. Any secondary lag, sampling interval, or filter time constant should be added to dead time $\theta$. A more recent set of tuning rules is called *internal model control* (IMC). Table 8-2 presents the PID controller tuning relations for the parallel form developed by Chien and Fruehauf [*Chem. Engr. Progress* **86**(10): 33 (1990)] for common types of process control models. For example, for model A, the control settings are $K_c K = \tau/\tau_c$ and $\tau_I = \tau_c$. The advantage of IMC is that it allows model uncertainty and trade-offs between performance and robustness to be considered with a closed-loop time constant $\tau_c$. So specifying the value of one tuning parameter can numerically determine all three controller modes. For lag-dominant models with load changes, a modification due to Skogestad [*J. Process Control* **13:** 291 (2003)] is effective.

**TABLE 8-1 Tuning Rules Using Known Process Parameters**

| Process | Controller | $P$ | $\tau_I$ | $\tau_D$ |
|---|---|---|---|---|
| Dead-time-dominant | PI | $250K$ | $0.5\theta$ | |
| Lag-dominant | PI | $106K\theta/\tau_m$ | $4.0\theta$ | |
| | $\text{PID}_n$ | $77K\theta/\tau_m$ | $1.8\theta$ | $0.45\theta$ |
| | $\text{PID}_i$ | $106K\theta/\tau_m$ | $1.5\theta$ | $0.55\theta$ |
| Non-self-regulating | PI | $106\theta/\tau_1$ | $4.0\theta$ | |
| | $\text{PID}_n$ | $78\theta/\tau_1$ | $1.9\theta$ | $0.48\theta$ |
| | $\text{PID}_i$ | $108\theta/\tau_1$ | $1.6\theta$ | $0.58\theta$ |
| Distributed lags | PI | $20K$ | $0.50\,\Sigma\tau$ | |
| | $\text{PID}_n$ | $10K$ | $0.30\,\Sigma\tau$ | $0.09\,\Sigma\tau$ |
| | $\text{PID}_i$ | $15K$ | $0.25\,\Sigma\tau$ | $0.10\Sigma\tau$ |

NOTE: $n$ = noninteracting, $i$ = interacting controller modes.

**TABLE 8-2 Tuning Rules Using Slope and Intercept**

| Controller | $P$ | $\tau_I$ | $\tau_D$ |
|---|---|---|---|
| PI | $150\theta/\tau_1$ | $3.5\theta$ | |
| $\text{PID}_n$ | $75\theta/\tau_1$ | $2.1\theta$ | $0.63\theta$ |
| $\text{PID}_i$ | $113\theta/\tau_1$ | $1.8\theta$ | $0.70\theta$ |

NOTE: $n$ = noninteracting, $i$ = interacting controller modes.

The principal limitation to using these rules is that the true process parameters are often unknown. Steady-state gain $K$ can be calculated from a process model, or determined from the steady-state results of a step test as $\Delta c/\Delta u$, as shown in Fig. 8-22. The test will not be viable, however, if the time constant of the process $\tau_m$ is longer than a few minutes, since five time constants must elapse to approach a steady state within 1 percent, and unexpected disturbances may intervene. Estimated dead time $\theta$ is the time from the step to the intercept of a straight line tangent to the steepest part of the response curve. The estimated time constant $\tau$ is the time from that point to 63 percent of the complete response. In the presence of a significant secondary lag, these results will not be completely accurate, however. The time for 63 percent response may be more accurately calculated as the residence time of the process: its volume divided by current volumetric flow rate.

**Tuning Methods When Process Model Is Unknown** Ziegler and Nichols developed two tuning methods for processes with unknown parameters. The open-loop method uses a step test without waiting for a steady state to be reached and is therefore applicable to very slow processes. Dead time is estimated from the intercept of the steepest tangent to the response curve in Fig. 8-22, whose slope is also used. If the process is non-self-regulating, the controlled variable will continue to follow this slope, changing by an amount equal to $\Delta u$ in a time equal to its time constant $\tau_1$. This time estimate $\tau_1$ is used along with $\theta$ to tune controllers according to Table 8-2, applicable to lag-dominant processes. If the process is known to be a distributed lag, such as a heat exchanger, distillation column, or stirred tank, then better results will be obtained by converting the estimated values of $\theta$ and $\tau_1$ to $K$ and $\Sigma\tau$ and using Table 8-1. The conversion factors are $K = 7.5\theta/\tau_1$ and $\Sigma\tau = 7.0\theta$.

The Ziegler and Nichols closed-loop method requires forcing the loop to cycle uniformly under proportional control, by setting the integral time to maximum and derivative time to zero and reducing the proportional band until a constant-amplitude cycle results. The natural period $\tau_n$ of the cycle (the proportional controller contributes no phase shift to alter it) is used to set the optimum integral and derivative time constants. The optimum proportional band is set relative to the undamped proportional band $P_u$, which was found to produce the uniform oscillation. Table 8-3 lists the tuning rules for a lag-dominant process.

A uniform cycle can also be forced by using on/off control to cycle the manipulated variable between two limits. The period of the cycle will be close to $\tau_n$ if the cycle is symmetric; the peak-to-peak amplitude $A_c$ of the controlled variable divided by the difference between the output limits $A_u$ is a measure of process gain at that period and is therefore related to $P_u$ for the proportional cycle:

$$P_u = 100 \frac{\pi}{4} \frac{A_c}{A_u} \tag{8-18}$$

The factor $\pi/4$ compensates for the square wave in the output. Tuning rules are given in Table 8-3.

**Set-Point Response** All the above tuning methods are intended to minimize IAE for step load changes. When applied to lag-dominant processes, the resulting controller settings produce excessive overshoot of set-point changes. This behavior has led to the practice of tuning to optimize

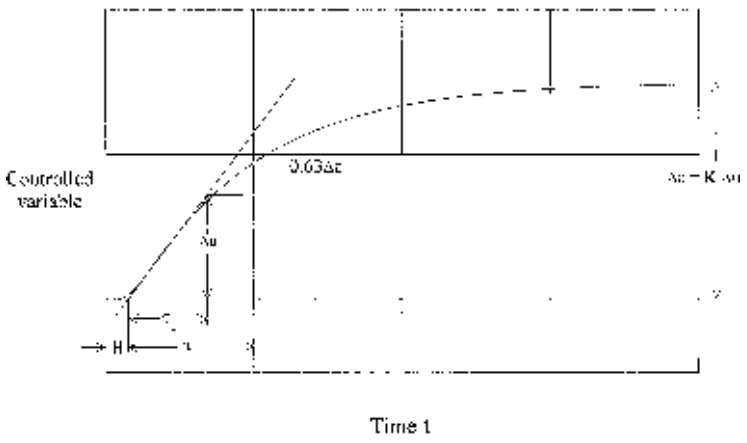

**FIG. 8-22** If a steady state can be reached, gain $K$ and time constant $t$ can be estimated from a step response; if not, use $t_1$ instead.

**TABLE 8-3 Tuning Rules Using Proportional Cycle**

| Controller | $P$ | $\tau_I$ | $\tau_D$ |
|---|---|---|---|
| PI | $1.70P_u$ | $0.81\tau_n$ | |
| $PID_n$ | $1.30P_u$ | $0.48\tau_n$ | $0.11\tau_n$ |
| $PID_i$ | $1.80P_u$ | $0.38\tau_n$ | $0.14\tau_n$ |

NOTE: $n$ = noninteracting, $i$ = interacting controller modes.

set-point response, which unfortunately degrades the load response of lag-dominant loops. An option has been available with some controllers to remove proportional action from set-point changes, which eliminates set-point overshoot but lengthens settling time. A preferred solution to this dilemma is available in many modern controllers which feature an independent gain adjustment for the set point, through which set-point response can be optimized after the controller has been tuned to optimize load response.

Figure 8-23 shows set-point and load responses of a distributed lag for both set-point and load tuning, including the effects of fractional set-point gain $K_r$. The set point was stepped at time 0, and the load stepped at time 2.4. With full set-point gain, the PI controller was tuned for minimum-IAE set-point response with $P = 29K$ and $\tau_I = \Sigma\tau$, compared to $P = 20K$ and $\tau_I = 0.50 \times \Sigma\tau$ for minimum-IAE load response. These settings increase its IE for load response by a factor of 2.9, and its peak deviation by 20 percent, over optimum load tuning. However, with optimum load tuning, that same set-point overshoot can be obtained with set-point gain $K_r = 0.54$. The effects of full set-point gain (1.0) and no set-point gain (0) are shown for comparison.

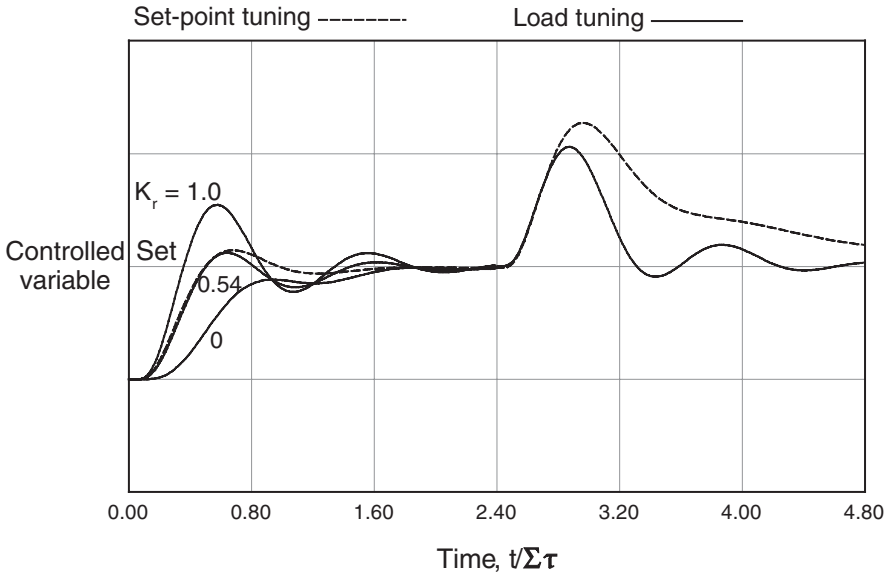

**FIG. 8-23** Tuning proportional and integral settings to optimize set-point response degrades load response; using a separate set-point gain adjustment allows both responses to be optimized.

# ADVANCED CONTROL SYSTEMS

## BENEFITS OF ADVANCED CONTROL

The economics of most processes are determined by the steady-state operating conditions. Excursions from these steady-state conditions usually have a less important effect on the economics of the process, except when the excursions lead to off-specification products. To enhance the economic performance of a process, the steady-state operating conditions must be altered in a manner that leads to more efficient process operation.

The hierarchy shown in Fig. 8-24 indicates that process control activities consist of the following five levels:

Level 1: Measurement devices and actuators
Level 2: Safety, environmental/equipment protection
Level 3: Regulatory control
Level 4: Real-time optimization
Level 5: Planning and scheduling

Levels 4 and 5 clearly affect the process economics, as both levels are directed to optimizing the process in some manner. In contrast, levels 1, 2, and 3 would appear to have no effect on process economics. Their direct effect is indeed minimal, although indirectly they can have a major effect. Basically, these levels provide the foundation for all higher levels. A process cannot be optimized until it can be operated consistently at the prescribed targets. Thus, satisfactory regulatory control must be the first goal of any automation effort. In turn, the measurements and actuators provide the process interface for regulatory control.

For most processes, the optimum operating point is determined by a constraint. The constraint might be a product specification (a product stream can contain no more than 2 percent ethane); violation of this constraint causes off-specification product. The constraint might be an equipment limit (e.g., vessel pressure rating is 300 psig); violation of this constraint causes the equipment protection mechanism (pressure relief device) to activate. As the penalties are serious, violation of such constraints must be very infrequent.

If the regulatory control system were perfect, the target could be set exactly equal to the constraint (i.e., the target for the pressure controller could be set at the vessel relief pressure). However, no regulatory control system is perfect. Therefore, the value specified for the target must be on the safe side of the constraint, thus allowing the control system some operating margin. How much depends on the following:

1. *The performance of the control system* (*i.e., how effectively it responds to disturbances*). The faster the control system reacts to a disturbance, the closer the process can be operated to the constraint.
2. *The magnitude of the disturbances to which the control system must respond.* If the magnitude of the major disturbances can be reduced, the process can be operated closer to the constraint.

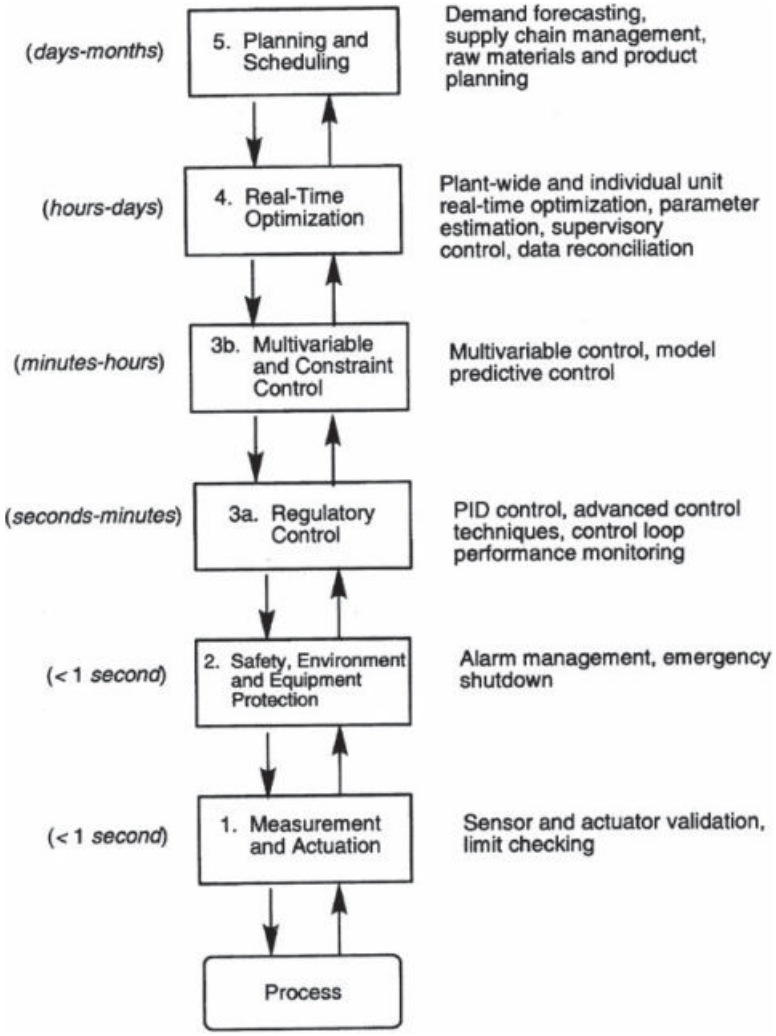

**FIG. 8-24** The five levels of process control and optimization in manufacturing. Time scales are shown for each level. (*Source:* Seborg et al., *Process Dynamics and Control*, 3d ed., Wiley, New York, 2010.)

One measure of the performance of a control system is the variance of the controlled variable from the target. Both improving the control system and reducing the disturbances will lead to a lower variance in the controlled variable.

In a few applications, improving the control system leads to a reduction in off-specification product and thus improved process economics. However, in most situations, the process is operated sufficiently far from the constraint that very little, if any, off-specification product results from control system deficiencies. Management often places considerable emphasis on avoiding off-specification production, so consequently the target is actually set far more conservatively than it should be.

In most applications, simply improving the control system does not directly lead to improved process economics. Instead, the control system improvement must be accompanied by shifting the target closer to the constraint. There is always a cost of operating a process in a conservative manner. The cost may be a lower production rate, a lower process efficiency, a product giveaway, or other. When management places undue emphasis on avoiding off-specification production, the natural reaction is to operate very conservatively, thus incurring other costs.

The immediate objective of an advanced control effort is to reduce the variance in an important controlled variable. However, this effort must be coupled with a commitment to adjust the target for this controlled variable so that the process is operated closer to the constraint. In large-throughput (commodity) processes, very small shifts in operating targets can lead to large economic returns.

## ADVANCED CONTROL TECHNIQUES

**General References:** Seborg, Edgar, Mellichamp, and Doyle, *Process Dynamics and Control*, 4th ed., Wiley, New York, 2016. Bequette, *Process Control: Modeling, Design and Simulation*, 2d ed., Prentice-Hall, Upper Saddle River, N.J., 2017. Shinskey, *Process Control Systems*, 4th ed., McGraw-Hill, New York, 1996. Ogunnaike and Ray, *Process Dynamics, Modeling, and Control*, Oxford University Press, New York, 1994.

While the single-loop PID controller is satisfactory in many process applications, it does not perform well for processes with slow dynamics, time delays, frequent disturbances, or multivariable interactions. We discuss several advanced control methods below that can be implemented via computer control, namely, feedforward control, cascade control, time-delay compensation, selective and override control, adaptive control, fuzzy logic control, and statistical process control.

**Feedforward Control** If the process exhibits slow dynamic response and disturbances are frequent, then the application of feedforward control may be advantageous. Feedforward (FF) control differs from feedback (FB) control in that the primary disturbance or load ($D$) is measured via a sensor and the manipulated variable ($U$) is adjusted so that deviations in the controlled variable from the set point are minimized or eliminated (see Fig. 8-25). By taking control action based on measured disturbances rather than controlled variable error, the controller can reject disturbances before they affect the controlled variable $Y$. To determine the appropriate settings for the manipulated variable, one must develop mathematical models that relate

1. The effect of the manipulated variable $U$ on the controlled variable $Y$
2. The effect of the disturbance $D$ on the controlled variable $Y$

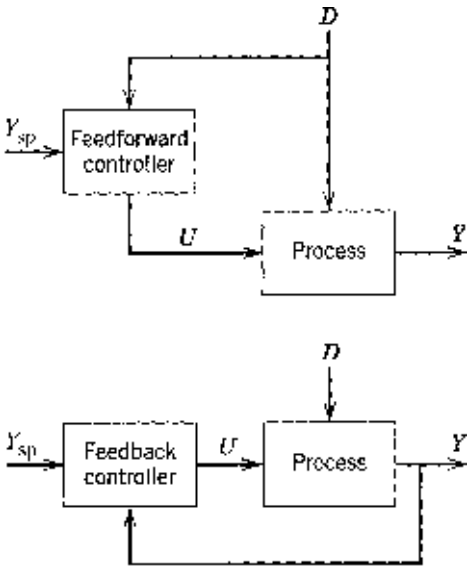

**FIG. 8-25** Simplified block diagrams for feedforward and feedback control.

These models can be based on steady-state or dynamic analysis. The performance of the feedforward controller depends on the accuracy of both models. If the models are exact, then feedforward control offers the potential of perfect control (i.e., holding the controlled variable precisely at the set point at all times because of the ability to predict the appropriate control action). However, since most mathematical models are only approximate and since not all disturbances are measurable, it is standard practice to utilize feedforward control in conjunction with feedback control. Table 8-4 lists the relative advantages and disadvantages of feedforward and feedback control. By combining the two control methods, the strengths of both schemes can be utilized.

FF control therefore attempts to eliminate the effects of measurable disturbances, while FB control would correct for unmeasurable disturbances and modeling errors. This latter case is often referred to as *feedback trim*. These controllers have become widely accepted in the chemical process industries since the 1960s.

***Design Based on Material and Energy Balances*** Consider a heat exchanger example (see Fig. 8-26) to illustrate the use of FF and FB control. The control objective is to maintain $T_2$, the exit liquid temperature, at the desired value (or set point) $T_{2sp}$ despite variations in the inlet liquid flow rate $F$ and inlet liquid temperature $T_1$. This is done by manipulating $W$, the steam flow rate. A feedback control scheme would entail measuring $T_2$, comparing $T_2$ to $T_{2sp}$, and then adjusting $W$. A feedforward control scheme requires measuring $F$ and $T_1$ and adjusting $W$ (knowing $T_{2sp}$), in order to control exit temperature $T_2$.

**TABLE 8-4 Relative Advantages and Disadvantages of Feedforward and Feedback**

| Advantages | Disadvantages |
|---|---|
| Feedforward | |
| • Acts before the effect of a disturbance has been felt by the system<br>• Is good for systems with large time constant or dead time<br>• Does not introduce instability in the closed-loop response | • Requires direct measurement of all possible disturbances<br>• Cannot cope with unmeasured disturbances<br>• Is sensitive to process/model error |
| Feedback | |
| • Does not require identification and measurement of any disturbance for corrective action<br>• Does not require an explicit process model<br>• Is possible to design controller to be robust to process/model errors | • Control action not taken until the effect of the disturbance has been felt by the system<br>• Is unsatisfactory for processes with large time constants and frequent disturbances<br>• May cause instability in the closed-loop response |

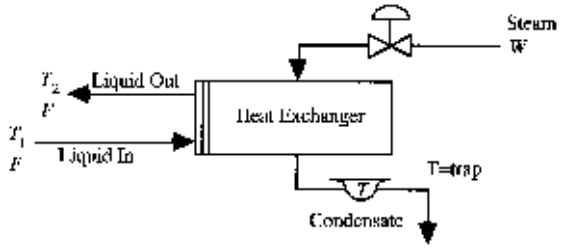

**FIG. 8-26** A heat exchanger diagram.

Figure 8-27*a* and *b* shows the control system diagrams for FB and FF control. A feedforward control algorithm can be designed for the heat exchanger in the following manner. Using a steady-state energy balance and assuming no heat loss from the heat exchanger,

$$WH = FC(T_2 - T_1) \tag{8-19}$$

where $H$ = latent heat of vaporization and $C_L$ = specific heat of liquid

$$W = \frac{C_L}{H} F(T_2 - T_1) \tag{8-20}$$

or

$$W = K_1 F(T_2 - T_1) \tag{8-21}$$

with

$$K_1 = \frac{C_L}{H} \tag{8-22}$$

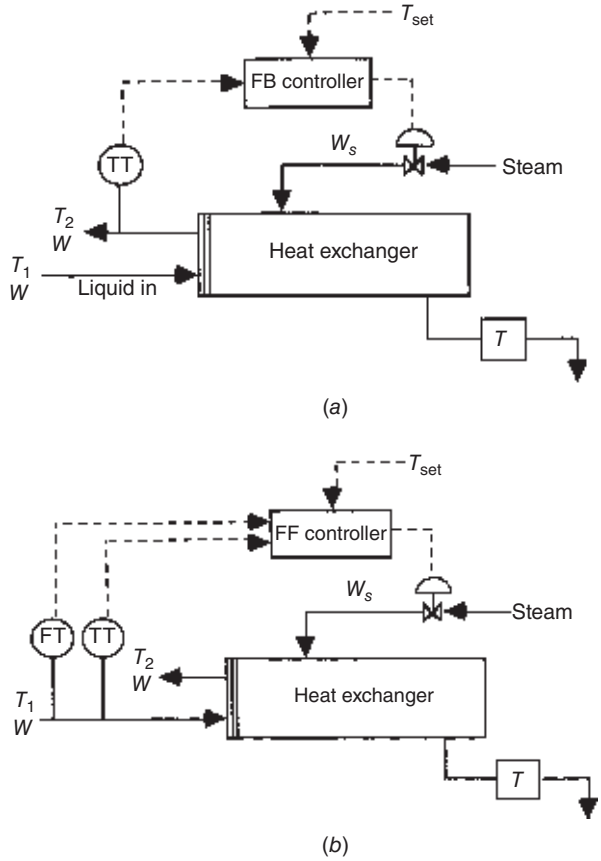

**FIG. 8-27** (*a*) Feedback control of a heat exchanger. (*b*) Feedforward control of a heat exchanger.

Replace $T_2$ by $T_{2sp}$

$$W = K_1 F(T_{2sp} - T_1) \tag{8-23}$$

Equation (8-23) can be used in the FF calculation, assuming one knows the physical properties $C_L$ and $H$. Of course, it is probable that the model will contain errors (e.g., unmeasured heat losses, incorrect $C_L$ or $H$). Therefore, $K_1$ can be designated as an adjustable parameter that can be tuned. The use of a physical model for FF control is desirable because it provides a physical basis for the control law and gives an a priori estimate of what the tuning parameters should be. Note that such a model could be nonlinear [e.g., in Eq. (8-23), $F$ and $T_{2sp}$ are multiplied].

***Block Diagram Analysis*** One shortcoming of this feedforward design procedure is that it is based on the steady-state characteristics of the process and, as such, neglects process dynamics (i.e., how fast the controlled variable responds to changes in the load and manipulated variables). Thus, it is often necessary to include "dynamic compensation" in the feedforward controller. The most direct method of designing the FF dynamic compensator is to use a block diagram of a general process, as shown in Fig. 8-28, where $G_t$ represents the disturbance transmitter, $G_f$ is the feedforward controller, $G_d$ relates the disturbance to the controlled variable, $G_v$ is the valve, $G_p$ is the process, $G_m$ is the output transmitter, and $G_c$ is the feedback controller. All blocks correspond to transfer functions (input-output models).

For disturbance rejection ($D \neq 0$) we require that $Y = 0$, or zero error. Using each block as a "multiplier," there are two paths from $D$ to $Y$: One involves the feedforward controller $G_f$ and the other involves the disturbance model. Thus $0 = G_d D + G_t G_f G_v G_p D$; solving for the feedforward controller gives

$$G_f = \frac{-G_d}{G_t G_v G_p} \tag{8-24}$$

Suppose there are no dynamics in $G_d$ and $G_p$ and all models are constant gains ($G_c = K_c$ and $G_t = K_t$). Then $G_f$ is equal to $-K_d/K_t K_v K_p = K_f$. If there are first-order dynamics in the process models for $G_p$ (time constant $\tau_p$) and $G_d$ (time constant $\tau_d$), then the feedforward controller is a lead-lag controller, which is a standard vendor controller configuration (Shinskey, *Process Control Systems: Application, Design, and Timing*, McGraw-Hill, New York, 1996). The lead-lag controller is comprised of a PD controller in series with a first-order filter.

The above FF controller can be implemented by using a digital computer. Figure 8-29*a* and *b* compares typical responses for PID FB control, steady-state FF control ($s = 0$), dynamic FF control, and combined FF/FB control. In practice, the engineer can tune $K$, $\tau_p$, and $\tau_d$ in the field to improve the performance of the FF controller.

***Other Considerations in Feedforward Control*** The tuning of feedforward and feedback control systems can be performed independently. In analyzing the block diagram in Fig. 8-28, note that $G_f$ is chosen to cancel the effects of the disturbance $D$, as long as there are no model errors. For the feedback loop, therefore, the effects of $D$ can also be ignored.

The feedback control stability limits will be unchanged for the FF + FB system. In general, the tuning of the FF/FB controller can be less conservative than for the case of FB alone, because smaller excursions from the set point will result.

For more information on feedforward/feedback control applications and design of such controllers, refer to the General References.

**Cascade Control** One of the disadvantages of using conventional feedback control for processes with large time lags or delays is that disturbances are not recognized until after the controlled variable deviates from its set point. In these processes, correction by feedback control is generally slow and results in long-term deviation from the set point. One way to improve the dynamic response to load changes is by using a secondary measurement point and a secondary controller; the secondary measurement point is located so that it recognizes the upset condition before the primary controlled variable is affected.

One such approach is called *cascade control*, which is routinely used in most modern computer control systems. Consider a chemical reactor, where reactor temperature is to be controlled by coolant flow to the jacket of the reactor. The reactor temperature can be influenced by changes in disturbance variables such as feed rate or feed temperature; a feedback controller could be employed to compensate for such disturbances by adjusting a valve on the coolant flow to the reactor jacket. However, suppose an increase occurs in the coolant temperature as a result of changes in the plant coolant system. This will cause a change in the reactor temperature measurement, although such a change will not occur quickly, and the corrective action taken by the controller will be delayed.

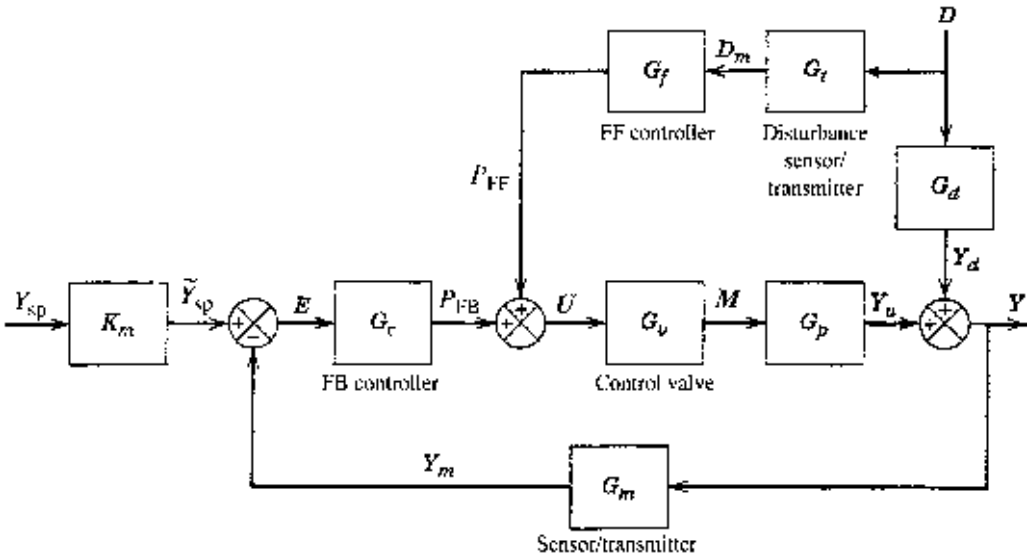

**FIG. 8-28** A block diagram of a feedforward-feedback control system. (*Source:* Seborg et al., *Process Dynamics and Control*, 3d ed., Wiley, New York, 2010.)

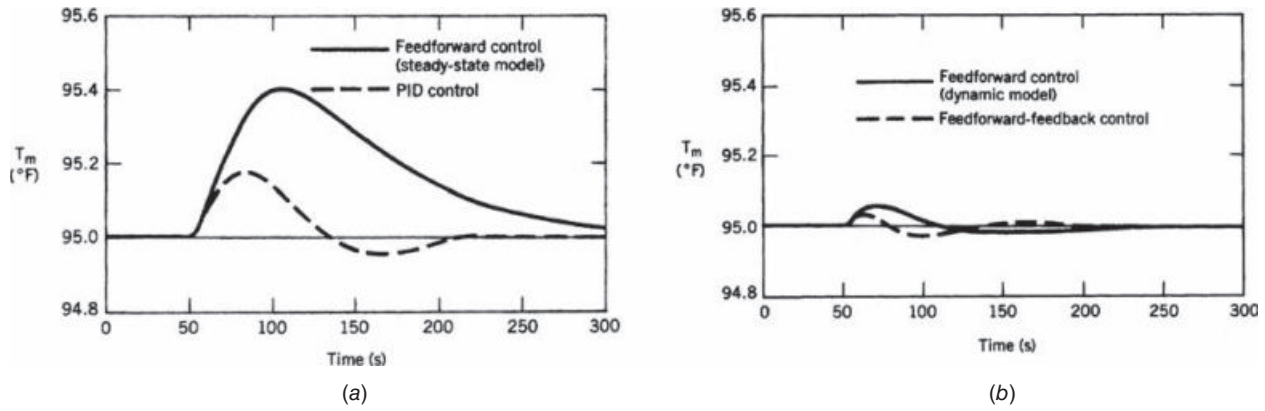

**FIG. 8-29** (*a*) Comparison of FF (steady-state model) and PID FB control for disturbance change. (*b*) Comparison of FF (dynamic model) and combined FF/FB control.

Cascade control is one solution to this problem (see Fig. 8-30). Here the jacket temperature is measured, and an error signal is sent from this point to the coolant control valve; this reduces coolant flow, maintaining the heat-transfer rate to the reactor at a constant level and rejecting the disturbance. The cascade control configuration will also adjust the setting of the coolant control valve when an error occurs in the reactor temperature. The cascade control scheme shown in Fig. 8-30 contains two controllers. The primary controller is the reactor temperature controller. It measures the reactor temperature, compares it to the set point, and computes an output, which is the set point for the coolant flow rate controller. The secondary controller compares this set point to the coolant temperature measurement and adjusts the valve. The principal advantage of cascade control is that the secondary measurement (jacket temperature) is located closer to a potential disturbance in order to improve the closed-loop response.

Figure 8-31 shows the block diagram for a general cascade control system. In tuning of a cascade control system, the secondary controller (in the inner loop) is tuned first with the primary controller in manual. Often only a proportional controller is needed for the secondary loop, because offset in the secondary loop can be treated by using proportional-plus-integral action in the primary loop. When the primary controller is transferred to automatic, it can be tuned by using the techniques described earlier in this section. For more information on theoretical analysis of cascade control systems, see the General References for a discussion of applications of cascade control.

**Time-Delay Compensation** Time delays are a common occurrence in the process industries because of the presence of recycle loops, fluid-flow distance lags, and dead time in composition measurements resulting from

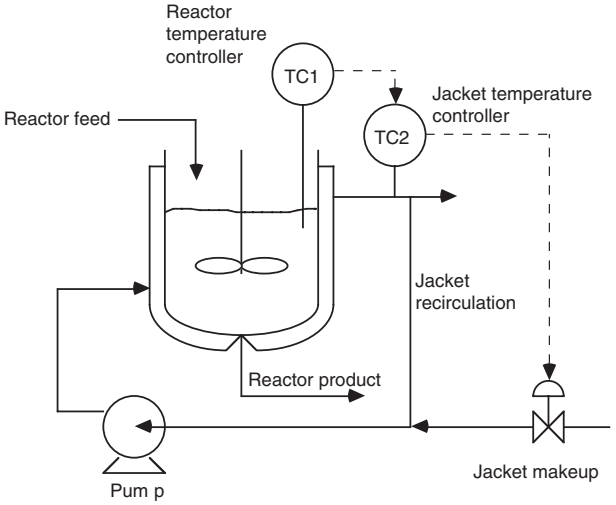

**FIG. 8-30** Cascade control of an exothermic chemical reactor. (*Source:* Bequette, *Process Control: Modeling, Design and Simulation*, 2d ed., Prentice-Hall, Upper Saddle River, N.J., 2017.)

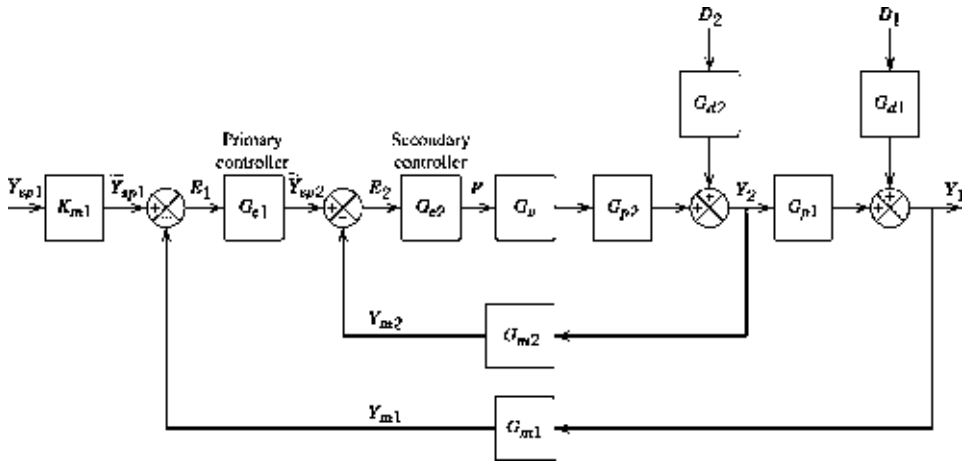

**FIG. 8-31** Block diagram of the cascade control system.

use of chromatographic analysis. The presence of a time delay in a process severely limits the performance of a conventional PID control system, reducing the stability margin of the closed-loop control system. Consequently, the controller gain must be reduced below that which could be used for a process without delay. Thus, the response of the closed-loop system will be sluggish compared to that of the system with no time delay.

To improve the performance of time-delay systems, special control algorithms have been developed to provide time-delay compensation. The Smith predictor technique is the best-known algorithm; a related method is called the *analytical predictor*. Various investigators have found that, based on integral squared error, the performance of the Smith predictor can be better than that for a conventional controller, as long as the time delay is known accurately.

**Selective and Override Control** When there are more controlled variables than manipulated variables, a common solution to this problem is to use a selector to choose the appropriate process variable from among a number of available measurements. Selectors can be based on multiple measurement points, multiple final control elements, or multiple controllers, as discussed below. Selectors are used to improve the control system performance as well as to protect equipment from unsafe operating conditions.

One type of selector device chooses as its output signal the highest (or lowest) of two or more input signals. This approach is often referred to as *auctioneering*. On instrumentation diagrams, the symbol > denotes a high selector and < a low selector. For example, a high selector can be used to determine the hot-spot temperature in a fixed-bed chemical reactor. In this case, the output from the high selector is the input to the temperature controller. In an exothermic catalytic reaction, the process may run away due to disturbances or changes in the reactor. Immediate action should be taken to prevent a dangerous rise in temperature. Because a hot spot may potentially develop at one of several possible locations in the reactor, multiple (redundant) measurement points should be employed. This approach minimizes the time required to identify when a temperature has risen too high at some point in the bed.

The use of high or low limits for process variables is another type of selective control, called an *override*. The feature of antireset windup in feedback controllers is a type of override. Another example is a distillation column with lower and upper limits on the heat input to the column reboiler. The minimum level ensures that liquid will remain on the trays, while the upper limit is determined by the onset of flooding. Overrides are also used in forced-draft combustion control systems to prevent an imbalance between airflow and fuel flow, which could result in unsafe operating conditions.

Other types of selective systems employ multiple final control elements or multiple controllers. In some applications, several manipulated variables are used to control a single process variable (also called *split-range control*). Typical examples include the adjustment of both inflow and outflow from a chemical reactor to control reactor pressure or the use of both acid and base to control pH in wastewater treatment. In this approach, the selector chooses among several controller outputs which final control element should be adjusted.

**Split-Range Control** Split-range control is a common strategy for processes that must operate over a wide range of conditions. A batch reactor, for example, may need to be heated up from ambient temperature to a higher temperature, yet may need to be cooled once the exothermic reaction is initiated. A split-range controller allows both heating and cooling fluids to be admitted to the heat-transfer jacket, as shown in Fig. 8-32. This diagram illustrates the combination of cascade control (the output of the reactor temperature controller is the set point to the jacket temperature controller) and split-range control, where the jacket temperature controller output opens both the hot and cold glycol valves. The cold glycol valve is fully open at 0 percent controller output and fully closed at 50 percent controller output; similarly, the hot glycol valve is fully closed at 50 percent controller output (and below) and fully open at 100 percent controller output, as shown in Fig. 8-33. Notice that the cold glycol valve fails open while the hot glycol valve fails closed. Another common application of split-range control is pH control, where both control valves on both acid and base streams may be used to regulate pH.

**Adaptive Control** Process control problems inevitably require online tuning of the controller constants to achieve a satisfactory degree of control. If the process operating conditions or the environment changes significantly, the controller may have to be retuned. If these changes occur quite frequently, then adaptive control techniques should be considered. An *adaptive control system* is one in which the controller parameters are adjusted automatically to compensate for changing process conditions.

The subject of adaptive control is one of current interest. New algorithms continue to be developed, but these need to be field-tested before industrial acceptance can be expected. An adaptive controller is inherently nonlinear

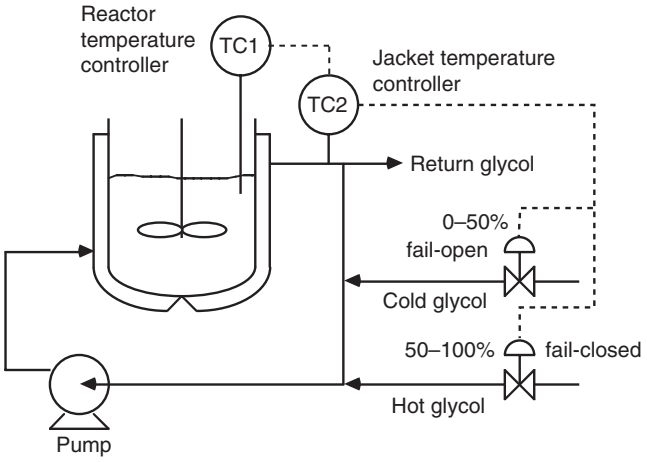

**FIG. 8-32** Batch reactor temperature control. The jacket temperature controller has a split-range output, where the cold glycol valve is open during "cooling mode" and the hot glycol valve is open during "heating mode." (*Source:* Bequette, *Process Control: Modeling, Design and Simulation*, 2d ed., Prentice-Hall, Upper Saddle River, N.J., 2017.)

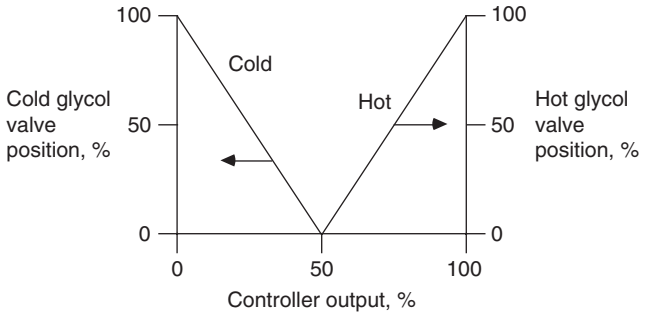

**FIG. 8-33** Depiction of the split-range controller action. (*Source:* Bequette, *Process Control: Modeling, Design and Simulation*, 2d ed., Prentice-Hall, Upper Saddle River, N.J., 2017.)

and therefore more complicated than the conventional PID controller. One type of adaptive controller uses gain scheduling, where different controller settings are used for different operating conditions.

**Fuzzy Logic Control** The application of fuzzy logic to process control requires the concepts of fuzzy rules and fuzzy inference. A fuzzy rule, also known as a fuzzy IF-THEN statement, has the form

If $x$ then $y$

if input1 = high

and input2 = low

then output = medium

Three functions are required to perform logical inferencing with fuzzy rules. The fuzzy AND is the product of a rule's input membership values, generating a weight for the rule's output. The fuzzy OR is a normalized sum of the weights assigned to each rule that contributes to a particular decision. The third function used is *defuzzification*, which generates a crisp final output. In one approach, the crisp output is the weighted average of the peak element values.

With a single feedback control architecture, information that is readily available to the algorithm includes the error signal, difference between the process variable and the set-point variable, change in error from previous cycles to the current cycle, changes to the set-point variable, change of the manipulated variable from cycle to cycle, and change in the process variable from past to present. In addition, multiple combinations of the system response data are available. As long as the irregularity lies in that dimension wherein fuzzy decisions are being based or associated, the result should be enhanced performance. This enhanced performance should be demonstrated in both the transient and steady-state response. If the system tends to have changing dynamic characteristics or exhibits nonlinearities, fuzzy logic control should offer a better alternative to using constant PID settings. Most fuzzy logic software begins building its information base during the autotune function. In fact, the majority of the information used in the early stages of system start-up comes from the autotune solutions.

In addition to single-loop process controllers, products that have benefited from the implementation of fuzzy logic are camcorders, elevators, antilock braking systems, and televisions with automatic color, brightness, and sound control. Sometimes fuzzy logic controllers are combined with pattern recognition software such as artificial neural networks (Jantzen, *Foundations of Fuzzy Control*, Wiley, New York, 2007; Blevins, Wojsznis, and Nixon, *Advanced Control Foundation: Tools Techniques and Applications*, International Society of Automation, Research Triangle Park, N.C., 2013).

## EXPERT SYSTEMS

An *expert system* is a computer program that uses an expert's knowledge in a particular domain to solve a narrowly focused, complex problem. An offline system uses information entered manually and produces results in visual form to guide the user in solving the problem at hand. An online system uses information taken directly from process measurements to perform tasks automatically or instruct or alert operating personnel to the status of the plant.

Each expert system has a rule base created by the expert to respond as the expert would to sets of input information. Expert systems used for plant diagnostics and management usually have an open rule base, which can be changed and augmented as more experience accumulates and more tasks are automated. The "expert" in this case would be the person or persons having the deepest knowledge about the process, its problems, its symptoms, and remedies. Converting these inputs to meaningful outputs is the principal task in constructing a rule base. First-principles models (deep knowledge) produce the most accurate results, although heuristics are always required to establish limits. Often modeling tools such as artificial neural nets are used to develop relationships among the process variables.

A number of process control vendors offer comprehensive, object-oriented software environments for building and deploying expert systems. Advantages of such software include transforming complex real-time data to useful information through knowledge-based reasoning and analysis, monitoring for potential problems before they adversely impact operations, diagnosing root causes of time-critical problems to speed up resolution, and recommending or taking corrective actions to help ensure successful recovery.

## MULTIVARIABLE AND MULTILOOP CONTROL

**GENERAL REFERENCES:** Shinskey, *Process Control Systems*, 4th ed., McGraw-Hill, New York, 1996. Seborg, Edgar, Mellichamp, and Doyle, *Process Dynamics and Control*, 4th ed., Wiley, New York, 2016. McAvoy, *Interaction Analysis*, ISA, Research Triangle Park, N.C., 1983.

Process control books and journal articles tend to emphasize problems with a single controlled variable. In contrast, many processes require multivariable control with many process variables to be controlled. In fact, for virtually any important industrial process, at least two variables must be controlled: product quality and throughput. In this section, strategies for multivariable control are considered.

Three examples of simple multivariable control systems are shown in Fig. 8-34. The in-line blending system blends pure components $A$ and $B$ to produce a product stream with flow rate $w$ and mass fraction of $A$ denoted by $x$. Adjusting either inlet flow rate $w_A$ or $w_B$ affects both of the controlled variables $w$ and $x$. For the pH neutralization process in Fig. 8-34*b*, liquid level $h$ and exit stream pH are to be controlled by adjusting the acid and base flow rates $w_A$ and $w_B$. Each of the manipulated variables affects both of the controlled variables. Thus, both the blending system and the pH neutralization process are said to exhibit strong process interactions. In contrast, the process interactions for the gas-liquid separator in Fig. 8-34*c* are not as strong because one manipulated variable, liquid flow rate $L$, has only a small and indirect effect on one of the controlled variables, pressure $P$.

Strong process interactions can cause serious problems if a conventional multiloop feedback control scheme (e.g., either PI or PID controllers) is employed. The process interactions can produce undesirable control loop interactions where the controllers fight one another. Also, it may be difficult to determine the best pairing of controlled and manipulated variables. For example, in the in-line blending process in Fig. 8-34*a*, should $w$ be controlled with $w_A$ and $x$ with $w_B$, or vice versa?

**Control Strategies for Multivariable Control Problems** If a conventional multiloop control strategy performs poorly because of control loop interactions, a number of solutions are available:

1. Detune one or more of the control loops.
2. Choose different controlled or manipulated variables (or their pairings).
3. Use a multivariable control scheme (e.g., model predictive control).

Detuning a controller (e.g., using a smaller controller gain or a larger reset time) tends to reduce control loop interactions by sacrificing the performance for the detuned loops. This approach may be acceptable if some of the controlled variables are faster or less important than others.

The selection of controlled and manipulated variables is of crucial importance in designing a control system. In particular, a judicious choice may significantly reduce control loop interactions. For the blending process in Fig. 8-34*a*, a straightforward control strategy would be to control $x$ by adjusting $w_A$, and $w$ by adjusting $w_B$. But physical intuition suggests that it would be better to control $x$ by adjusting the ratio $w_A/(w_A + w_B)$ and to control product flow rate $w$ by the sum $w_A + w_B$. Thus, the new manipulated variables would be $U_1 = w_A/(w_A + w_B)$ and $U_2 = w_A + w_B$. In this control scheme, $U_1$ affects only $x$, and $U_2$ affects only $w$. Thus, the control loop interactions have been eliminated. Similarly, for the pH neutralization process in Fig. 8-34*b*, the control loop interactions would be greatly reduced if pH were controlled by $U_1 = w_A/(w_A + w_B)$ and liquid level $h$ were controlled by $U_2 = w_A + w_B$.

**Pairing of Controlled and Manipulated Variables** A key decision in multiloop control system design is the pairing of manipulated and controlled variables. Suppose there are $N$ controlled variables and $N$ manipulated variables. Then $N!$ distinct single-loop control configurations exist. For example, if $N = 5$, then there are 120 different multiloop control schemes. In practice, many would be rejected based on physical insight or previous experience. But a smaller number (say, 5 to 15) may appear to be feasible, and further analysis would be warranted. Thus, it is very useful to have a simple method for choosing the most promising control configuration.

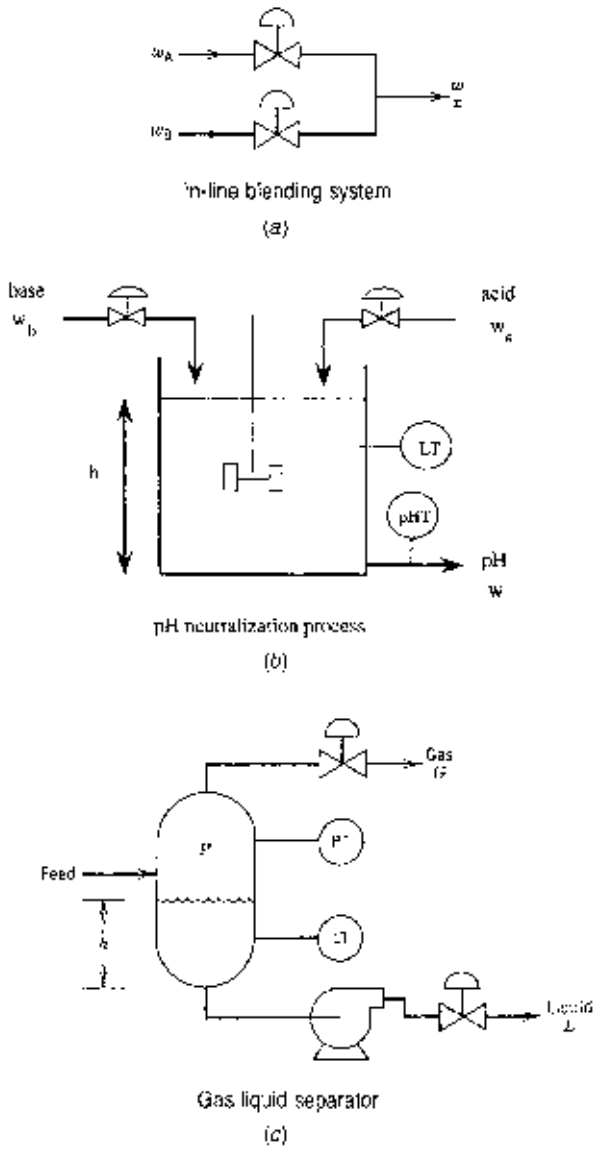

**FIG. 8-34** Physical examples of multivariable control problems.

The most popular and widely used technique for determining the best controller pairing is the *relative gain array* (RGA) method [Bristol, "On a New Measure of Process Interaction," *IEEE Trans. Auto. Control* **AC-11:** 133 (1966)]. The RGA method provides two important items of information:

1. A measure of the degree of process interactions between the manipulated and controlled variables
2. A recommended controller pairing

An important advantage of the RGA method is that it requires minimal process information, namely, steady-state gains. Another advantage is that the results are independent of both the physical units used and the scaling of the process variables. The chief disadvantage of the RGA method is that it neglects process dynamics, which can be an important factor in the pairing decision. Thus, the RGA analysis should be supplemented with an evaluation of process dynamics via simulation. Although extensions of the RGA method that incorporate process dynamics have been reported, these extensions have not been widely applied.

**RGA Method for 2 × 2 Control Problems** To illustrate the use of the RGA method, consider a control problem with two inputs and two outputs. The more general case of $N \times N$ control problems is considered elsewhere (McAvoy, *Interaction Analysis*, ISA, Research Triangle Park, N.C., 1983). As a starting point, it is assumed that a linear, steady-state process model in Eqs. (8-25) and (8-26) is available, where $U_1$ and $U_2$ are steady-state values of the manipulated inputs; $Y_1$ and $Y_2$ are steady-state values of the controlled outputs; and the $K$ values are steady-state gains. The $Y$ and $U$ variables are deviation variables from nominal steady-state values. This process model could be obtained in a variety of ways, such as by linearizing a theoretical model or by calculating steady-state gains from experimental data or a steady-state simulation.

$$Y_1 = K_{11}U_1 + K_{12}U_2 \tag{8-25}$$

$$Y_2 = K_{21}U_1 + K_{22}U_2 \tag{8-26}$$

By definition, the relative gain $\lambda_{ij}$ between the $i$th manipulated variable and the $j$th controlled variable is defined as

$$\lambda_{ij} = \frac{\text{open-loop gain between } Y_i \text{ and } U_j}{\text{closed-loop gain between } Y_i \text{ and } U_j} \tag{8-27}$$

where the open-loop gain is simply $K_{ij}$ from Eqs. (8-25) and (8-26). The *closed-loop gain* is defined to be the steady-state gain between $U_j$ and $Y_i$ when the other control loop is closed and no offset occurs in the other controlled variable due to the presence of integral control action. The RGA for the $2 \times 2$ process is denoted by

$$\Lambda = \begin{bmatrix} \lambda_{11} & \lambda_{12} \\ \lambda_{21} & \lambda_{22} \end{bmatrix} \tag{8-28}$$

The RGA has the important normalization property that the sum of the elements in each row and each column is exactly 1. Consequently, the RGA in Eq. (8-28) can be written as

$$\Lambda = \begin{bmatrix} \lambda & 1-\lambda \\ 1-\lambda & \lambda \end{bmatrix} \tag{8-29}$$

where $\lambda$ can be calculated from the following formula:

$$\lambda = \frac{1}{1 - K_{12}K_{21}/(K_{11}K_{22})} \tag{8-30}$$

Ideally, the relative gains that correspond to the proposed controller pairing should have a value of 1 because Eq. (8-27) implies that the open- and closed-loop gains are then identical. If a relative gain equals 1, the steady-state operation of this loop will not be affected when the other control loop is changed from manual to automatic, or vice versa. Consequently, the recommendation for the best controller pairing is to pair the controlled and manipulated variables so that the corresponding relative gains are positive and close to 1.

**RGA Example** To illustrate use of the RGA method, consider the following steady-state version of a transfer function model for a pilot-scale, methanol-water distillation column [Wood and Berry, "Terminal Composition Control of a Binary Distillation Column," *Chem. Eng. Sci.* **28:** 1707 (1973)]: $K_{11} = 12.8$, $K_{12} = -18.9$, $K_{21} = 6.6$, and $K_{22} = -19.4$. It follows that $\lambda = 2$ and

$$\Lambda = \begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix} \tag{8-31}$$

Thus it is concluded that the column is fairly interacting and the recommended controller pairing is to pair $Y_1$ with $U_1$ and $Y_2$ with $U_2$.

## MODEL PREDICTIVE CONTROL

**General References:** Qin and Badgwell, *Control Eng. Practice* **11:** 773 (2003). Camacho and Bordons, *Model Predictive Control*, 2d ed., Springer-Verlag, New York, 2004. The model-based control strategy that has been most widely applied in the process industries is *model predictive control* (MPC). It is a general method that is especially well suited for difficult multi-input, multi-output (MIMO) control problems where there are significant interactions between the manipulated inputs and the controlled outputs. Unlike other model-based control strategies, MPC can easily accommodate inequality constraints on input and output variables such as upper and lower limits and rate-of-change limits.

A key feature of MPC is that future process behavior is predicted by using a dynamic model and available measurements. The controller outputs are calculated to minimize the difference between the predicted process response and the desired response. At each sampling instant, the control calculations

are repeated and the predictions updated based on current measurements. In typical industrial applications, the set point and target values for the MPC calculations are updated by using online optimization based on a steady-state model of the process.

The current widespread interest in MPC techniques was initiated by pioneering research performed by two industrial groups in the 1970s. Shell Oil (Houston, Tex.) reported its Dynamic Matrix Control (DMC) approach in 1979, while a similar technique, marketed as IDCOM, was published by a small French company ADERSA in 1978. Since then, there have been thousands of applications of these and related MPC techniques in oil refineries and petrochemical plants around the world. Thus, MPC has had a substantial impact and is currently the method of choice for difficult multivariable control problems in these industries. However, relatively few applications have been reported in other process industries, even though MPC is a very general approach that is not limited to a particular industry.

**Advantages and Disadvantages of MPC** Model predictive control offers a number of important advantages in comparison with conventional multiloop PID control:

1. It is a general control strategy for MIMO processes with inequality constraints on input and output variables.
2. It can easily accommodate difficult or unusual dynamic behavior such as large time delays and inverse responses.
3. Because the control calculations are based on optimizing control system performance, MPC can be readily integrated with online optimization strategies to optimize plant performance.
4. The control strategy can be easily updated online to compensate for changes in process conditions, constraints, or performance criteria.

But current versions of MPC have significant disadvantages in comparison with conventional multiloop control:

1. The MPC strategy is very different from conventional multiloop control strategies and thus initially unfamiliar to plant personnel.
2. The MPC calculations can be relatively complicated [e.g., solving a linear programming (LP) or quadratic programming (QP) problem at each sampling instant] and thus require a significant amount of computer resources and effort. These optimization strategies are described in the next section.
3. The development of a dynamic model from plant data is time-consuming, typically requiring days, or even weeks, of around-the-clock plant tests.
4. Because empirical models are generally used, they are valid only over the range of conditions considered during the plant tests.
5. MPC can perform poorly for some types of process disturbances, especially when the additive output disturbance assumption of DMC is used.

Because MPC has been widely used and has had considerable impact, there is a broad consensus that its advantages far outweigh its disadvantages.

**Economic Incentives for Automation Projects** Industrial applications of advanced process control strategies such as MPC are motivated by the need for improvements regarding safety, product quality, environmental standards, and economic operation of the process. One view of the economic incentives for advanced automation techniques is illustrated in Fig. 8-35.

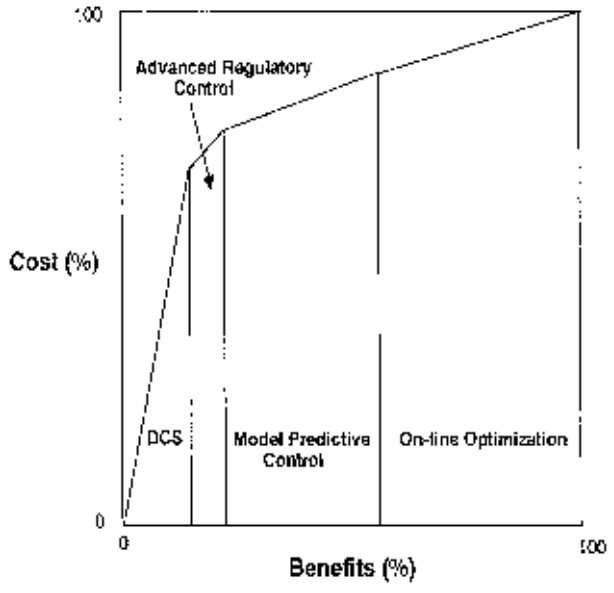

**FIG. 8-35** Economic incentives for automation projects in the process industries.

Distributed control systems (DCSs) are widely used for data acquisition and conventional single-loop (PID) control. The addition of advanced regulatory control systems such as selective controls, gain scheduling, and time-delay compensation can provide benefits for a modest incremental cost. But experience has indicated that the major benefits can be obtained for relatively small incremental costs through a combination of MPC and online optimization. The results in Fig. 8-35 are shown qualitatively, rather than quantitatively, because the actual costs and benefits are application-dependent.

A key reason why MPC has become a major commercial and technical success is that there are numerous vendors who are licensed to market MPC products and install them on a turnkey basis. Consequently, even medium-size companies are able to take advantage of this new technology. Payout times of 3 to 12 months have been widely reported.

**Basic Features of MPC** Model predictive control strategies have a number of distinguishing features:

1. A dynamic model of the process is used to predict the future outputs over a prediction *horizon* consisting of the next $P$ sampling periods.
2. A reference trajectory is used to represent the desired output response over the prediction horizon.
3. Inequality constraints on the input and output variables can be included as an option.
4. At each sampling instant, a control policy consisting of the next $M$ control moves is calculated. The control calculations are based on minimizing a quadratic or linear performance index over the prediction horizon while satisfying the constraints.
5. The performance index is expressed in terms of future control moves and the predicted deviations from the reference trajectory.
6. A *receding horizon approach* is employed. At each sampling instant, only the first control move (of the $M$ moves that were calculated) is actually implemented.
7. Then the predictions and control calculations are repeated at the next sampling instant.

These distinguishing features of MPC will now be described in greater detail.

***Dynamic Model*** A key feature of MPC is that a dynamic model of the process is used to predict future values of the controlled outputs. There is considerable flexibility concerning the choice of the dynamic model. For example, a physical model based on first principles (e.g., mass and energy balances) or an empirical model developed from data could be employed. Also, the empirical model could be a linear model (e.g., transfer function, step response model, or state space model) or a nonlinear model (e.g., neural net model). However, most industrial applications of MPC have relied on linear empirical models, which may include simple nonlinear transformations of process variables.

The original formulations of MPC (i.e., DMC and IDCOM) were based on empirical linear models expressed in either step response or impulse response form. For simplicity, we consider only a single-input, single-output (SISO) model. However, the SISO model can be easily generalized to the MIMO models that are used in industrial applications. The step response model relating a single controlled variable $y$ and a single manipulated variable $u$ can be expressed as

$$\hat{y}(k+1) = y_0 + \sum_{i=1}^{N-1} S_i \Delta u(k-i+1) + S_N u(k-N+1) \tag{8-32}$$

where $\hat{y}(k+1)$ is the predicted value of $y$ at the $k+1$ sampling instant, $u(k)$ is the value of the manipulated input at time $k$, and the model parameters $S_i$ are referred to as the *step response coefficients*. The initial value $y_0$ is assumed to be known. The change in the manipulated input from one sampling instant to the next is denoted by

$$\Delta u(k) = u(k) - u(k-1) \tag{8-33}$$

The step response model is also referred to as a *discrete convolution model*, which is quite different from the first-order plus time delay model used for PID controller design.

In principle, the step response coefficients can be determined from the output response to a step change in the input. A typical response to a unit step change in input $u$ is shown in Fig. 8-36. The step response coefficients $S_i$ are simply the values of the output variable at the sampling instants, after the initial value $y_0$ has been subtracted. Theoretically, they can be determined from a single step response, but, in practice, a number of "bump tests" are required to compensate for unanticipated disturbances, process nonlinearities, and noisy measurements.

***Horizons*** Step and impulse response models typically contain a large number of parameters because the model horizon $N$ is usually quite large ($30 < N < 120$). In fact, these models are often referred to as *nonparametric models*.

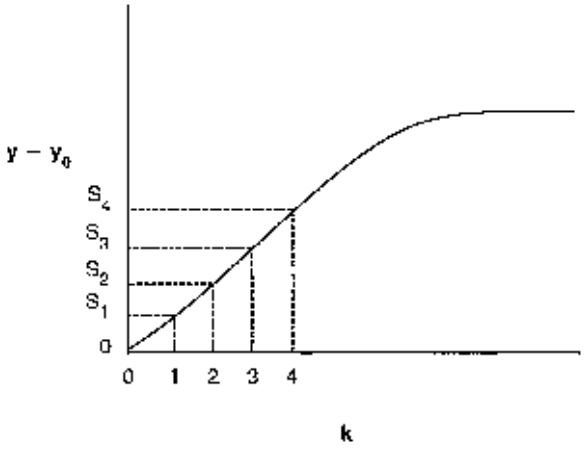

**FIG. 8-36** Step response for a unit step change in the input.

The receding horizon feature of MPC is shown in the top portion of Fig. 8-37 with the current sampling instant denoted by $k$. Past and present input signals $[u(i)$ for $i \le k]$ are used to predict the output at the next $P$ sampling instants $[y(k+i)$ for $i = 1, 2, \ldots, P]$. The control calculations are performed to generate an $M$-step control policy $[u(k), u(k+1), \ldots, u(k+M-1)]$, which optimizes a performance index. The first control action $u(k)$ is implemented. Then at the next sampling instant $k+1$, illustrated in the bottom portion of Fig. 8-37, the new measurement is compared with the model predicted output, the model is updated to account for this difference, and the prediction and control calculations are repeated in order to determine $u(k+1)$. Note that one of the key steps is compensating for the plant-model mismatch before the optimization problem is solved at step $k+1$. In the original DMC formulation, a simple additive bias term was used, but this can lead to poor input disturbance rejection performance. See Muske and Badgwell ["Disturbance Modeling for Offset-Free Linear Model Predictive Control," *J. Proc. Control* **12**(5): 617–632 (2003)] for a more detailed discussion of how to improve disturbance rejection by using MPC. In Fig. 8-37 the reference trajectory (or target) is considered to be constant. Other possibilities include a gradual or step set-point change that can be generated by online optimization.

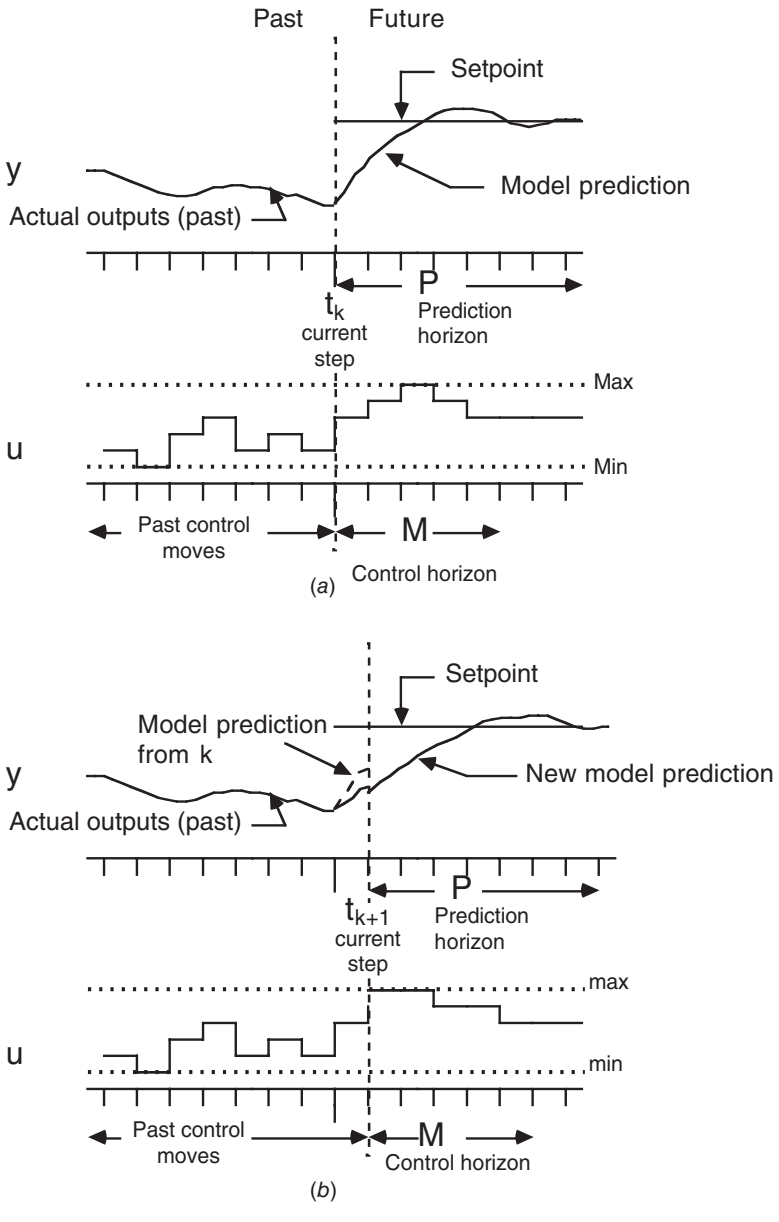

**FIG. 8-37** Basic concept of model predictive control. (*a*) Top. Current and future control moves solved at time step $k$. (*b*) Bottom. After first control move is implemented at time step $k$, a new measurement is obtained and a new problem is solved at step $k+1$.

***Performance Index*** The performance index for MPC applications is usually a linear or quadratic function of the predicted errors and calculated future control moves. For example, the following quadratic performance index has been widely used:

$$\min_{\Delta\mathbf{u}(k)} \; J = \sum_{i=1}^{P} Q_i e^2(k+i) + \sum_{i=1}^{M} R_i \, \Delta u^2(k+i-1) \tag{8-34}$$

where $e(k + i)$ is the predicted error from the set point and $\Delta\mathbf{u}(k)$ denotes the column vector of current and future control moves over the next $M$ sampling instants:

$$\Delta\mathbf{u}(k) = [\Delta u(k), \Delta u(k+1), \ldots, \Delta u(k+M-1)]^T \tag{8-35}$$

Equation (8-34) contains two types of design parameters that can also be used for tuning purposes. Weighting factor $R_i$ penalizes large control moves, while weighting factor $Q_i$ allows the predicted errors to be weighed differently at each time step, if desired.

***Inequality Constraints*** Inequality constraints on the future inputs or their rates of change are widely used in the MPC calculations. For example, if both upper and lower limits are required, the constraints could be expressed as

$$u^-(k) \le u(k+j) \le u^+(k) \qquad \text{for } j = 0, 1, \ldots, M-1 \tag{8-36}$$

$$\Delta u^-(k) \le \Delta u(k+j) \le \Delta u^+(k) \qquad \text{for } j = 0, 1, \ldots, M-1 \tag{8-37}$$

where $B_i$ and $C_i$ are constants. Constraints on the predicted outputs $\hat{y}(k+j)$ are sometimes included as well:

$$y^-(k) \le \hat{y}(k+j) \le y^+(k) \qquad \text{for } j = 0, 1, \ldots, P \tag{8-38}$$

It is possible that including output constraints will result in an infeasible solution, so any practical algorithm must relax the constraints until the solution becomes feasible. The minimization of the quadratic performance index in Eq. (8-34), subject to the constraints in Eqs. (8-36) to (8-38) and the step response model in Eq. (8-32), can be solved by efficient QP (quadratic programming) techniques. When the inequality constraints in Eqs. (8-36) to (8-38) are omitted, the optimization problem has an analytical solution (Camacho and Bordons, *Model Predictive Control*, 2d ed., Springer-Verlag, New York, 2004; Maciejowski, *Predictive Control with Constraints*, Prentice-Hall, Upper Saddle River, N.J., 2002). If the quadratic terms in Eq. (8-34) are replaced by linear terms, an LP (linear programming) problem results that can also be solved by using standard optimization methods. This MPC formulation for SISO control problems can easily be extended to MIMO problems.

**Implementation Issues** For a new MPC application, a cost/benefit analysis is usually performed prior to project approval. Then the steps involved in the implementation of MPC can be summarized as follows [Hokanson and Gerstle, "Dynamic Matrix Control Multivariable Controllers," in Luyben (ed.), *Practical Distillation Control*, Van Nostrand Reinhold, New York, 1992, p. 248; Qin and Badgwell, *Control Eng. Practice* **11:** 773 (2003)].

***Step 1 Initial Controller Design*** The first step in MPC design is to select the controlled, manipulated, and measured disturbance variables. These choices determine the structure of the MPC system and should be based on process knowledge and control objectives. In typical applications the number of controlled variables ranges from 5 to 40, and the number of manipulated variables is typically between 5 and 20.

***Step 2 Pretest Activity*** During the pretest activity, the plant instrumentation is checked to ensure that it is working properly and to decide whether additional sensors should be installed. The pretest data can be used to estimate the steady-state gain and approximate settling times for each input/output pair. This information is used to plan the full plant tests of step 3.

As part of the pretest, it is desirable to benchmark the performance of the existing control system for later comparison with MPC performance (step 8).

***Step 3 Plant Tests*** The dynamic model for the MPC calculations is developed from data collected during special plant tests. The excitation for the plant tests usually consists of changing an input variable or a disturbance variable (if possible) from one value to another, using either a series of step changes with different durations or a pseudorandom binary sequence (PRBS). To ensure that sufficient data are obtained for model identification, each input variable is typically moved to a new value, 8 to 15 times during a plant test [Qin and Badgwell, *Control Eng. Practice* **11:** 773 (2003)]. Identification during closed-loop operation is becoming more common.

***Step 4 Model Development*** The dynamic model is developed from the plant test data by selecting a model form (e.g., a step response model) and then estimating the model parameters. However, first it is important to eliminate periods of test data where plant upsets or other abnormal situations have occurred. Decisions to omit portions of the test data are based on visual inspection of the data, knowledge of the process, and experience. Parameter estimation is usually based on least-squares estimation.

***Step 5 Control System Design and Simulation*** The preliminary control system design from step 1 is critically evaluated and modified, if necessary. Then the MPC design parameters are selected including the sampling periods, weighting factors, and control and prediction horizons. Next, the closed-loop system is simulated, and the MPC design parameters are adjusted, if necessary, to obtain satisfactory control system performance and robustness over the specified range of operating conditions.

***Step 6 Operator Interface Design and Operator Training*** Operator training is important because MPC concepts such as predictive control, multivariable interactions, and constraint handling are very different from conventional regulatory control concepts. Thus, understanding why the MPC system responds as it does, especially for unusual operating conditions, can be a challenge for both operators and engineers.

***Step 7 Installation and Commissioning*** After an MPC control system is installed, first it is evaluated in a "prediction mode." Model predictions are compared with measurements, but the process continues to be controlled by the existing control system. After the output predictions are judged to be satisfactory, the calculated MPC control moves are evaluated to determine if they are reasonable. Finally, the MPC software is evaluated during closed-loop operation with the calculated control moves implemented as set points to the DCS control loops. The MPC design parameters are tuned, if necessary. The commissioning period typically requires some troubleshooting and can take as long as, or even longer than, the plant tests of step 3.

***Step 8 Measuring Results and Monitoring Performance*** The evaluation of MPC system performance is not easy, and widely accepted metrics and monitoring strategies are not available. However, useful diagnostic information is provided by basic statistics such as the means and standard deviations for both measured variables and calculated quantities, such as control errors and model residuals. Another useful statistic is the relative amount of time that an input is saturated or a constraint is violated, expressed as a percentage of the total time the MPC system is in service.

**Integration of MPC and Online Optimization** As indicated in Fig. 8-35, significant potential benefits can be realized by using a combination of MPC and online optimization. At present, most commercial MPC packages integrate the two methodologies in a hierarchical configuration such as the one shown in Fig. 8-38. The MPC calculations are performed quite often (e.g., every 1 to 10 min) and implemented as set points for PID control loops at the DCS level. The targets and constraints for the MPC calculations are generated by solving a steady-state optimization problem (LP or QP) based on a linear process model. These calculations may be performed as often as the MPC calculations. As an option, the targets and constraints for the LP or QP optimization can be generated from a nonlinear process model using a nonlinear optimization technique. These calculations tend to be performed less frequently (e.g., every 1 to 24 h) due to the complexity of the calculations and the process models.

The combination of MPC and frequent online optimization has been successfully applied in oil refineries and petrochemical plants around the world.

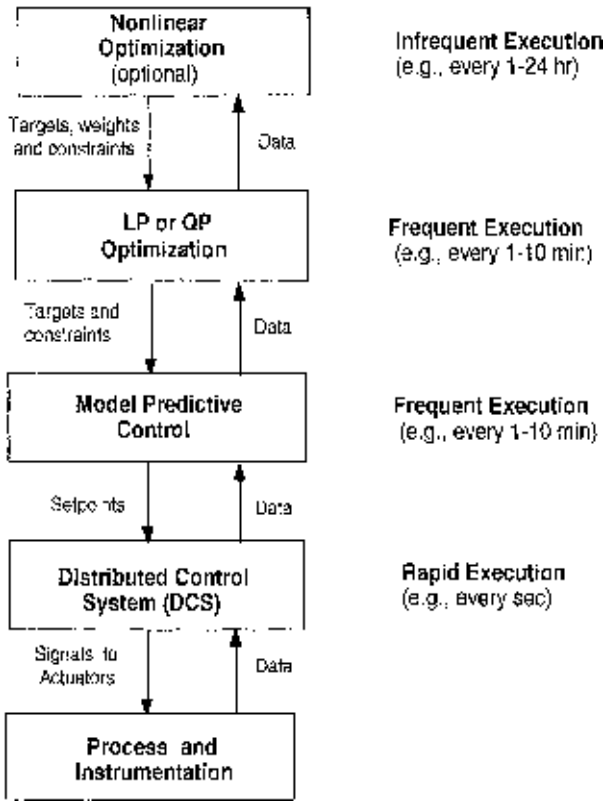

**FIG. 8-38** Hierarchical control configuration for MPC and online optimization.

The chemical industry has undergone significant changes during the past 20 years due to the increased cost of energy and raw materials, more stringent environmental regulations, and intense worldwide competition. Modifications of both plant design procedures and plant operating conditions have been implemented to reduce costs and meet constraints. One of the most important engineering tools that can be employed in such activities is optimization. As plant computers have become more powerful, the size and complexity of problems that can be solved by optimization techniques have correspondingly expanded. A wide variety of problems in the operation and analysis of chemical plants (as well as many other industrial processes) can be solved by optimization. Real-time optimization means that the process operating conditions (set points) are evaluated on a regular basis and optimized, as shown earlier in level 4 in Fig. 8-22. Sometimes this is called *steady-state optimization* or *supervisory control.* This subsection examines the basic characteristics of optimization problems and their solution techniques and describes some representative benefits and applications in the chemical and petroleum industries.

Typical problems in chemical engineering process design or plant operation have many possible solutions. Optimization is concerned with selecting the best among the entire set of solutions by efficient quantitative methods. Computers and associated software make the computations involved in the selection manageable and cost-effective. Engineers work to improve the initial design of equipment and strive for enhancements in the operation of the equipment once it is installed in order to realize the greatest production, the greatest profit, the maximum cost, the least energy usage, and so on. In plant operations, benefits arise from improved plant performance, such as improved yields of valuable products (or reduced yields of contaminants), reduced energy consumption, higher processing rates, and longer times between shutdowns. Optimization can also lead to reduced maintenance costs, less equipment wear, and better staff utilization. It is helpful to systematically identify the objectives, constraints, and degrees of freedom in a process or a plant if such benefits as improved quality of designs, faster and more reliable troubleshooting, and faster decision making are to be achieved.

Optimization can take place at many levels in a company, ranging from a complex combination of plants and distribution facilities down through individual plants, combinations of units, individual pieces of equipment, subsystems in a piece of equipment, or even smaller entities. Problems that can be solved by optimization can be found at all these levels.

While process design and equipment specification are usually performed prior to the implementation of the process, optimization of operating conditions is carried out monthly, weekly, daily, hourly, or even every minute. Optimization of plant operations determines the set points for each unit at the temperatures, pressures, and flow rates that are the best in some sense. For example, the selection of the percentage of excess air in a process heater is quite critical and involves balancing the fuel/air ratio to ensure complete combustion and at the same time making maximum use of the heating potential of the fuel. Typical day-to-day optimization in a plant minimizes steam consumption or cooling water consumption, optimizes the reflux ratio in a distillation column, or allocates raw materials on an economic basis.

A *real-time optimization* (RTO) system determines set-point changes and implements them via the computer control system without intervention from unit operators. The RTO system completes all data transfer, optimization calculations, and set-point implementation before unit conditions change that may invalidate the computed optimum. In addition, the RTO system should perform all tasks without upsetting plant operations. Several steps are necessary for implementation of RTO, including determination of the plant steady state, data gathering and validation, updating of model parameters (if necessary) to match current operations, calculation of the new (optimized) set points, and the implementation of these set points.

To determine if a process unit is at steady state, a program monitors key plant measurements (e.g., compositions, product rates, feed rates, and so on) and determines if the plant is close enough to steady state to start the sequence. Only when all the key measurements are within the allowable tolerances is the plant considered steady and the optimization sequence started. Tolerances for each measurement can be tuned separately. Measured data are then collected by the optimization computer. The optimization system runs a program to screen the measurements for unreasonable data (gross error detection). This validity checking automatically modifies the model updating calculation to reflect any bad data or when equipment is taken out of service. Data validation and reconciliation (online or offline) is an extremely critical part of any optimization system.

The optimization system then may run a parameter-fitting case that updates model parameters to match current plant operation. The integrated process model calculates such items as exchanger heat-transfer coefficients, reactor performance parameters, furnace efficiencies, and heat and material balances for the entire plant. Parameter fitting allows for continual updating of the model to account for plant deviations and degradation of process equipment. After completion of the parameter fitting, the information regarding the current plant constraints, control status data, and economic values for feed products, utilities, and other operating costs is collected. The economic values are updated by the planning and scheduling department on a regular basis. The optimization system then calculates the optimized set points. The steady-state condition of the plant is rechecked after the optimization case is successfully completed. If the plant is still steady, then the values of the optimization targets are transferred to the process control system for implementation. After a line-out period, the process control computer resumes the steady-state detection calculations, restarting the cycle.

**Essential Features of Optimization Problems** The solution of optimization problems involves the use of various tools of mathematics, which is discussed in detail in Sec. 3. The formulation of an optimization problem requires the use of mathematical expressions. From a practical viewpoint, it is important to mesh properly the problem statement with the anticipated solution technique. Every optimization problem contains three essential categories:

1. An objective function to be optimized (revenue function, cost function, etc.)
2. Equality constraints (equations)
3. Inequality constraints (inequalities)

Categories 2 and 3 comprise the model of the process or equipment; category 1 is sometimes called the *economic model.*

No single method or algorithm of optimization exists that can be applied efficiently to all problems. The method chosen for any particular case will depend primarily on (1) the character of the objective function, (2) the nature of the constraints, and (3) the number of independent and dependent variables. Table 8-5 summarizes the six general steps for the analysis and solution of optimization problems (Edgar, Himmelblau, and Lasdon, *Optimization of Chemical Processes*, 2d ed., McGraw-Hill, New York, 2001). You do not have to follow the cited order exactly, but you should cover all the steps at some level of detail. Shortcuts in the procedure are allowable, and the easy steps can be performed first. Steps 1, 2, and 3 deal with the mathematical definition of the problem: identification of variables, specification of the objective function, and statement of the constraints. If the process to be optimized is very complex, it may be necessary to reformulate the problem so that it can be solved with reasonable effort. Later in

**TABLE 8-5 Six Steps Used to Solve Optimization Problems**

1. Analyze the process itself so that the process variables and specific characteristics of interest are defined (i.e., make a list of all the variables).
2. Determine the criterion for optimization, and specify the objective function in terms of the above variables together with coefficients. This step provides the performance model (sometimes called the economic model, when appropriate).
3. Develop via mathematical expressions a valid process or equipment model that relates the input/output variables of the process and associated coefficients. Include both equality and inequality constraints. Use well-known physical principles (mass balances, energy balances), empirical relations, implicit concepts, and external restrictions. Identify the independent and dependent variables (number of degrees of freedom).
4. If the problem formulation is too large in scope, (*a*) break it up into manageable parts and/or (*b*) simplify the objective function and model.
5. Apply a suitable optimization technique to the mathematical statement of the problem.
6. Check the answers and examine the sensitivity of the result to changes in the coefficients in the problem and the assumptions.

this section, we discuss the development of mathematical models for the process and the objective function (the economic model) in typical RTO applications.

Step 5 in Table 8-5 involves the computation of the optimum point. Quite a few techniques exist to obtain the optimal solution for a problem. We describe several classes of methods below. Over the past 15 years, substantial progress has been made in developing efficient and robust computational methods for optimization. Much is known about which methods are most successful. Virtually all numerical optimization methods involve iteration, and the effectiveness of a given technique can depend on a good first guess for the values of the variables at the optimal solution. After the optimum is computed, a sensitivity analysis for the objective function value should be performed to determine the effects of errors or uncertainty in the objective function, mathematical model, or other constraints.

**Development of Process (Mathematical) Models** Constraints in optimization problems arise from physical bounds on the variables, empirical relations, physical laws, and so on. The mathematical relations describing the process also comprise constraints. Two general categories of models exist:

1. Those based on physical theory
2. Those based on strictly empirical descriptions

Mathematical models based on physical and chemical laws (e.g., mass and energy balances, thermodynamics, chemical reaction kinetics) are frequently employed in optimization applications. These models are conceptually attractive because a general model for any system size can be developed before the system is constructed. On the other hand, an empirical model can be devised that simply correlates input/output data without any physiochemical analysis of the process. For these models, optimization is often used to fit a model to process data, using parameter estimation. One example is the yield matrix, where the percentage yield of each product in a unit operation is estimated for each feed component by using process data rather than employing a mechanistic set of chemical reactions.

**Formulation of the Objective Function** The formulation of objective functions is one of the crucial steps in the application of optimization to a practical problem. You must be able to translate the desired objective to mathematical terms. In the chemical process industries, the objective function often is expressed in units of currency per unit time (e.g., U.S. dollars per week, month, or year) because the normal industrial goal is to minimize costs or maximize profits subject to a variety of constraints.

A typical economic model involves the costs of raw materials, values of products, and costs of production as functions of operating conditions, projected sales figures, and the like. An objective function can be expressed in terms of these quantities; e.g., annual operating profit ($/yr) might be expressed as

$$J = \sum_s F_s V_s - \sum_r F_r C_r - \text{OC} \tag{8-39}$$

where $J$ = profit/time

$\sum_s F_s V_s$ = sum of product flow rates times respective product values (income)

$\sum_r F_r C_r$ = sum of feed flows times respective unit costs

OC = operating costs/time

**Unconstrained Optimization** *Unconstrained optimization* refers to the case where no inequality constraints are present and all equality constraints can be eliminated by solving for selected dependent variables followed by substitution for them in the objective function. Very few realistic problems in process optimization are unconstrained. However, the availability of efficient unconstrained optimization techniques is important because these techniques must be applied in real time, and iterative calculations may require excessive computer time. Two classes of unconstrained techniques are single-variable optimization and multivariable optimization.

**Single-Variable Optimization** Many real-time optimization problems can be reduced to the variation of a single-variable optimization so as to maximize profit or some other overall process objective function. Some examples of single-variable optimization include optimizing the reflux ratio in a distillation column or the air/fuel ratio in a furnace. While most processes actually are multivariable processes with several operating degrees of freedom, often we choose to optimize only the most important variable in order to keep the strategy uncomplicated. One characteristic implicitly required in a single-variable optimization problem is that the objective function $J$ be unimodal in variable $x$.

There are three classes of techniques that can be used efficiently for one-dimensional search: indirect, region elimination, and interpolation.

Indirect methods seek to solve the necessary condition $dJ/dx = 0$ by iteration, but these methods are not as popular as the second two classes. Region elimination methods include equal interval search, dichotomous search (or bisecting), Fibonacci search, and golden section. These methods do not use information on the shape of the function (other than its being unimodal) and thus tend to be rather conservative. The third class of techniques uses repeated polynomial fitting to predict the optimum. These interpolation methods tend to converge rapidly to the optimum without being very complicated. Two interpolation methods—quadratic and cubic interpolation—are used in many optimization packages.

**Multivariable Optimization** The numerical optimization of general nonlinear multivariable objective functions requires that efficient and robust techniques be employed. Efficiency is important since iteration is employed. For example, in multivariable "grid" search for a problem with four independent variables, an equally spaced grid for each variable is prescribed. For 10 values of each of the four variables, $10^4$ total function evaluations would be required to find the best answer for the grid intersections; but this result may not be close enough to the true optimum and would require further search. A larger number of variables (say, 20) would require exponentially more computation, so grid search is a very inefficient method for most problems.

In multivariable optimization, the difficulty of dealing with multivariable functions is usually resolved by treating the problem as a series of one-dimensional searches. For a given starting point, a search direction $s$ is specified, and the optimum is found by searching along that direction. The step size $\varepsilon$ is the distance moved along $s$. Then a new search direction is determined, followed by another one-dimensional search. The algorithm used to specify the search direction depends on the optimization method selected.

There are two basic types of unconstrained optimization algorithms: (1) those requiring function derivatives and (2) those that do not. Here we give only an overview and refer the reader to Sec. 3 or the references for more details. The nonderivative methods are of interest in optimization applications because these methods can be readily adapted to the case in which experiments are carried out directly on the process. In such cases, an actual process measurement (such as yield) can be the objective function, and no mathematical model for the process is required. Methods that do not require derivatives are called *direct methods* and include sequential simplex (Nelder-Meade) and Powell's method. The sequential simplex method is quite satisfactory for optimization with two or three independent variables, is simple to understand, and is fairly easy to execute. Powell's method is more efficient than the simplex method and is based on the concept of conjugate search directions. This class of methods can be used in special cases but is not recommended for optimization involving more than 6 to 10 variables.

The second class of multivariable optimization techniques in principle requires the use of partial derivatives of the objective function, although finite difference formulas can be substituted for derivatives. Such techniques are called *indirect methods* and include the following classes:

1. Steepest descent (gradient) method
2. Conjugate gradient (Fletcher-Reeves) method
3. Newton's method
4. Quasi-Newton methods

The steepest descent method is quite old and utilizes the intuitive concept of moving in the direction in which the objective function changes the most. However, it is clearly not as efficient as the other three. Conjugate gradient utilizes only first-derivative information, as does steepest descent, but generates improved search directions. Newton's method requires second-derivative information but is very efficient, while quasi-Newton retains most

of the benefits of Newton's method but utilizes only first-derivative information. All these techniques are also used with constrained optimization.

**Constrained Optimization** When constraints exist and cannot be eliminated in an optimization problem, more general methods must be employed than those described above, because the unconstrained optimum may correspond to unrealistic values of the operating variables. The general form of a nonlinear programming problem allows for a nonlinear objective function and nonlinear constraints, or

$$\begin{aligned} &\text{Minimize} && J(x_1, x_2, \ldots, x_n) \\ &\text{Subject to} && h_i(x_1, x_2, \ldots, x_n) = 0 \qquad i = 1, r_c \\ & && g_i(x_1, x_2, \ldots, x_n) > 0 \qquad i = 1, m_c \end{aligned} \tag{8-40}$$

In this case, there are $n$ process variables with $r_c$ equality constraints and $m_c$ inequality constraints. Such problems pose a serious challenge to performing optimization calculations in a reasonable amount of time. Typical constraints in chemical process optimization include operating conditions (temperatures, pressures, and flows have limits), storage capacities, and product purity specifications.

An important class of constrained optimization problems is one in which both the objective function and the constraints are linear. The solution of these problems is highly structured and can be obtained rapidly. The accepted procedure, linear programming (LP), has become quite popular in the past 20 years, solving a wide range of industrial problems. It is increasingly being used for online optimization. For processing plants, there are several different kinds of linear constraints that may arise, making the LP method of great utility.

1. Production limitation due to equipment throughput restrictions, storage limits, or market constraints.
2. Raw material ( feedstock) limitation.
3. Safety restrictions on allowable operating temperatures and pressures.
4. Physical property specifications placed on the composition of the final product. For blends of various products, we usually assume that a composite property can be calculated through the mass-averaging of pure-component physical properties.
5. Material and energy balances of the steady-state model.

The optimum in linear programming lies at the constraint intersections. The simplex algorithm is a matrix-based numerical procedure for which many digital computer codes exist (Edgar, Himmelblau, and Lasdon, *Optimization of Chemical Processes*, 2d ed., McGraw-Hill, New York, 2001; Nash and Sofer, *Linear and Nonlinear Programming*, McGraw-Hill, New York, 1996). The algorithm can handle virtually any number of inequality constraints and any number of variables in the objective function, and it utilizes the observation that only the constraint boundaries need to be examined to find the optimum. In some instances, nonlinear optimization problems even with nonlinear constraints can be linearized so that the LP algorithm can be employed to solve them (called *successive linear programming*, or SLP). In the process industries, LP and SLP have been applied to a wide range of RTO problems, including refinery scheduling, olefins production, the optimal allocation of boiler fuel, and the optimization of a total plant.

Figure 8-39 gives an overview of which optimization algorithms are appropriate for certain types of RTO problems. No single NLP algorithm is best for every problem, so several solvers should be tested on a given application. See Biegler, *Nonlinear Programming: Concepts*, *Algorithms*, *and Applications to Chemical Process*es, MPS-SIAM Series on Optimization, Philadelphia, Pa., 2010.

**Nonlinear Programming** The most general case for optimization in Fig. 8-39 occurs when both the objective function and the constraints are nonlinear, a case referred to as nonlinear programming. While the ideas behind the search methods used for unconstrained multivariable problems are applicable, the presence of constraints complicates the solution procedure. All the methods discussed below have been utilized to solve nonlinear programming problems in the field of chemical engineering design and operations. Nonlinear programming is now used extensively in the area of real-time optimization.

A good overview of nonlinear programming is contained in Sec. 3 in this text. One popular NLP algorithm called the *generalized reduced gradient* (GRG) algorithm employs iterative linearization and is used in the Excel Solver. The CONOPT software package uses a reduced gradient algorithm that works well for large-scale problems and nonlinear constraints. Successive quadratic programming (SQP) solves a sequence of quadratic programs that approach the solution of the original NLP by linearizing the constraints and using a quadratic approximation to the objective function, which is used in MATLAB's constrained optimizer ( fmincon). MINOS and NPSOL are SQP-based software packages originally developed in the 1980s. For large-scale NLPs, IPOPT is an interior point line search with barrier functions that is very effective (Biegler, *Nonlinear Programming: Concepts*, *Algorithms*, *and Applications to Chemical Process*es, SIAM, Philadelphia, Pa., 2010). Successive linear programming (SLP) is used less often for solving RTO problems and requires linear approximations of both the objective function and constraints.

Software libraries such as GAMS (General Algebraic Modeling System) or NAG (Numerical Algorithms Group) offer one or more NLP algorithms, but rarely are all algorithms available from a single source. Web sources that serve as comprehensive repositories of optimization packages include Optic Toolbox (http://www.i2c2.aut.ac.nz/Wiki/OPTI/), NEOS Server (http://www.neos-server.org/neos/) (Czyzyk et al., University of Wisconsin http://pages.cs.wisc.edu/~swright/PCx/, 2016), and COIN-OR (http://www.coin-or.org/) [Lougee-Heimer, The Common Optimization Interface for Operations Research, *IBM Journal of Research and Development* **47:** 57 (2003); Nocedal and Wright, *Numerical Optimization*, 2d ed., Springer, New York, 2006]. No single NLP algorithm is best for every problem, so several solvers should be tested on a given application.

Other optimization software packages are designed to solve mixed-integer problems (MIPs), with both discrete and continuous variables (MILP, MINLP) and also so-called *global optimization* problems that can converge to a nonconvex optimum. Impressive speed-ups in MIP solution have occurred during the past 20 years. See Biegler, *Nonlinear Programming: Concepts*, *Algorithms*, *and Applications to Chemical Process*es, MPS-SIAM Series on Optimization, Philadelphia, Pa., 2010 for more details.

Linear and nonlinear programming solvers have been interfaced to spreadsheet software, which has become a popular user interface for entering and manipulating numeric data. Spreadsheet software increasingly incorporates analytic tools that are accessible from the spreadsheet interface and permit access to external databases. For example, Microsoft Excel incorporates an optimization-based routine called Solver that operates on the values and formulas of a spreadsheet model. Current versions include LP and NLP solvers and mixed integer programming (MIP) capability for both linear and nonlinear problems. The user specifies a set of cell addresses to be independently adjusted (the decision variables), a set of formula cells whose values are to be constrained (the constraints), and a formula cell designated as the optimization objective.

Referring to Fig. 8-24, the highest level of process control, planning, and scheduling also employs optimization extensively, often with variables that are integer. Level 5 sets production goals to meet supply and logistics constraints and addresses time-varying capacity and workforce utilization decisions. Enterprise resource planning (ERP) and supply chain management (SCM) in level 5 refer to the links in a web of relationships involving retailing (sales), distribution, transportation, and manufacturing. Planning and scheduling usually operate over relatively long time scales and tend to be decoupled from the rest of the activities in lower levels. For example, all the refineries owned by an oil company are usually included in a comprehensive planning and scheduling model. This model can be optimized to obtain target levels and prices for interrefinery transfers, crude oil and product allocations to each refinery, production targets, inventory targets, optimal operating conditions, stream allocations, and blends for each refinery.

Some planning and scheduling problems are mixed integer optimization problems that involve both continuous and integer problems; whether to operate or use a piece of equipment is a binary (on/off) decision that arises in batch processing. Solution techniques for this type of problem include branch and bound methods and global search. This latter approach handles very complex problems with multiple optima by using algorithms such as tabusearch, scatter search, simulated annealing, and genetic evolutionary algorithms (see Edgar, Himmelblau, and Lasdon, *Optimization of Chemical Processes*, 2d ed., McGraw-Hill, New York, 2001).

## STATISTICAL PROCESS CONTROL

In industrial plants, large numbers of process variables must be maintained within specified limits in order for the plant to operate properly. Excursions of key variables beyond these limits can have significant consequences for plant safety, the environment, product quality, and plant profitability. *Statistical process control* (SPC), also called *statistical quality control* (SQC), involves the application of statistical techniques to determine whether a process is operating normally or abnormally. Thus, SPC is a process monitoring technique that relies on *quality control charts* to monitor measured variables, especially product quality.

The basic SPC concepts and control chart methodology were introduced by Shewhart in the 1930s. The current widespread interest in SPC techniques began in the 1950s when they were successfully applied first in Japan and then elsewhere. Control chart methodologies are now widely used to monitor product quality and other variables that are measured infrequently or irregularly. The basic SPC methodology is described in introductory

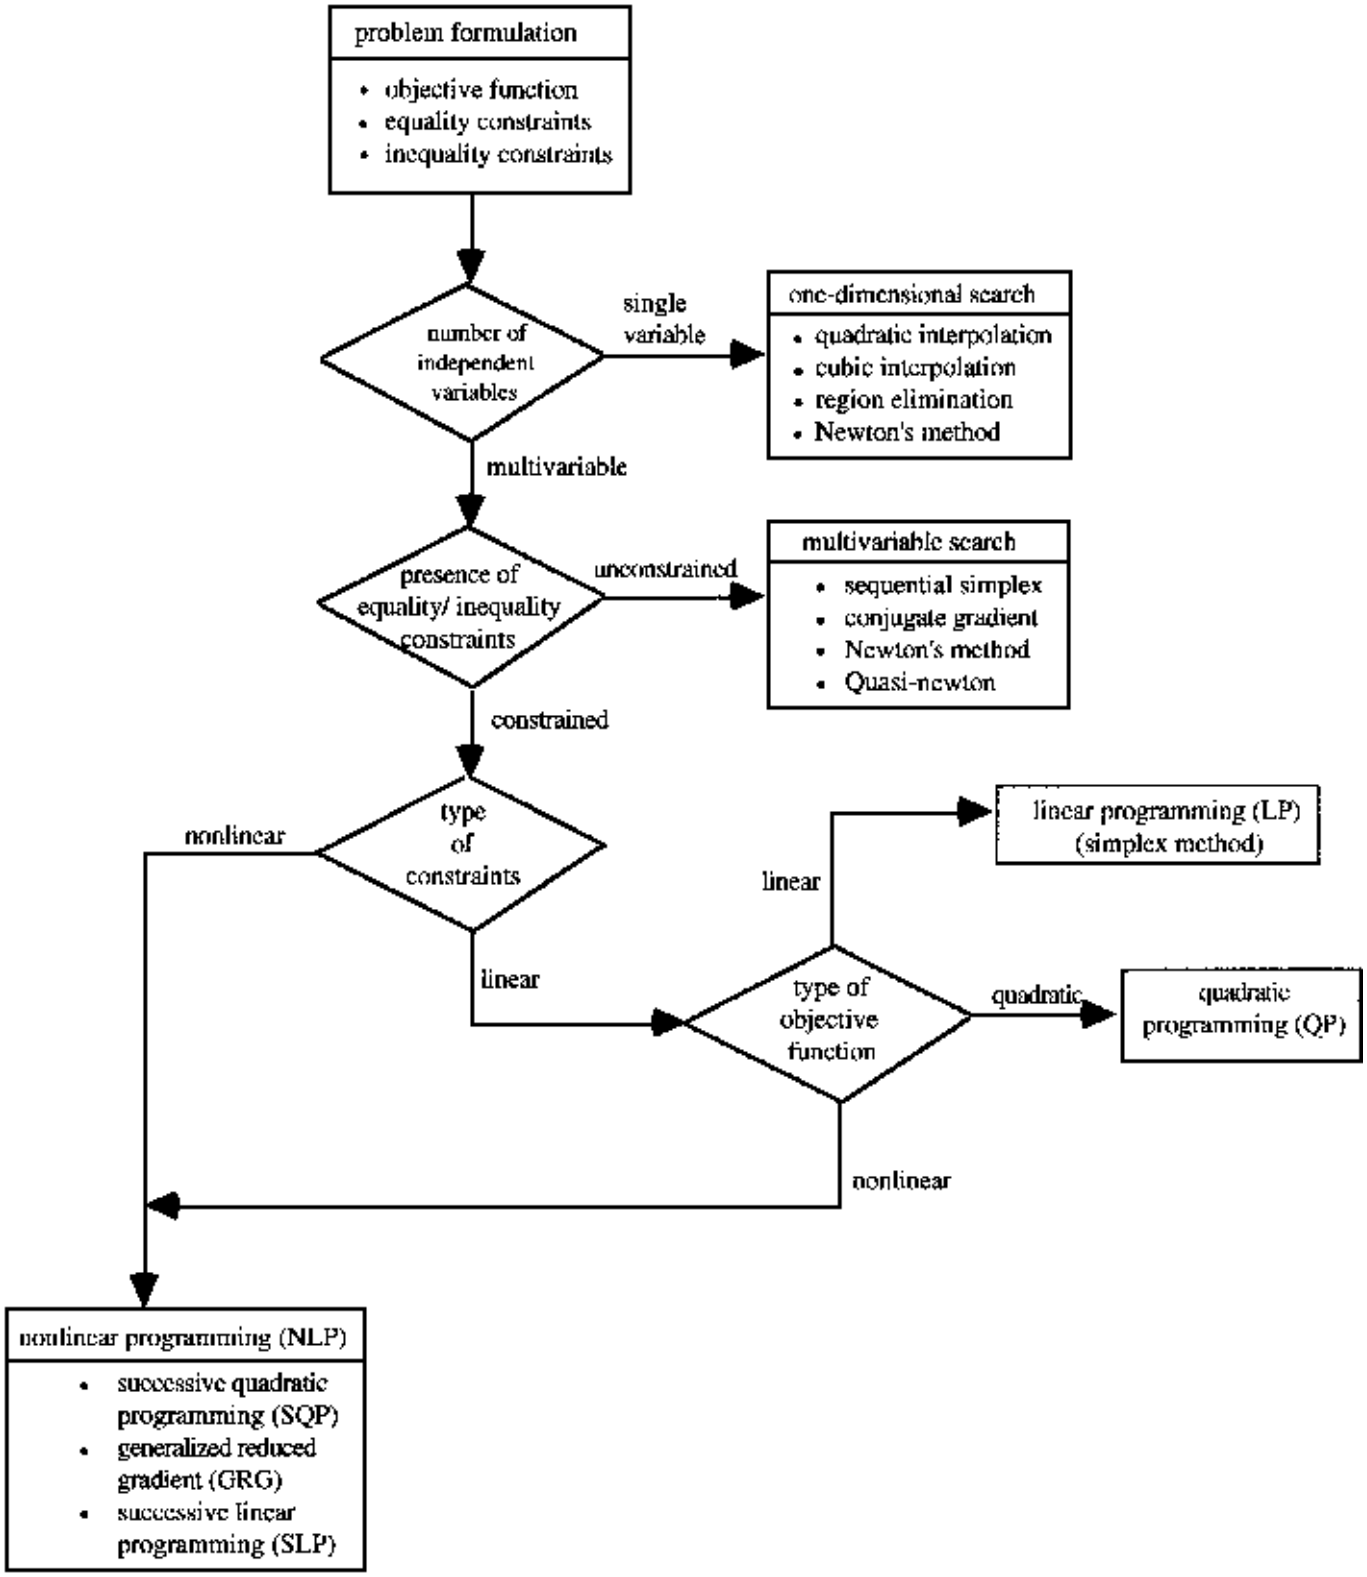

**FIG. 8-39** Diagram for selection of optimization techniques with algebraic constraints and objective function.

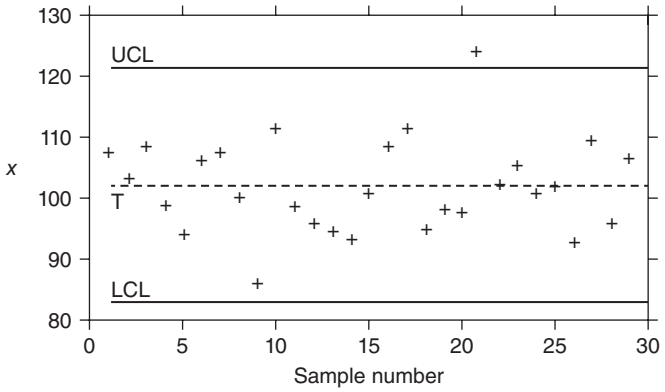

**FIG. 8-40** The Shewhart chart. (*Source:* Seborg et al., *Process Dynamics and Control*, 3d ed., Wiley, New York, 2010.)

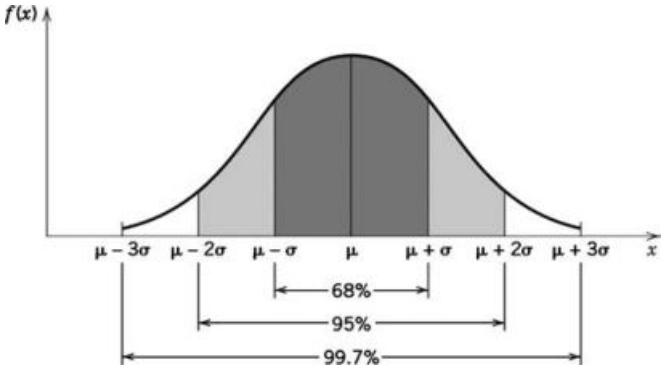

**FIG. 8-41** Probabilities associated with the normal distribution. From Montgomery and Runger (2007). (*Source:* Seborg et al., *Process Dynamics and Control*, 3d ed., Wiley, New York, 2010.)

statistics textbooks (e.g., Montgomery and Runger, *Applied Statistics and Probability for Engineers*, 6th ed., Wiley, New York, 2013) and some process control textbooks (e.g., Seborg, Edgar, Mellichamp, and Doyle, *Process Dynamics and Control*, 4th ed., Wiley, New York, 2016).

An example of the most common control chart, the Shewhart chart, is shown in Fig. 8-40. It merely consists of measurements plotted versus sample number with control limits that indicate the range for normal process operation. The plotted data are either an individual measurement $x$ or the sample mean $\bar{x}$ if more than one sample is measured at each sampling instant. The sample mean for $k$ samples is calculated as

$$\bar{x} = \frac{1}{n}\sum_{j=1}^{n} x_j \tag{8-41}$$

The Shewhart chart in Fig. 8-40 has a *target* ($T$), an *upper control limit* (UCL), and a *lower control limit* (LCL). The target (or centerline) is the desired (or expected) value for $\bar{x}$ while the region between UCL and LCL defines the range of normal variability. If all the $\bar{x}$ data are within the control limits, the process operation is considered to be normal or "in a state of control." Data points outside the control limits are considered to be abnormal, indicating that the process operation is out of control. This situation occurs for the 21st sample. A single measurement slightly beyond a control limit is not necessarily a cause for concern. But frequent or large chart violations should be investigated to determine the root cause.

The major objective in SPC is to use process data and statistical techniques to determine whether the process operation is normal or abnormal. The SPC methodology is based on the fundamental assumption that normal process operation can be characterized by random variations around a mean value. The random variability is caused by the cumulative effects of a number of largely unavoidable phenomena such as electrical measurement noise, turbulence, and random fluctuations in feedstock or catalyst preparation. If this situation exists, the process is said to be *in a state of statistical control* (or *in control*), and the control chart measurements tend to be normally distributed about the mean value. By contrast, frequent control chart violations would indicate abnormal process behavior or an *out-of-control* situation. Then a search would be initiated to attempt to identify the *assignable cause* or the *special cause* of the abnormal behavior.

The control limits in Fig. 8-40 (UCL and LCL) are based on the assumption that the measurements follow a normal distribution. Figure 8-41 shows the probability distribution for a normally distributed random variable $x$ with mean $\mu$ and standard deviation $\sigma$. There is a very high probability (99.7 percent) that any measurement is within 3 standard deviations of the mean. Consequently, the control limits for $x$ are typically chosen to be $T \pm 3\hat{\sigma}$, where $\hat{\sigma}$ is an estimate of $\sigma$. This estimate is usually determined from a set of representative data for a period of time when the process operation is believed to be typical. For the common situation in which the plotted variable is the sample mean, its standard deviation is estimated.

Shewhart control charts enable average process performance to be monitored, as reflected by the sample mean. It is also advantageous to monitor process variability. Process variability within a sample of $k$ measurements can be characterized by its range, standard deviation, or sample variance. Consequently, control charts are often used for one of these three statistics.

**Western Electric Rules** Shewhart control charts can detect abnormal process behavior by comparing individual measurements with control chart limits. In addition, the pattern of measurements can provide useful information. For example, if 10 consecutive measurements are all increasing, then it is very unlikely that the process is in a state of control. A wide variety of *pattern tests* (also called *zone rules*) can be developed based on the properties of the normal distribution. For example, the following excerpts from the *Western Electric Rules* (Western Electric Company, *Statistical Quality Control Handbook*, Delmar Printing Company, Charlotte, N.C., 1956; Montgomery and Runger, *Applied Statistics and Probability for Engineers*, 6th ed., Wiley, New York, 2013) indicate that the process is out of control if one or more of the following conditions occur:

1. One data point outside the $3\sigma$ control limits
2. Two out of three consecutive data points beyond a $2\sigma$ limit
3. Four out of five consecutive data points beyond a $1\sigma$ limit and on one side of the centerline
4. Eight consecutive points on one side of the centerline

Note that the first condition is the familiar Shewhart chart limits. Pattern tests can be used to augment Shewhart charts. This combination enables out-of-control behavior to be detected earlier, but the false-alarm rate is higher than that for Shewhart charts alone.

**CUSUM Control Charts** Although Shewhart charts with $3\sigma$ limits can quickly detect large process changes, they are ineffective for small, sustained process changes (e.g., changes smaller than $1.5\sigma$). Alternative control charts have been developed to detect small changes such as the CUSUM control chart. They are often used in conjunction with Shewhart charts. The *cumulative sum* (CUSUM) is defined to be a running summation of the deviations of the plotted variable from its target. If the sample mean is plotted, the cumulative sum at sampling instant $k$, denoted $C(k)$, is

$$C(k) = \sum_{j=1}^{k} [\bar{x}(j) - T] \tag{8-42}$$

where $T$ is the target for $\bar{x}$. During normal process operation, $C(k)$ fluctuates about zero. But if a process change causes a small shift in $\bar{x}$, then $C(k)$ will drift either upward or downward.

The CUSUM control chart was originally developed using a graphical approach based on *V masks*. However, for computer calculations, it is more convenient to use an equivalent algebraic version that consists of two recursive equations

$$C^+(k) = \max[0, \bar{x}(k) - (T + K) + C^+(k-1)] \tag{8-43}$$

$$C^-(k) = \max[0, (T - K) - \bar{x}(k) + C^-(k-1)] \tag{8-44}$$

where $C^+$ and $C^-$ denote the sums for the high and low directions and $K$ is a constant, the *slack parameter*. The CUSUM calculations are initialized by setting $C^+(0) = C - 0 = 0$. A deviation from the target that is larger than $K$ increases either $C^+$ or $C^-$. A control limit violation occurs when either $C^+$ or $C^-$ exceeds a specified control limit (or *threshold*) $H$. After a limit violation occurs, that sum is reset to zero or to a specified value.

The selection of the threshold $H$ can be based on considerations of *average run length* (ARL), the average number of samples required to detect a disturbance of specified magnitude. For example, suppose that the objective is to be able to detect if the sample mean $\bar{x}$ has shifted from the target by a small amount $\delta$. The slack parameter $K$ is usually specified as $K = 0.5\delta$.

**TABLE 8-6 Average Run Lengths for CUSUM Control Charts**

| Shift from target (in multiples of σ) | ARL for $H = 4\sigma$ | ARL for $H = 5\sigma$ |
|---|---|---|
| 0 | 168. | 465. |
| 0.25 | 74.2 | 139. |
| 0.50 | 26.6 | 38.0 |
| 0.75 | 13.3 | 17.0 |
| 1.00 | 8.38 | 10.4 |
| 2.00 | 3.34 | 4.01 |
| 3.00 | 2.19 | 2.57 |

Adapted from Ryan, *Statistical Methods for Quality Improvement*, 2d ed., Wiley, New York, 2000.

For the ideal situation (e.g., normally distributed, uncorrelated disturbances), ARL values have been tabulated for different values of δ, *K*, and *H*. Table 8-6 summarizes ARL values for two values of *H* and different values of δ. (The values of δ are usually expressed as multiples of the standard deviation σ.) The ARL values indicate the average number of samples before a change of δ is detected. Thus the ARL values for $\delta = 0$ indicate the average time between false alarms, i.e., the average time between successive CUSUM alarms when no shift in $\bar{x}$ has occurred. Ideally, we would like the ARL value to be very large for $\delta = 0$ and small for $\delta \neq 0$. Table 8-6 shows that as the magnitude of the shift δ increases, ARL decreases and thus the CUSUM control chart detects the change faster. Increasing the value of *H* from 4σ to 5σ increases all the ARL values and thus provides a more conservative approach.

The relative performance of the Shewhart and CUSUM control charts is compared in Fig. 8-42 for a set of simulated data for the tensile strength of a resin. It is assumed that the tensile strength *x* is normally distributed with a mean of $\mu = 70$ MPa and a standard deviation of $\sigma = 3$ MPa. A single measurement is available at each sampling instant. A constant ($\delta = 0.5\sigma = 1.5$) was added to $x(k)$ for $k \geq 10$ in order to evaluate each chart's ability to detect a small process shift. The CUSUM chart was designed using $K = 0.5\sigma$ and $H = 5\sigma$.

The Shewhart chart fails to detect the 0.5σ shift in *x* at $k = 10$. But the CUSUM chart quickly detects this change because a limit violation occurs at $k = 20$. The mean shift can also be detected by applying the Western Electric Rules in the previous section.

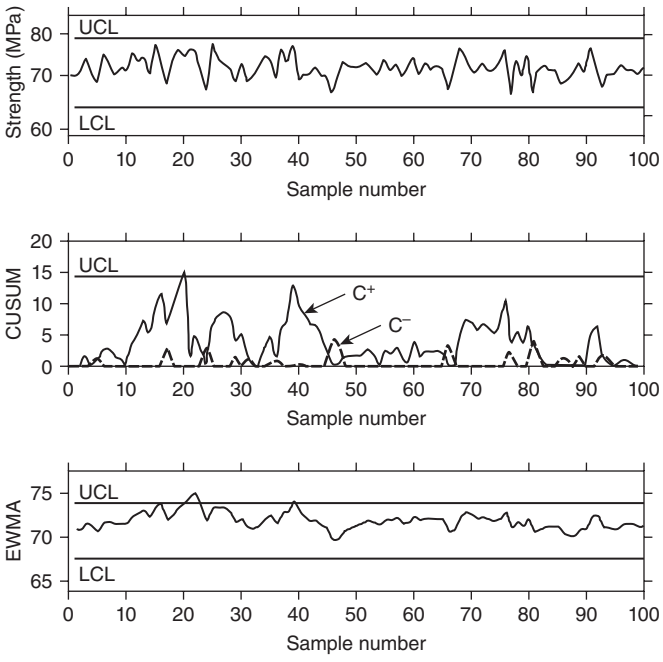

**FIG. 8-42** Comparison of Shewhart (*top*), CUSUM (*middle*), and EWMA (*bottom*) control charts. (*Source:* Seborg et al., *Process Dynamics and Control*, 3d ed., Wiley, New York, 2010.)

**Process Capability Indices** Also known as *process capability ratios*, these provide a measure of whether an in-control process is meeting its product specifications. Suppose that a quality variable *x* must have a value between an *upper specification limit* (USL) and a *lower specification limit* (LSL) in order for product to satisfy customer requirements. The *capability index* $C_p$ is defined as

$$C_p = \frac{\text{USL} - \text{LSL}}{6\sigma} \tag{8-45}$$

where σ is the standard deviation of *x*. Suppose that $C_p = 1$ and *x* is normally distributed. Based on the normal distribution, we would expect that 99.7 percent of the measurements satisfy the specification limits, or equivalently, we would expect that only 2700 out of 1 million measurements would lie outside the specification limits. If $C_p < 1$, the product specifications are satisfied; for $C_p > 1$, they are not. However, capability indices are applicable even when the data are not normally distributed.

A second capability index $C_{pk}$ is based on average process performance $\bar{x}$ as well as process variability σ. It is defined as

$$C_{pk} = \frac{\text{Min}\,[\bar{x} - \text{LSL},\ \text{USL} - \bar{x}]}{3\sigma} \tag{8-46}$$

Although both $C_p$ and $C_{pk}$ are used, we consider $C_{pk}$ to be superior to $C_p$ for the following reason. If $\bar{x} = T$, the process is said to be "centered" and $C_{pk} = C_p$. But for $\bar{x} \neq T$, $C_p$ does not change, even though the process performance is worse, while $C_{pk}$ does decrease. For this reason, $C_{pk}$ is preferred.

If the standard deviation σ is not known, it is replaced by an estimate $\hat{\sigma}$ in Eqs. (8-45) and (8-46). For situations where there is only a single specification limit, either USL or LSL, the definitions of $C_p$ and $C_{pk}$ can be modified accordingly.

In practical applications, a common objective is to have a capability index of 2.0 while a value greater than 1.5 is considered to be acceptable. If the $C_{pk}$ value is too low, it can be improved by making a change that either reduces process variability or causes $\bar{x}$ to move closer to the target. These improvements can be achieved in a number of ways that include better process control, better process maintenance, reduced variability in raw materials, improved operator training, and process changes.

**Six-Sigma Approach** Product quality specifications continue to become more stringent as a result of market demands and intense worldwide competition. Meeting quality requirements is especially difficult for products that consist of a very large number of components and for manufacturing processes that consist of hundreds of individual steps. For example, the production of a microelectronic device typically requires 100 to 300 batch processing steps. Suppose that there are 200 steps and that each one must meet a quality specification for the final product to function properly. If each step is independent of the others and has a 99 percent success rate, the overall yield of satisfactory product is $(0.99)^{200} = 0.134$, or only 13.4 percent. This low yield is clearly unsatisfactory. Similarly, even when a processing step meets 3σ specifications (99.73 percent success rate), it will still result in an average of 2700 "defects" for every 1 million produced. Furthermore, the overall yield for this 200-step process is still only 58.2 percent.

The six-sigma approach was pioneered by the Motorola Corporation in the early 1980s as a strategy for achieving both six-sigma quality and continuous improvement. Since then, other large corporations have adopted companywide programs that apply the six-sigma approach to all their business operations, both manufacturing and nonmanufacturing. Thus, although the six-sigma approach is "data-driven" and based on statistical techniques, it has evolved into a broader management philosophy that has been implemented successfully by many large corporations. The six-sigma programs have also had a significant financial impact.

**Multivariate Statistical Techniques** For common SPC monitoring problems, two or more quality variables are important, and they can be highly correlated. For these situations, multivariable (or *multivariate)* SPC techniques can offer significant advantages over the single-variable methods discussed earlier. Multivariate monitoring based on the classical Hotelling $T^2$ statistic (Montgomery, *Introduction to Statistical Quality Control*, 7th ed., Wiley, New York, 2012) can be effective if the data are not highly correlated and the number of variables *p* is not large ( for example, $p < 10$). Fortunately, alternative multivariate monitoring techniques such as *principal-component analysis* (PCA) and *partial least-squares* (PLS) methods have been developed that are very effective for monitoring problems with large numbers of variables and highly correlated data [Piovoso and Hoo (eds.), Special Issue of *IEEE Control Systems Magazine*, 22(5): 2002].

# UNIT OPERATIONS CONTROL

## PIPING AND INSTRUMENTATION DIAGRAMS

**General References:** Shinskey, *Process Control Systems*, 4th ed., McGraw-Hill, New York, 1996. Luyben, *Practical Distillation Control*, Van Nostrand Reinhold, New York, 1992. Luyben, Tyreus, and Luyben, *Plantwide Process Control*, McGraw-Hill, New York, 1999.

The piping and instrumentation (P&I) diagram provides a graphical representation of the control configuration of the process. P&I diagrams illustrate the measuring devices that provide inputs to the control strategy, the actuators that will implement the results of the control calculations, and the function blocks that provide the control logic. They may also include piping details such as line sizes and the location of hand valves and condensate traps.

The symbology for drawing P&I diagrams generally follows standards developed by the Instrumentation, Systems, and Automation Society (ISA). The chemicals, refining, and food industries generally follow this standard. The standards are updated from time to time, primarily because the continuing evolution in control system hardware and software provides additional capabilities for implementing control schemes. The ISA symbols are simple and represent a device or function as a circle containing its tag number and identifying the type of variable being controlled, e.g., pressure, and the function performed, e.g., control: PC-105. Examples of extensions of the ISA standard appear on the pages following.

Figure 8-43 presents a simplified P&I diagram for a temperature control loop that applies the ISA symbology. The measurement devices and most elements of the control logic are shown as circles:

1. TT102 is the temperature transmitter.
2. TC102 is the temperature controller.
3. TY102 is the current-to-pneumatic (I/P) transducer.

The symbol for the control valve in Fig. 8-43 is for a pneumatic modulating valve without a valve positioner.

Electronic (4- to 20-mA) signals are represented by dashed lines. In Fig. 8-43, these include the signal from the transmitter to the controller and the signal from the controller to the I/P transducer. Pneumatic signals are represented by solid lines with double crosshatching at regular intervals. The signal from the I/P transducer to the valve actuator is pneumatic.

The ISA symbology provides different symbols for different types of actuators. Furthermore, variations for the controller symbol distinguish control algorithms implemented in distributed control systems from those in panel-mounted single-loop controllers.

## CONTROL OF HEAT EXCHANGERS

**Steam-Heated Exchangers** Steam, the most common heating medium, transfers its latent heat in condensing, causing heat flow to be proportional to steam flow. Thus a measurement of steam flow is essentially a measure of heat transfer. Consider raising a liquid from temperature $T_1$ to $T_2$ by condensing steam:

$$Q = WH = M_v C_L (T_2 - T_1) \tag{8-47}$$

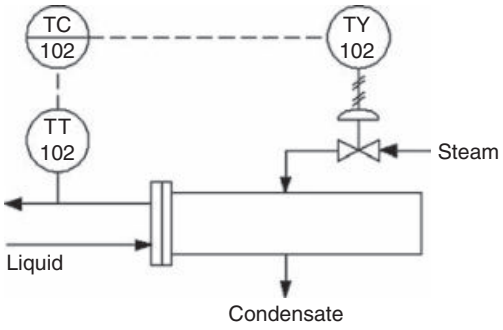

**FIG. 8-43** Example of a simplified piping and instrumentation diagram.

where $W$ and $H$ are the mass flow of steam and its latent heat, $M_v$ and $C_L$ are the mass flow and specific heat of the liquid, and $Q$ is the rate of heat transfer. The response of controlled temperature to steam flow is linear:

$$\frac{dT_2}{dW} = \frac{H}{M_v C_L} \tag{8-48}$$

However, the steady-state process gain described by this derivative varies inversely with liquid flow: adding a given increment of heat flow to a smaller flow of liquid produces a greater temperature rise.

Dynamically, the response of liquid temperature to a step in steam flow is that of a distributed lag, shown in Fig. 8-20 (uncontrolled); the time required to reach 63 percent complete response $\Sigma\tau$ is essentially the residence time of the fluid in the exchanger, which is its volume divided by its flow. The residence time then varies inversely with flow. Table 8-1 gives optimum settings for PI and PID controllers for distributed lags, the proportional band varying directly with steady-state gain, and integral and derivative settings directly with $\Sigma\tau$. Since both these parameters vary inversely with liquid flow, fixed settings for the temperature controller are optimal at only one flow rate.

The variability of the process parameters with flow causes variability in load response, as shown in Fig. 8-44. The PID controller was tuned for optimum (minimum-IAE) load response at 50 percent flow. Each curve represents the response of exit temperature to a 10 percent step in liquid flow, culminating at the stated flow. The 60 percent curve is overdamped, and the 40 percent curve is underdamped. The differences in gain are reflected in the amplitude of the deviation, and the differences in dynamics are reflected in the period of oscillation.

If steam flow is linear with controller output, as it is in Fig. 8-44, undamped oscillations will be produced when the flow decreases by one-third from the value at which the controller was optimally tuned—in this example at 33 percent flow. The stable operating range can be extended to one-half the original flow by using an equal-percentage (logarithmic) steam valve, whose gain varies directly with steam flow, thereby compensating for the variable process gain. Further extension requires increasing the integral setting and reducing the derivative setting from their optimum values. The best solution is to adapt all three PID settings to change inversely with measured flow, thereby keeping the controller optimally tuned for all flow rates.

Feedforward control can also be applied, as described previously under Advanced Control Techniques. The feedforward system solves Eq. (8-78) for the manipulated set point to the steam flow controller, first by subtracting inlet temperature $T_1$ from the output of the outlet temperature controller (in place of $T_2$) and then by multiplying the result by the dynamically compensated liquid flow measurement. If the inlet temperature is not subject to rapid or wide variation, it can be left out of the calculation. Feedforward is capable of a reduction in integrated error as much as 100-fold, but requires the use of a steam flow loop and lead-lag compensator to approach this effectiveness. Multiplication of the controller output by liquid flow varies the feedback loop gain directly proportional to flow, extending the

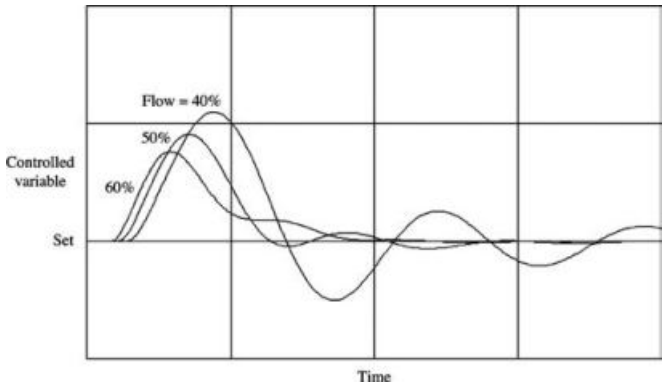

**FIG. 8-44** The response of a heat exchanger varies with flow in both gain and dynamics; here the PID temperature controller was tuned for optimum response at 50 percent flow.

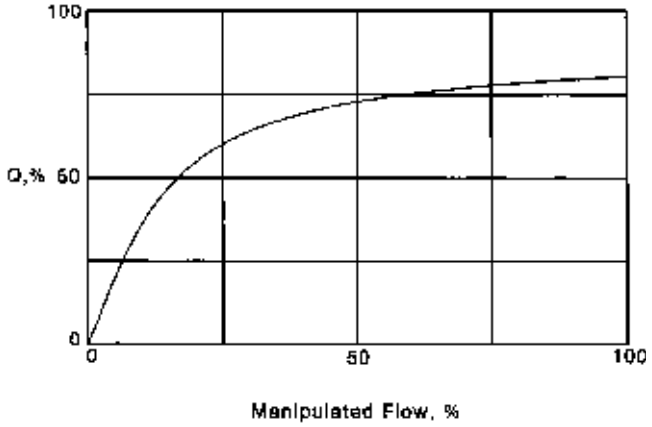

**FIG. 8-45** Heat-transfer rate in sensible-heat exchange varies nonlinearly with flow of the manipulated fluid, requiring equal-percentage valve characterization.

stable operating range of the feedback loop much as the equal-percentage steam valve did without feedforward. (This system is eminently applicable to control of fired heaters in oil refineries, which commonly provide a circulating flow of hot oil to several distillation columns and are therefore subject to frequent disturbances.)

Steam flow is sometimes controlled by manipulating a valve in the condensate line rather than the steam line, because it is smaller and hence less costly. Heat transfer then is changed by raising or lowering the level of condensate flooding the heat-transfer surface, an operation that is slower than manipulating a steam valve. Protection also needs to be provided against an open condensate valve blowing steam into the condensate system.

**Exchange of Sensible Heat** When there is no change in phase, the rate of heat transfer is no longer linear with the flow of the manipulated stream, but is a function of the mean temperature difference $\Delta T_m$:

$$Q = UA\,\Delta T_m = M_H C_H (T_{H1} - T_{H2}) = M_C C_C (T_{C2} - T_{C1}) \tag{8-48}$$

where $U$ and $A$ are the overall heat-transfer coefficient and area and subscripts $H$ and $C$ refer to the hot and cold fluids, respectively. An example would be a countercurrent cooler, where the hot-stream outlet temperature is controlled. Using the logarithmic mean temperature difference and solving for $T_{H2}$ give

$$T_{H2} = T_{c1} + (T_{H1} - T_{c1}) \frac{1 - M_H C_H / M_c C_C}{\varepsilon - M_H C_H / M_c C_C} \tag{8-50}$$

where

$$\varepsilon = \exp\left[ -UA \left( \frac{1}{M_c C_c} - \frac{1}{M_H C_H} \right) \right] \tag{8-51}$$

At a given flow of hot fluid, the heat-transfer rate is plotted as a function of coolant flow in Fig. 8-45, as a percentage of its maximum value (corresponding to $T_{C2} = T_{C1}$). The extreme nonlinearity of this relationship requires the use of an equal-percentage coolant valve for gain compensation. The variable dynamics of the distributed lag also apply, limiting the stable operating range in the same way as for the steam-heated exchanger.

Sensible-heat exchangers are also subject to variations in the temperature of the manipulated stream, an increasingly common problem where heat is being recovered at variable temperatures for reuse. Figure 8-46 shows a temperature controller (TC) setting a heat flow controller (QC) in cascade. A measurement of the manipulated flow is multiplied by its temperature difference across the heat exchanger to calculate the current heat-transfer rate, by using the right side of Eq. (8-47). Variations in supply temperature then appear as variations in calculated heat-transfer rate, which the QC can quickly correct by adjusting the manipulated flow. An equal-percentage valve is still required to linearize the secondary loop, but the primary loop of temperature-setting heat flow is linear. Feedforward can be added by multiplying the dynamically compensated flow measurement of the other fluid by the output of the temperature controller.

When a stream is manipulated whose flow is independently determined, such as the flow of a product or of a heat-transfer fluid from a fired heater, a three-way valve is used to divert the required flow to the heat exchanger. This does not alter the linearity of the process or its sensitivity to supply variations, and it even adds the possibility of independent flow variations. The three-way valve should have equal-percentage characteristics, and heat flow control may be even more beneficial.

## DISTILLATION COLUMN CONTROL

Distillation columns have four or more closed loops—increasing with the number of product streams and their specifications—all of which interact with one another to some extent. Because of this interaction, there are many possible ways to pair manipulated and controlled variables through controllers and other mathematical functions, with widely differing degrees of effectiveness. Columns also differ from one another, so that no single rule of configuring control loops can be applied successfully to all. The following rules apply to the most common separations.

**Controlling Quality of a Single Product** If one of the products of a column is far more valuable than the other(s), its quality should be controlled to satisfy given specifications, and its recovery should be maximized by minimizing losses of its principal component in other streams. This is achieved by maximizing the reflux ratio consistent with flooding limits on trays, which means maximizing the flow of internal reflux or vapor, whichever is limiting. The same rule should be followed when heating and cooling have little value. A typical example is the separation of high-purity propylene from much lower-valued propane, usually achieved with the waste heat of quench water from the cracking reactors.

The most important factor affecting product quality is the material balance. In separating a feed stream $F$ into distillate $D$ and bottom $B$ products, an overall mole flow balance must be maintained

$$F = D + B \tag{8-52}$$

as well as a balance on each component

$$Fz_i = Dy_i + Bx_i \tag{8-53}$$

where $z$, $y$, and $x$ are mole fractions of component $i$ in the respective streams. Combining these equations gives a relationship between the composition of the products and their relative portion of the feed:

$$\frac{D}{F} = 1 - \frac{B}{F} = \frac{z_i - x_i}{y_i - x_i} \tag{8-54}$$

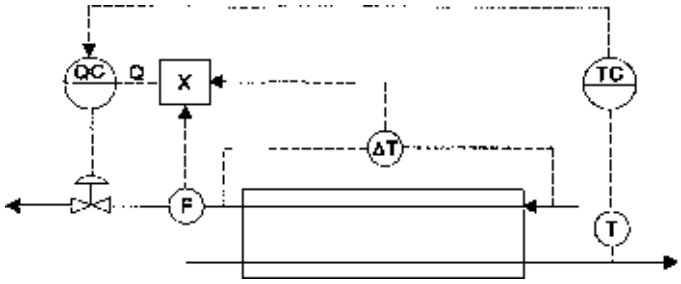

**FIG. 8-46** Manipulating heat flow linearizes the loop and protects against variations in supply temperature.

From the above, it can be seen that control of either $x_i$ or $y_i$ requires both product flow rates to change with feed rate and feed composition.

Figure 8-47 shows a propylene-propane fractionator controlled at maximum boil-up by the differential pressure controller (DPC) across the trays. This loop is fast enough to reject upsets in the temperature of the quench water quite easily. Pressure is controlled by manipulating the heat-transfer surface in the condenser through flooding. If the condenser should become overloaded, pressure will rise above the set point, but this has no significant effect on the other control loops. Temperature measurements on this column are not helpful, as the difference between the component boiling points is too small. Propane content in the propylene distillate is measured by a chromatographic analyzer sampling the overhead vapor for fast response, and it is controlled by the analyzer controller (AC) manipulating the ratio of distillate to feed rates. The feedforward signal from the feed rate is dynamically compensated and nonlinearly characterized to account for variations in propylene recovery as the feed rate changes. Distillate flow can be measured and controlled more accurately than reflux flow by a factor equal to the reflux ratio, which in this column is typically between 10 and 20. Therefore, reflux flow is placed under accumulator level control (LC). Yet composition responds to the difference between internal vapor and reflux flow rates. To eliminate the lag inherent in the response of the accumulator level controller, reflux flow is driven by the subtractor in the direction opposite to distillate flow—this is essential to fast response of the composition loop. The gain of converting distillate flow changes to reflux flow changes can even be increased beyond −1, thereby changing the accumulator level loop from a lag into a dominant lead.

**Controlling Quality of Two Products** Where the two products have similar values, or where heating and cooling costs are comparable to product losses, the compositions of both products should be controlled. This introduces the possibility of strong interaction between the two composition loops, as they tend to have similar speeds of response. Interaction in most columns can be minimized by controlling distillate composition with reflux ratio and bottom composition with boil-up, or preferably boil-up/bottom flow ratio. These loops are insensitive to variations in feed rate, eliminating the need for feedforward control, and they also reject heat balance upsets quite effectively. Figure 8-48 shows a depropanizer controlled by reflux and boil-up ratios. The actual mechanism through which these ratios are manipulated is $D/(L + D)$ and $B/(V + B)$, where $L$ is reflux flow and $V$ is vapor boil-up, which decouples the temperature loops from the liquid-level loops. Column pressure here is controlled by flooding both the condenser and accumulator; however, there is no level controller on the accumulator, so this arrangement will not function with an overloaded condenser. Temperatures are used as indications of composition in this column because of the substantial differences in boiling points between propane and butanes. However, off-key components such as ethane do affect the accuracy of the relationship, so that an analyzer controller is used to set the top temperature controller (TC) in cascade.

If the products from a column are especially pure, even this configuration may produce excessive interaction between the composition loops. Then the composition of the less pure product should be controlled by manipulating its own flow; the composition of the remaining product should be controlled by manipulating the reflux ratio if it is the distillate, or the boil-up ratio if it is the bottom product.

Most sidestream columns have a small flow dedicated to removing an off-key impurity entering the feed, and that stream must be manipulated to control its content in the major product. For example, an ethylene fractionator separates its feed into a high-purity ethylene sidestream, an ethane-rich bottom product, and a small flow of methane overhead. This small flow must be withdrawn to control the methane content in the ethylene product. The key impurities may then be controlled in the same way as in a two-product column.

Most volatile mixtures have a relative volatility that varies inversely with column pressure. Therefore, their separation requires less energy at lower pressure, and savings in the range of 20 to 40 percent have been achieved. Column pressure can be minimized by floating on the condenser, i.e., by operating the condenser with minimal or no restrictions. In some columns, such as the propylene-propane splitter, pressure can be left uncontrolled. Where it cannot, the set point of the pressure controller can be indexed by an integral-only controller acting to slowly drive the pressure control valve toward a position just short of maximum cooling. In the case of a flooded condenser, the degree of reflux subcooling can be controlled in place of the condenser valve position. Where column temperatures are used to indicate product composition, their measurements must be pressure-compensated.

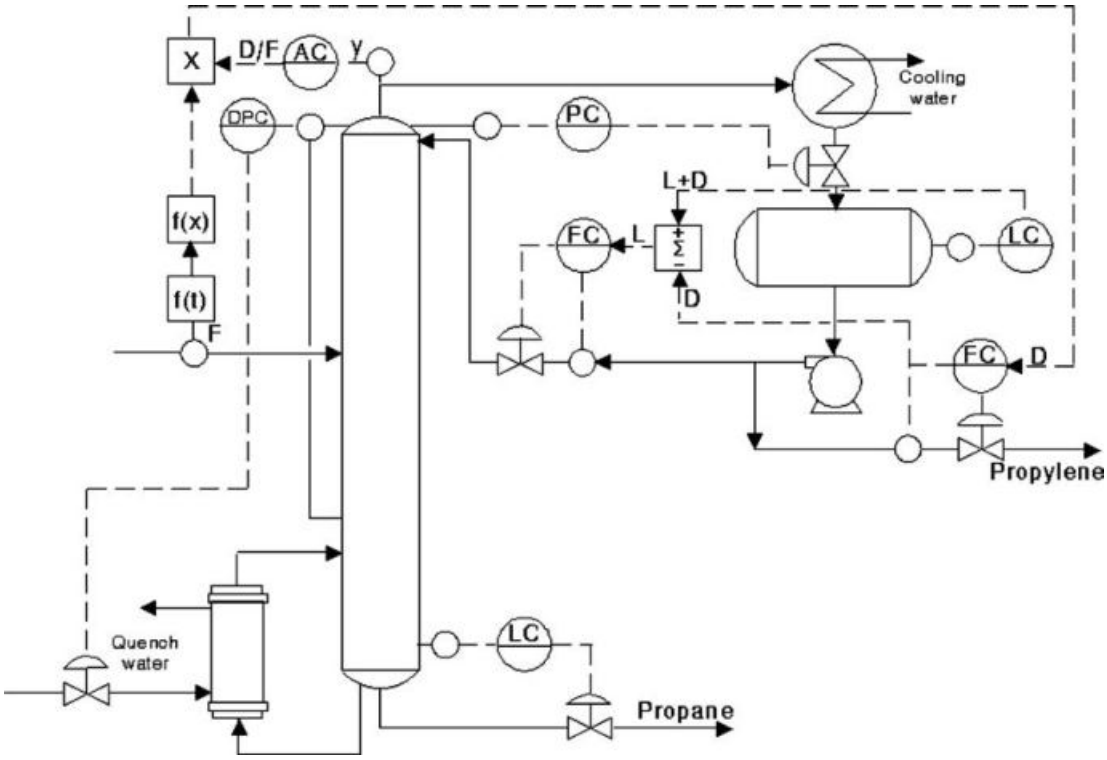

**FIG. 8-47** The quality of high-purity propylene should be controlled by manipulating the material balance.

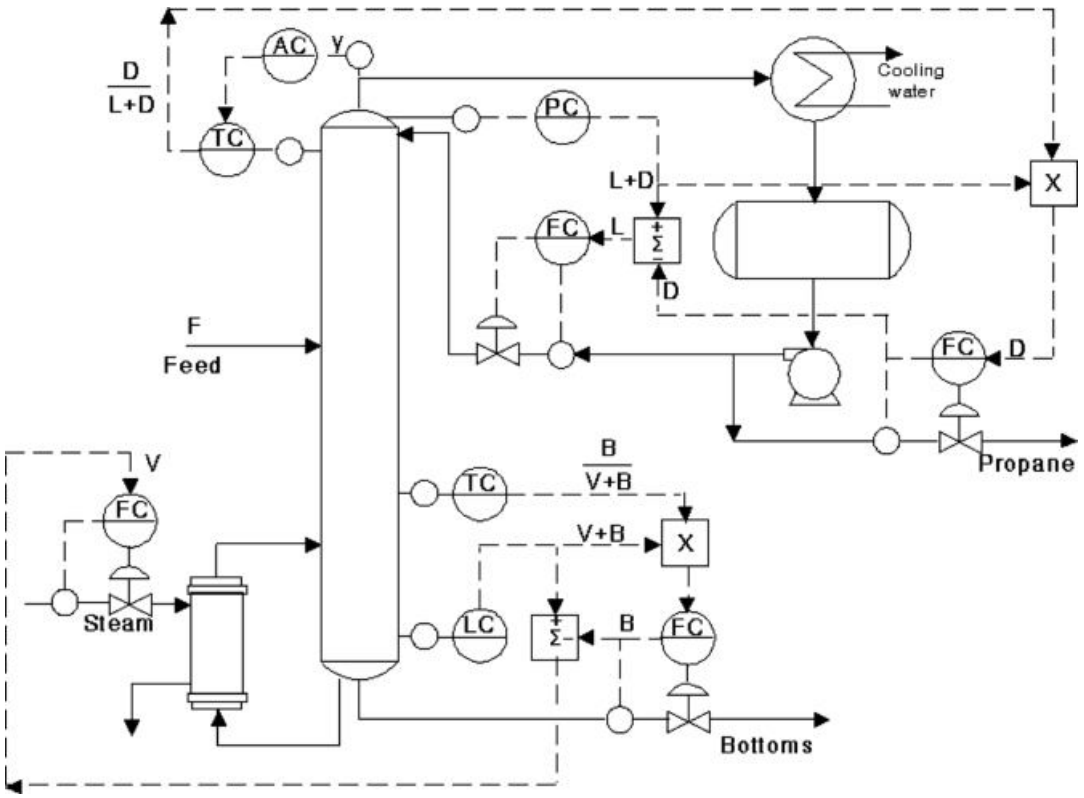

**FIG. 8-48** Depropanizers require control of the quality of both products, here using the reflux ratio and boil-up ratio manipulation.

## CHEMICAL REACTORS

**Composition Control** The first requirement for successful control of a chemical reactor is to establish the proper stoichiometry, i.e., to control the flow rates of the reactants in the proportions needed to satisfy the reaction chemistry. In a continuous reactor, this begins by setting ingredient flow rates in ratio to one another. However, because of variations in the purity of the feed streams and inaccuracy in flow metering, some indication of excess reactant such as pH or a composition measurement should be used to trim the ratios. Many reactions are incomplete, leaving one or more reactants unconverted. They are separated from the products of the reaction and recycled to the reactor, usually contaminated with inert components. While reactants can be recycled to complete conversion (extinction), inerts can accumulate to the point of impeding the reaction and must be purged from the system. Inerts include noncondensable gases that must be vented and nonvolatiles from which volatile products must be stripped.

If one of the reactants differs in phase from the others and the product(s), it may be manipulated to close the material balance on that phase. For example, a gas reacting with liquids to produce a liquid product may be added as it is consumed to control reactor pressure; a gaseous purge would be necessary. Similarly, a liquid reacting with a gas to produce a gaseous product could be added as it is consumed to control the liquid level in the reactor; a liquid purge would be required. Where a large excess of one reactant *A* is used to minimize side reactions, the unreacted excess is sent to a storage tank for recycling. Its flow from the recycle storage tank is set in the desired ratio to the flow of reactant *B*, with the flow of fresh *A* manipulated to control the recycle tank level if the feed is a liquid, or tank pressure if it is a gas. Some catalysts travel with the reactants and must be recycled in the same way.

With batch reactors, it may be possible to add all reactants in their proper quantities initially, if the reaction rate can be controlled by injection of initiator or adjustment of temperature. In semibatch operation, one key ingredient is flow-controlled into the batch at a rate that sets the production. This ingredient should not be manipulated for temperature control of an exothermic reactor, as the loop includes two dominant lags—concentration of the reactant and heat capacity of the reaction mass—and can easily go unstable. It also presents the unfavorable dynamic of inverse response—increasing feed rate may lower temperature by its sensible heat before the increased reaction rate raises temperature.

**Temperature Control** Reactor temperature should always be controlled by heat transfer. Endothermic reactions require heat and therefore are eminently self-regulating. Exothermic reactions produce heat, which tends to raise the reaction temperature, thereby increasing the reaction rate and producing greater heat. This positive feedback is countered by negative feedback in the cooling system, which removes more heat as the reactor temperature rises. Most continuous reactors have enough heat-transfer surface relative to reaction mass that negative feedback dominates and they are self-regulating. But most batch reactors do not, and they are therefore steady-state unstable. Unstable reactors can be controlled if their temperature controller gain can be set high enough, and if their cooling system has enough margin to accommodate the largest expected disturbance in heat load. Stirred-tank reactors are lag-dominant, and their dynamics allow a high controller gain, but plug flow reactors are dead-time-dominant, preventing their temperature controller from providing enough gain to overcome steady-state instability. Therefore, unstable plug flow reactors are also uncontrollable, their temperature tending to limit-cycle in a sawtooth wave. A stable reactor can become unstable as its heat-transfer surface fouls, or as the production rate is increased beyond a critical point (Shinskey, "Exothermic Reactors: The Stable, the Unstable, and the Uncontrollable," *Chem. Eng.*, pp. 54–59, March 2002).

Figure 8-49 shows the recommended system for controlling the temperature of an exothermic stirred-tank reactor, either continuous or batch. The circulating pump on the coolant loop is absolutely essential to effective temperature control in keeping dead time minimum and constant—without it, dead time varies inversely with cooling load, causing limit-cycling at low loads. Heating is usually required to raise the temperature to reaction conditions, although it is often locked out of a batch reactor once the initiator is introduced. The valves are operated in split range, the heating valve opening from 50 to 100 percent of controller output and the cooling valve opening from 50 to 0 percent. The cascade system linearizes the reactor temperature loop, speeds its response, and protects it from disturbances in the cooling system. The flow of heat removed per unit of coolant flow is directly proportional to the temperature rise of the coolant, which varies with both the temperature of the reactor and the rate of heat transfer from it. Using an

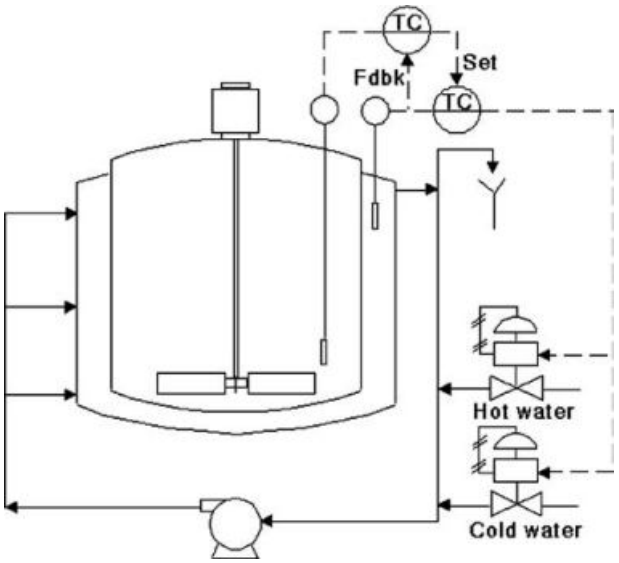

**FIG. 8-49** The stirred-tank reactor temperature controller sets the coolant outlet temperature in cascade, with primary integral feedback taken from the secondary temperature measurement.

equal-percentage cooling valve helps compensate for this nonlinearity, but incompletely.

The flow of heat across the heat-transfer surface is linear with both temperatures, leaving the primary loop with a constant gain. Using the coolant exit temperature as the secondary controlled variable, as shown in Fig. 8-49, places the jacket dynamics in the secondary loop, thereby reducing the period of the primary loop. This is dynamically advantageous for a stirred-tank reactor because of the slow response of its large heat capacity. However, a plug flow reactor cooled by an external heat exchanger lacks this heat capacity, and requires the faster response of the coolant inlet temperature loop.

Performance and robustness are both improved by using the secondary temperature measurement as the feedback signal to the integral mode of the primary controller. (This feature may be available only with controllers that integrate by positive feedback.) This places the entire secondary loop in the integral path of the primary controller, effectively pacing its integral time to the rate at which the secondary temperature is able to respond. It also permits the primary controller to be left in the automatic mode at all times without integral windup.

The primary time constant of the reactor is

$$\tau_1 = \frac{M_r C_r}{UA} \tag{8-55}$$

where $M_r$ and $C_r$ are the mass and heat capacity of the reactants and $U$ and $A$ are the overall heat-transfer coefficient and area, respectively. The control system of Fig. 8-49 was tested on a pilot reactor where the heat-transfer area and mass could both be changed by a factor of 2, changing $\tau_1$ by a factor of 4 as confirmed by observations of the rates of temperature rise. Yet neither controller required retuning as $\tau_1$ varied. The primary controller should be PID and the secondary controller at least PI in this system (if the secondary controller has no integral mode, the primary will control with offset). Set-point overshoot in batch reactor control can be avoided by setting the derivative time of the primary controller higher than its integral time, but this is effective only with interacting PID controllers.

## DRYING OPERATIONS

Controlling dryers is difficult, because online measurements of feed rate and composition and product composition are rarely available. Most dryers transfer moisture from wet feed into hot dry air in a single pass. The process is generally very self-regulating, in that moisture becomes progressively harder to remove from the product as it dries: this is known as *falling-rate drying*. Controlling the temperature of the air leaving a cocurrent dryer tends to regulate the moisture in the product, as long as the rate and moisture content of the feed and air are reasonably constant. However, at constant outlet air temperature, product moisture tends to rise with all three of these disturbance variables.

In the absence of moisture analyzers, regulation of product quality can be improved by raising the temperature of the exhaust air in proportion to the evaporative load. The evaporative load can be estimated by the loss in temperature of the air passing through the dryer in the steady state. Changes in load are first observed in upsets in exhaust temperature at a given inlet temperature; the controller then responds by returning the exhaust air to its original temperature by changing that of the inlet air.

Figure 8-50 illustrates the simplest application of this principle because of the linear relationship

$$T_0 = T_b + K\Delta T \tag{8-56}$$

where $T_0$ is the set point for exhaust temperature elevated above a base temperature $T_b$ corresponds to zero-load operation and $\Delta T$ is the drop in air temperature from inlet to outlet. Coefficient $K$ must be set to regulate product moisture over the expected range of evaporative load. If $K$ is set too low, product moisture will increase with increasing load; if $K$ is set too high, product moisture will decrease with increasing load. While $K$ can be estimated from the model of a dryer, it does depend on the rate-of-drying curve for the product, its mean particle size, and whether the load variations are due primarily to changes in feed rate or feed moisture.

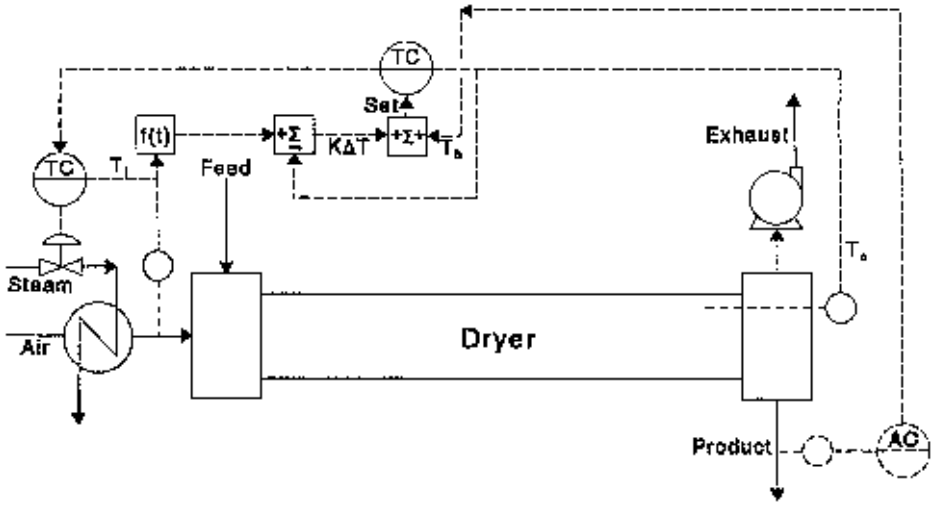

**FIG. 8-50** Product moisture from a cocurrent dryer can be regulated through temperature control indexed to heat load.

It is important to have the most accurate measurement of exhaust temperature attainable. Note that Fig. 8-50 shows the sensor inserted into the dryer upstream of the rotating seal, because air infiltration there could cause the temperature in the exhaust duct to read low—even lower than the wet-bulb temperature, an impossibility without either substantial heat loss or outside-air infiltration.

The calculation of the exhaust temperature set point forms a positive feedback loop capable of destabilizing the dryer. For example, an increase in evaporative load causes the controller to raise the inlet temperature, which will in turn raise the calculated set point, calling for a further increase in inlet temperature. The gain in the set-point loop $K$ is typically well below the gain of the exhaust temperature measurement responding to the same change in inlet temperature. Negative feedback then dominates in the steady state, but the response of the exhaust temperature measurement is delayed by the dryer. A compensating lag $f(t)$ is shown inserted in the set-point loop to prevent positive feedback from dominating in the short term, which could cause cycling. Lag time can be safely set equal to the integral time of the outlet-air temperature controller.

If product moisture is measured offline, analytical results can be used to adjust $K$ and $T_b$ manually. If an online analyzer is used, the analyzer controller would be most effective in adjusting the bias $T_b$, as is done in the figure.

While a rotary dryer is shown, commonly used for grains and minerals, this control system has been successfully applied to fluid-bed drying of plastic pellets, air-lift drying of wood fibers, and spray drying of milk solids. The air may be steam-heated as shown or heated by direct combustion of fuel, provided that a representative measurement of inlet air temperature can be made. If it cannot, then evaporative load can be inferred from a measurement of fuel flow, which then would replace $\Delta T$ in the set-point calculation.

If the feed flows countercurrent to the air, as is the case when drying granulated sugar, the exhaust temperature does not respond to variations in product moisture. For these dryers, the moisture in the product can better be regulated by controlling its temperature at the point of discharge. Conveyor-type dryers are usually divided into a number of zones, each separately heated with recirculation of air, which raises its wet-bulb temperature. Only the last two zones may require indexing of exhaust air temperature as a function of $\Delta T$.

Batch drying, used on small lots such as pharmaceuticals, begins operation by blowing air at constant inlet temperature through saturated product in constant-rate drying, where $\Delta T$ is constant at its maximum value $\Delta T_c$. When product moisture reaches the point where falling-rate drying begins, the exhaust temperature begins to rise. The desired product moisture will be reached at a corresponding exhaust temperature $T_f$, which is related to the temperature $T_c$ observed during constant-rate drying, as well as to $\Delta T_c$:

$$T_f = T_c + K\,\Delta T_c \tag{8-57}$$

The control system requires that the values of $T_c$ and $\Delta T_c$ observed during the first minutes of operation be stored as the basis for the above calculation of end-point. When the exhaust temperature then reaches the calculated value of $T_f$, drying is terminated. Coefficient $K$ can be estimated from models, but requires adjustment online to reach product specifications repeatedly. Products having different moisture specifications or particle size will require different settings of $K$, but the system does compensate for variations in feed moisture, batch size, air moisture, and inlet temperature. Some exhaust air may be recirculated to control the dew point of the inlet air, thereby conserving energy toward the end of the batch and when the ambient air is especially dry.

## COMPRESSOR CONTROL

While it is usually more economical to condense a vapor stream and pump it than to vaporize a liquid stream and compress it, compressors are often used on recycle streams composed of light components (hydrogen, methane, etc.) or on streams with incondensable gases. Compressors that operate at a constant speed are often controlled using one of the strategies shown in Figure 8-51. Usually the "pinch" method will have lower operating costs than the "spillback" method. Variable speed control methods are shown in Fig. 8-52 for an electric motor drive and for a steam turbine drive. The operating costs of variable-speed compressors are generally lower than for fixed-speed systems, with perhaps a slightly higher initial capital cost.

When compressors are used on recycle streams, Douglas (*Conceptual Design of Chemical Processes*, McGraw-Hill, New York, 1988) recommends that they generally be operated "wide open," that is, at a constant maximum

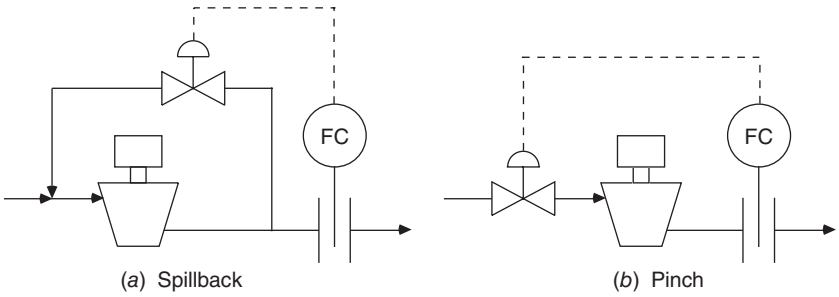

**FIG. 8-51** Compressor control using a constant-speed compressor. (*Source:* Bequette, *Process Control: Modeling, Design and Simulation*, 2d ed., Prentice-Hall, Upper Saddle River, N.J., 2017.)

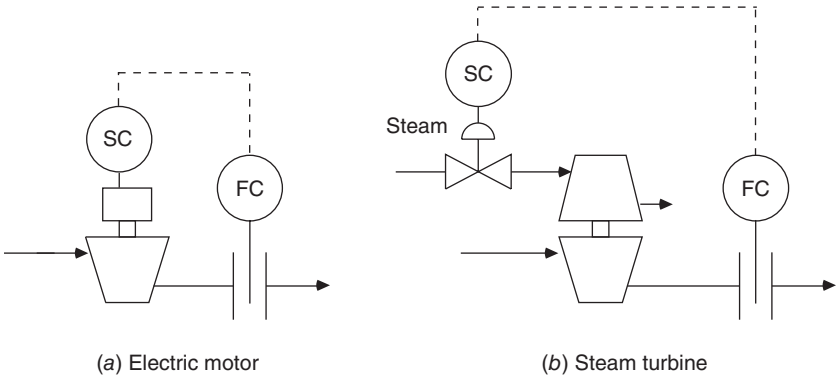

**FIG. 8-52** Compressor control using a variable-speed compressor. (*Source:* Bequette, *Process Control: Modeling, Design and Simulation*, 2d ed., Prentice-Hall, Upper Saddle River, N.J., 2017.)

flow rate. This is so because the economic return from the increased overall yield usually outweighs the incremental operating cost of the compressor.

## PLANTWIDE CONTROL

**General References:** Bequette, *Process Control: Modeling, Design and Simulation*, 2d ed., Prentice Hall, Upper Saddle River, N.J., 2017. Douglas, *Conceptual Design of Chemical Processes*, McGraw-Hill, New York, 1988. Seborg, Edgar, Mellichamp, and Doyle, III, *Process Dynamics and Control*, 4th ed., Wiley, New York, 2016. Luyben, Tyréus, and Luyben, *Plantwide Process Control*, McGraw-Hill, New York, 1999.

A process engineer must be concerned about the operation of an entire process plant or operating unit, and not just individual control loops or unit operations. The following questions must be addressed in development of a plantwide control strategy:

- What are the major operational objectives of the plant?
- What sensors should be paired with what manipulated inputs to form a control structure to achieve the major objectives?
- For any control valve or sensor failure, what steps will a process operator (and control system) need to take?

Much of this type of discussion occurs during the design or retrofit stage of a process. Here, process engineers develop and review process flow sheets and process and instrumentation diagrams. A detailed operational description of the proposed process and control strategy is developed, with consideration to all possible operating modes that can be selected by an operator, as well as to all equipment failure modes.

In this section we cannot do justice to the scope of work needed to develop a plantwide control strategy. We attempt to show some of the major issues in plantwide control by using an illustrative example.

**HDA Process Example** Toluene hydrodealkylation (HDA) is used for the production of benzene and is the basic case study process used in the textbook by Douglas (1988). A simplified process and instrumentation diagram for an HDA process is shown in Fig. 8-53. For clarity, a number of details are omitted, such as pumps on distillation reflux streams and furnace combustion air dampers.

The feed streams are high-purity (99.98 mol%) toluene and hydrogen (96 mol% hydrogen, 4 mol% methane). The objective is to produce a desired rate of benzene at a purity of 99.98 mol%. Because of coking considerations, a 5:1 hydrogen/aromatics ratio must be maintained at the reactor entrance. The reactor inlet pressure is to be maintained at just under 500 psig (the pressure of the hydrogen feed stream); the pressure drop between the feed stream mixing point and the flash drum is roughly 35 psi. The minimum reactor inlet temperature is 1150°F, while the maximum outlet temperature is 1300°F. The reactor exit stream must be immediately quenched to 1150°F to minimize secondary reactions.

The primary reaction is an irreversible reaction of toluene and hydrogen to produce benzene and methane, while the secondary reaction is the reversible reaction of benzene to form diphenyl and hydrogen:

$$C_7H_8 + H_2 \rightarrow C_6H_6 + CH_4$$

$$2C_6H_6 \leftrightarrow C_{12}H_{10} + H_2$$

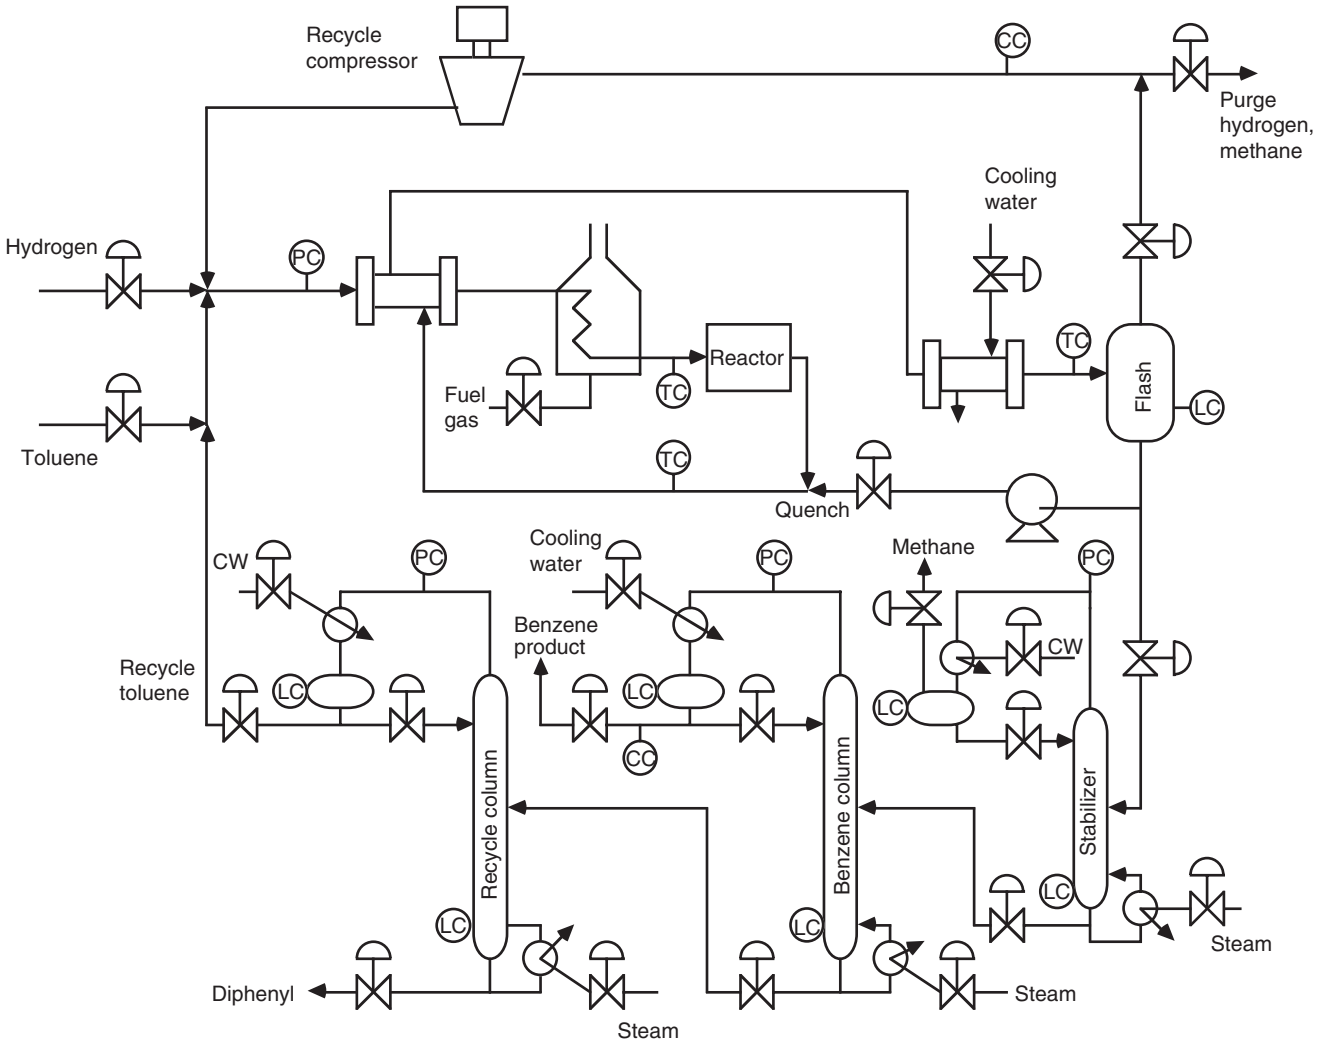

**FIG. 8-53** HDA process flowsheet with actuators and measurements shown. (*Source:* Bequette, *Process Control: Modeling, Design and Simulation*, 2d ed., Prentice-Hall, Upper Saddle River, N.J., 2017.)

The selectivity decreases as the temperature increases; a purge stream is necessary to eliminate methane from the process system.

Use the following suggestions to guide control structure development and place control loops on Fig. 8-53.

- A possible phenomenon associated with processes that have recycle streams is known as the *snowball effect*, whereby a minor disturbance results in a drastic change in a stream flow rate. To avoid the snowball effect, Luyben et al. (1999) recommend placing a flow control loop on a stream in the recycle path. For this process, they suggest placing the recycle toluene stream on flow control.
- Douglas (1988) recommends operating recycle compressors "wide open" because the value of recovered components is usually higher than the additional compressor power cost.
- A tray temperature in each column can be used to "infer" a product composition. Dual composition control for the columns is not necessary, and this petrochemical plant has had good success by placing reflux streams under flow control.

There are 23 control degrees of freedom, since there are 23 control valves. It is not necessary that all these valves be used for feedback control; one or more valves may be held at a constant valve position.

A solution to the HDA problem was developed by Luyben et al. (1999) and shown in Fig. 8-54. The important control structure decisions to note are as follows:

- The total toluene flow (recycle + feed) is set to prevent the snowball effect (it is recommended that one loop in a recycle system be placed on flow control). Notice that this flow also sets the production rate of benzene.
- The makeup (feed) toluene flow is manipulated by the recycle column distillate receiver level controller. Intuition may suggest that there would be a significant lag between the feed flow, through the various unit operations, to the final distillation column. This is not the case, however, since the total toluene flow is regulated. Any change in toluene feed has an immediate effect on the recycle toluene flow and hence the distillate receiver level.
- The overhead valve from the flash drum is set wide open to allow maximum flow through the recycle compressor. The flash drum operating pressure is then dictated by pressure drop through the system, since the pressure is controlled at the reactor entrance.
- Since the diphenyl flow rate from the recycle column is low, the level is controlled by the reboiler heat duty (steam to the reboiler).
- The benzene purity is maintained using a cascade strategy, where the output of the composition controller is the set point to a tray temperature controller. This strategy yields a faster rejection of feed disturbances and provides satisfactory composition control when the composition sensor fails or needs recalibration.

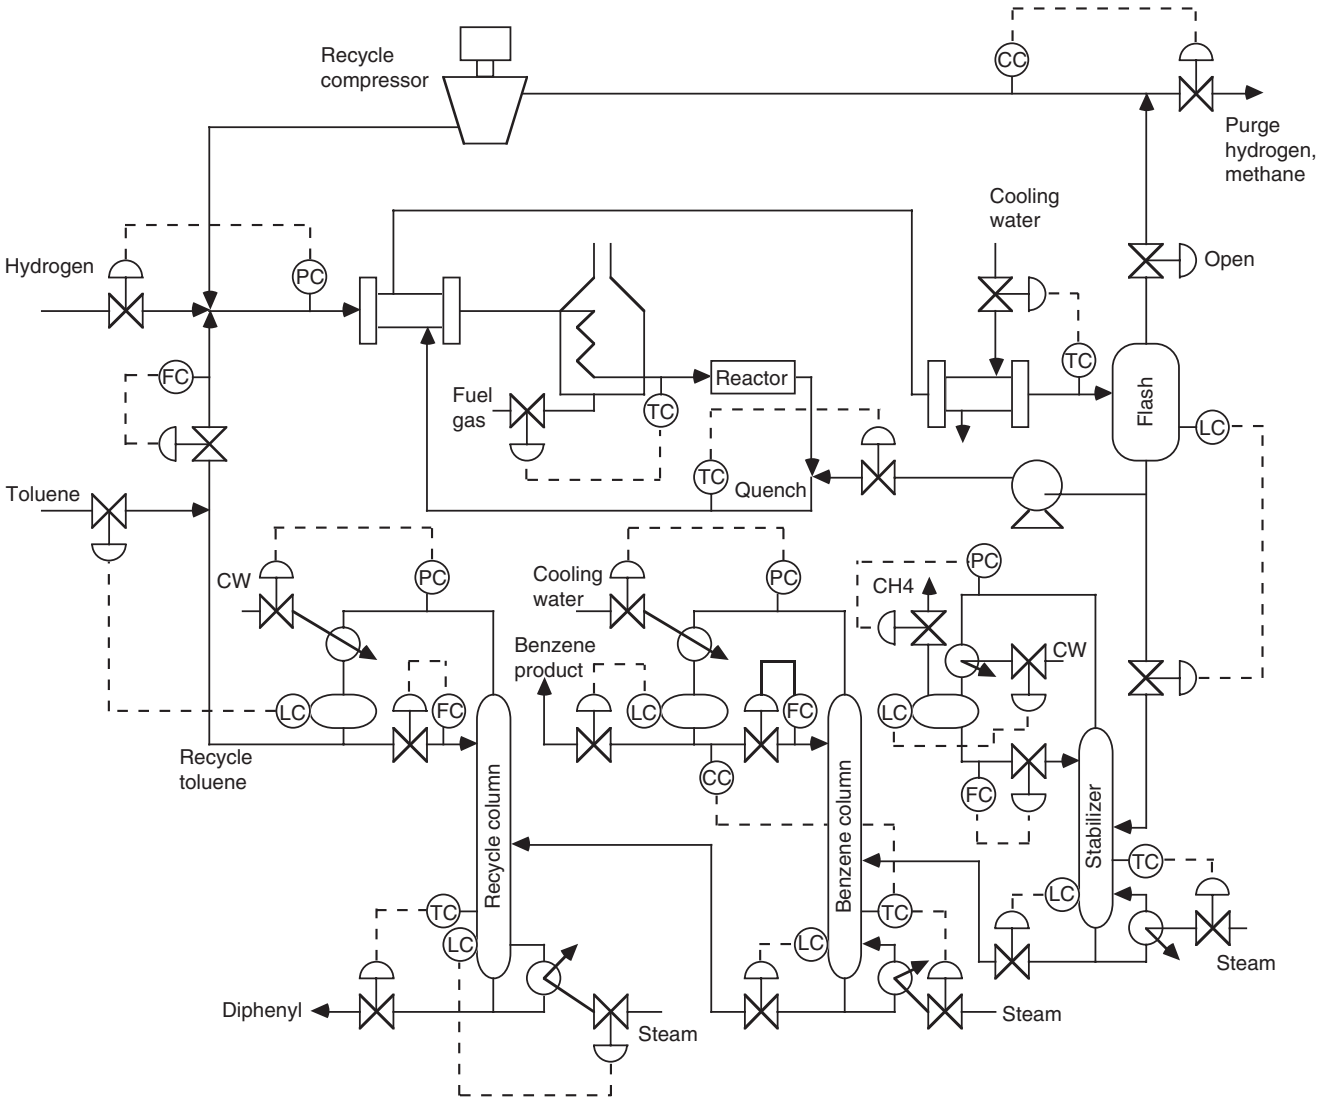

**FIG. 8-54** HAD process flowsheet with control loops suggested by Luyben et al. (1999). (*Source:* Bequette, *Process Control: Modeling, Design and Simulation*, 2d ed., Prentice-Hall, Upper Saddle River, N.J., 2017.)

# BATCH PROCESS CONTROL

**General References:** Rosenof and Ghosh, *Batch Process Automation*, Van Nostrand Reinhold, New York, 1987. Smith, *Control of Batch Processes*, Wiley, New York, 2014.

## BATCH VERSUS CONTINUOUS PROCESSES

When one is categorizing process plants, the following two extremes can be identified:

1. *Commodity plants.* These plants are custom-designed to produce large amounts of a single product (or a primary product plus one or more secondary products). An example is a chlorine plant, where the primary product is chlorine and the secondary products are hydrogen and sodium hydroxide. Usually the margins (product value less manufacturing costs) for the products from commodity plants are small, so the plants must be designed and operated for best possible efficiencies. Although a few are batch, most commodity plants are continuous. Factors such as energy costs are life-and-death issues for such plants.

2. *Specialty plants.* These plants are capable of producing small amounts of a variety of products. Such plants are common in fine chemicals, pharmaceuticals, foods, and so on. In specialty plants, the margins are usually high, so factors such as energy costs are important but not life-and-death issues. As the production amounts are relatively small, it is not economically feasible to dedicate processing equipment to the manufacture of only one product. Instead, batch processing is utilized so that several products (perhaps hundreds) can be manufactured with the same process equipment. The key issue in such plants is to manufacture consistently each product in accordance with its specifications.

The above two categories represent the extremes in process configurations. The term *semibatch* designates plants in which some processing is continuous but other processing is batch. Even processes that are considered to be continuous can have a modest amount of batch processing. For example, the reformer unit within a refinery is thought of as a continuous process, but catalyst regeneration is possibly batch.

In a continuous process, the conditions within the process are largely the same from one day to the next. Variations in feed composition, plant utilities (e.g., cooling water temperature), catalyst activities, and other variables occur, but normally these changes either are about an average (e.g., feed compositions) or exhibit a gradual change over an extended period (e.g., catalyst activities). Summary data such as hourly averages, daily averages, and the like are meaningful in a continuous process.

In a batch process, the conditions within the process are continually changing. The technology for making a given product is contained in the product recipe that is specific to that product. Such recipes normally state the following:

1. *Raw material amounts.* This is the stuff needed to make the product.
2. *Processing instructions.* This is what must be done with the stuff to make the desired product.

This concept of a *recipe* is quite consistent with the recipes found in cookbooks. Sometimes the term *recipe* is used to designate only the raw material amounts and other parameters to be used in manufacturing a batch. Although appropriate for some batch processes, this concept is far too restrictive for others. For some products, the differences from one product to the next are largely physical as opposed to chemical. For such products, the processing instructions are especially important. The term *formula* is more appropriate for the raw material amounts and other parameters, with *recipe* designating the formula and the processing instructions. This concept of a recipe permits the following three different categories of batch processes to be identified:

1. *Cyclical batch.* Both the formula and the processing instructions are the same from batch to batch. Batch operations within processes that are primarily continuous often fall into this category. A batch catalyst regenerator within a reformer unit is cyclical batch.

2. *Multigrade.* The processing instructions are the same from batch to batch, but the formula can be changed to produce modest variations in the product. In a batch PVC plant, the different grades of PVC are manufactured by changing the formula. In a batch pulp digester, the processing of each batch or cook is the same, but at the start of each cook, the process operator is permitted to change the formula values for chemical-to-wood ratios, cook time, cook temperature, and so on.

3. *Flexible batch.* Both the formula and the processing instructions can change from batch to batch. Emulsion polymerization reactors are a good example of a flexible batch facility. The recipe for each product must detail both the raw materials required and how conditions within the reactor must be sequenced to make the desired product.

Of these, the flexible batch is by far the most difficult to automate and requires a far more sophisticated control system than either the cyclical batch or the multigrade batch facility.

**Batches and Recipes** Each batch of product is manufactured in accordance with a product recipe, which contains all information ( formula and processing instructions) required to make a batch of the product (see Fig. 8-55). For each batch of product, there will be one and only one product recipe.

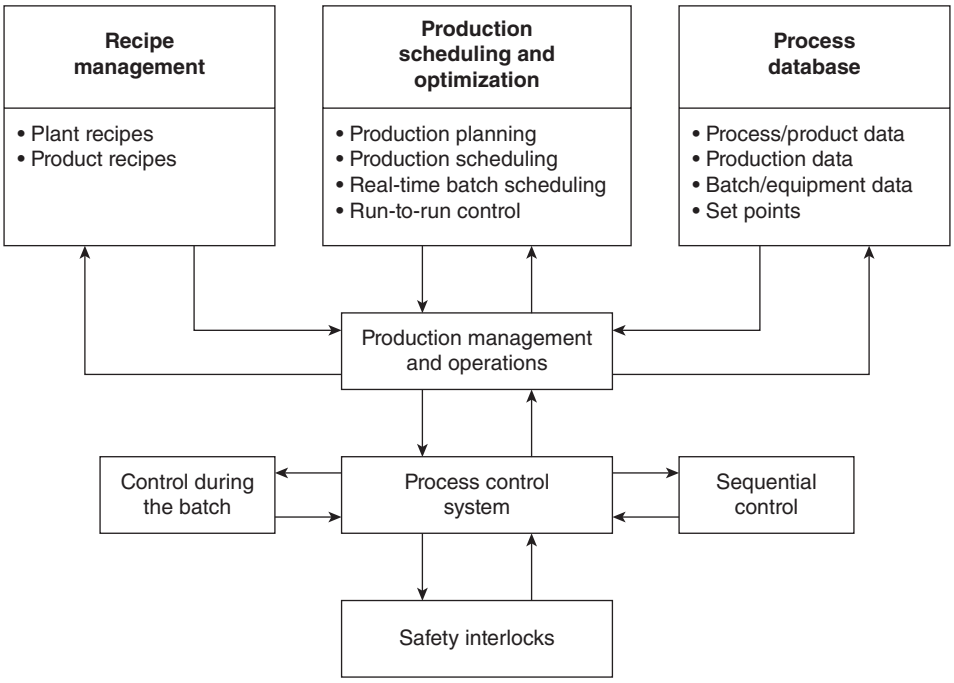

**FIG. 8-55** Batch control system—a more detailed view. (*Source:* Seborg et al., *Process Dynamics and Control*, 3d ed., Wiley, New York, 2010.)

However, a given product recipe is normally used to make several batches of product. To uniquely identify a batch of product, each batch is assigned a unique identifier called the *batch ID*. Most companies adopt a convention for generating the batch ID, but this convention varies from one company to the next. In most batch facilities, more than one batch of product will be in some stage of production at any given time. The batches in progress may or may not be using the same recipe. The maximum number of batches that can be in progress at any given time is a function of the equipment configuration for the plant.

The existence of multiple batches in progress at a given time presents numerous opportunities for the process operator to make errors, such as charging a material to the wrong batch. Charging a material to the wrong batch is almost always detrimental to the batch to which the material is incorrectly charged. Unless this error is recognized quickly so that the proper change can be made, the error is also detrimental to the batch to which the charge was supposed to have been made.

Errors of this type arise from product issues, and are very common in batch facilities. Possibilities include the following:

1. Adding a chemical to a vessel at an inappropriate time. Steam is a common material that is usually innocuous, but if added to some reacting systems, leads to adverse consequences.
2. Adding a chemical other than the one specified by the product recipe. Charging materials from drums on a weigh scale is common in specialty batch plants. Is the drum on the scale the appropriate drum? Does the drum on the scale contain the chemical that it should contain? Plants institute procedures to guard against such errors, but are they foolproof and will they be followed?

Such errors usually lead to an off-specification batch, but the consequences could be more serious and could result in a hazardous condition.

A critical issue in batch reacting systems can be summarized as follows: Is the desired reaction proceeding at the desired rate? To obtain the desired reaction, the appropriate materials must be charged to the vessel. To obtain the desired rate, the reaction must initiate and proceed in the proper manner. However, reactions can stop abruptly. In emulsion reaction systems, the content within the reactor is an emulsion and one of the feeds is an emulation. Emulsions occasionally break, causing the reaction to stop. When this occurs, continuing to feed reactive materials leads to a hazardous situation.

*Recipe management* refers to the assumption of such duties by the control system. Each batch of product is tracked throughout its production, which may involve multiple processing operations on various pieces of processing equipment. Recipe management ensures that all actions specified in the product recipe are performed on each batch of product made in accordance with that recipe. As the batch proceeds from one piece of processing equipment to the next, recipe management is also responsible for ensuring that the proper type of process equipment is used and that this processing equipment is not currently in use by another batch.

By assuming such responsibilities, the control system greatly reduces the incidences where operator error results in off-specification batches. Such a reduction in error is essential to implement just-in-time production practices, where each batch of product is manufactured at the last possible moment. When a batch (or batches) is made today for shipment by overnight truck, there is insufficient time for producing another batch to make up for an off-specification batch.

**Routing and Production Monitoring** In some facilities, batches are individually scheduled. However, in most facilities, production is scheduled by product runs (also called *process orders*), where a run is the production of a stated quantity of a given product. From the stated quantity and the standard yield of each batch, the number of batches can be determined. A production run is normally a sequence of some number of batches of the same product.

In executing a production run, the following issues must be addressed (see Fig. 8-55):

1. *Processing equipment must be dedicated to making the run.* More than one run is normally in progress at a given time. The maximum number of runs simultaneously in progress depends on the equipment configuration of the plant. Routing involves determining which processing equipment will be used for each production run.
2. *Raw materials must be available.* When a production run is scheduled, the necessary raw materials must be allocated to the production run. As the individual batches proceed, the consumption of raw materials must be monitored for consistency with the allocation of raw materials to the production run.
3. *The production quantity for the run must be achieved by executing the appropriate number of batches.* The number of batches is determined from a standard yield for each batch. However, some batches may achieve yields higher than the standard yield, but other batches may achieve yields lower than the standard yield. The actual yields from each batch must be monitored, and significant deviations from the expected yields must be communicated to those responsible for scheduling production.

The last two activities are key components of production monitoring, although production monitoring may also involve other activities such as tracking equipment utilization.

**Production Scheduling** In this regard, it is important to distinguish between scheduling runs (sometimes called *long-term scheduling*) and assigning equipment to runs (sometimes called *routing* or *short-term scheduling*). As used here, *production scheduling* refers to scheduling runs and is usually a corporate-level as opposed to a plant-level function. Short-term scheduling or routing was previously discussed and is implemented at the plant level. The long-term scheduling is basically a material resources planning (MRP) activity involving the following:

1. *Forecasting.* Orders for long-delivery raw materials are issued at the corporate level based on the forecast for the demand for products. The current inventory of such raw materials is also maintained at the corporate level. This constitutes the resources from which products can be manufactured. Functions of this type are now incorporated into supply chain management.
2. *Orders for products.* Orders are normally received at the corporate level and then assigned to individual plants for production and shipment. Although the scheduling of some products is based on required product inventory levels, scheduling based on orders and shipping directly to the customer (usually referred to as just-in-time) avoids the costs associated with maintaining product inventories.
3. *Plant locations and capacities.* While producing a product at the nearest plant usually lowers transportation costs, plant capacity limitations sometimes dictate otherwise. Any company competing in the world economy needs the flexibility to accept orders on a worldwide basis and then assign them to individual plants to be filled. Such a function is logically implemented within the corporate-level information technology framework.

## BATCH AUTOMATION FUNCTIONS

Automating a batch facility requires a spectrum of functions.

**Interlocks** Those provided for safety are properly called *safety interlocks* and are incorporated into the safety systems. Interlocks provided to avoid mistakes in processing the batch that do not lead to a process hazard are properly called *process interlocks*, and they are incorporated into the process controls. Terms such as *permissives* and *process actions* can be used so as to restrict the term *interlock* to a connection to safety (*interlock* is sometimes defined as a protective response initiated on the detection of a process hazard).

**Discrete Device States** Discrete devices such as two-position valves can be driven to either of two possible states. Such devices can be optionally outfitted with limit switches that indicate the state of the device. For two-position valves, the following combinations are possible:

1. No limit switches
2. One limit switch on the closed position
3. One limit switch on the open position
4. Two limit switches

In process control terminology, the discrete device driver is the software routine that generates the output to a discrete device such as a valve and also monitors the state feedback information to ascertain that the discrete device actually attains the desired state. Given the variety of discrete devices used in batch facilities, this logic must include a spectrum of capabilities. For example, valves do not instantly change states; instead each valve exhibits a travel time for the change from one state to another. To accommodate this characteristic of the field device, the processing logic within the discrete device driver must provide for a user-specified transition time for each field device. When equipped with limit switches, the potential states for a valve are as follows:

1. *Open.* The valve has been commanded to open, and the limit switch inputs are consistent with the open state.
2. *Closed.* The valve has been commanded to close, and the limit switch inputs are consistent with the closed state.
3. *Transition.* This is a temporary state that is possible only after the valve has been commanded to change state. The limit switch inputs are not consistent with the commanded state, but the transition time has not expired.
4. *Invalid.* The transition time has expired, and the limit switch inputs are not consistent with the commanded state for the valve.

The invalid state is an abnormal condition that is generally handled in a manner similar to process alarms. The transition state is not considered to be an abnormal state but may be implemented in either of the following ways:

1. *Drive and wait.* Further actions are delayed until the device attains its commanded state.
2. *Drive and proceed.* Further actions are initiated while the device is in the transition state.

The latter is generally necessary for devices with long travel times, such as flush-fitting reactor discharge valves that are motor-driven. Closing of such valves is normally done via drive and wait; however, drive and proceed is usually appropriate when opening the valve. Although two-state devices are most common, the need occasionally arises for devices with three or more states. For example, an agitator may be on high speed, on slow speed, or off.

**Process States** Batch processing usually involves imposing the proper sequence of states on the process. For example, a simple blending sequence might be as follows:

1. Transfer specified amount of material from tank A to tank R. The process state is "transfer from A."
2. Transfer specified amount of material from tank B to tank R. The process state is "transfer from B."
3. Agitate for specified time. The process state is "agitate without cooling."
4. Cool (with agitation) to specified target temperature. The process state is "agitate with cooling."

For each process state, the various discrete devices are expected to be in a specified device state. For process state "transfer from A," the device states might be as follows:

1. Tank A discharge valve: open
2. Tank R inlet valve: open
3. Tank A transfer pump: running
4. Tank R agitator: off
5. Tank R cooling valve: closed

For many batch processes, process state representations are a very convenient mechanism for representing the batch logic. A grid or table can be constructed, with the process states as rows and the discrete device states as columns (or vice versa). For each process state, the state of every discrete device is specified to be one of the following:

1. Device state 0, which may be valve closed, agitator off, and so on
2. Device state 1, which may be valve open, agitator on, and so on
3. No change or don't care

This representation is easily understandable by those knowledgeable about the process technology and is a convenient mechanism for conveying the process requirements to the control engineers responsible for implementing the batch logic.

Many batch software packages also recognize process states. A configuration tool is provided to define a process state. With such a mechanism, the batch logic does not need to drive individual devices but can simply command that the desired process state be achieved. The system software then drives the discrete devices to the device states required for the target process state. This normally includes the following:

1. Generating the necessary commands to drive each device to its proper state.
2. Monitoring the transition status of each device to determine when all devices have attained their proper states.
3. Continuing to monitor the state of each device to ensure that the devices remain in their proper states. Should any discrete device not remain in its target state, an appropriate response must be initiated.

**Regulatory Control** For most batch processes, the discrete logic requirements overshadow the continuous control requirements. Often the continuous control can be provided by simple loops for flow, pressure, level, and temperature. However, very sophisticated advanced control techniques are occasionally applied. As temperature control is especially critical in reactors, the simple feedback approach is replaced by model-based strategies that rival, if not exceed, the sophistication of advanced control loops in continuous plants.

In some installations, alternative approaches for regulatory control may be required. Where a variety of products are manufactured, the reactor may be equipped with alternative heat removal capabilities, including the following:

1. Jacket filled with cooling water. Jackets may be once-through or recirculating.
2. Heat exchanger in a pump-around loop.
3. Reflux condenser.

The heat removal capability to be used usually depends on the product being manufactured. Therefore, regulatory loops must be configured for each possible option, and sometimes for certain combinations of the possible options. These loops are enabled and disabled depending on the product being manufactured.

The interface between continuous controls and sequence logic (discussed shortly) is also important. For example, a feed might be metered into a reactor at a variable rate, depending on another feed or possibly on reactor temperature. However, the product recipe calls for a specified quantity of this feed. The flow must be totalized (i.e., integrated), and when the flow total attains a specified value, the feed must be terminated. The sequence logic must have access to operational parameters such as controller modes. That is, the sequence logic must be able to switch a controller to manual, automatic, or cascade. Furthermore, the sequence logic must be able to force the controller output to a specified value.

**Sequence Logic** Sequence logic must not be confused with discrete logic. Discrete logic is especially suitable for process interlocks; e.g., the reactor discharge valve must be closed for the feed valve to be opened. Sequence logic is used to force the process to attain the proper sequence of states. For example, a feed preparation might be to first charge A, then charge B, next mix, and finally cool. Although discrete logic can be used to implement sequence logic, other alternatives are often more attractive.

Sequence logic is often, but not necessarily, coupled with the concept of a process state. Basically, the sequence logic determines when the process should proceed from the current state to the next and sometimes what the next state should be.

Sequence logic must encompass both normal and abnormal process operations. Thus, sequence logic is often viewed as consisting of two distinct but related parts:

1. *Normal logic.* This sequence logic provides for the normal or expected progression from one process state to another.
2. *Failure logic.* This logic provides for responding to abnormal conditions, such as equipment failures.

Of these, the failure logic can easily be the most demanding. The simplest approach is to stop or hold on any abnormal condition and let the process operator sort things out. However, this is not always acceptable. Failures that lead to hazardous conditions require immediate action; waiting for the operator to decide what to do is not acceptable. The appropriate response to such situations is best determined in conjunction with the process hazards analysis.

No single approach has evolved as the preferred way to implement sequence logic. The approaches utilized include the following:

1. *Discrete logic.* Although sequence logic is different from discrete logic, sequence logic can be implemented using discrete logic capabilities. Simple sequences are commonly implemented as ladder diagrams in programmable logic controllers (PLCs). Sequence logic can also be implemented using the boolean logic functions provided by a distributed control system (DCS), although this approach is now infrequently pursued.
2. *Programming languages.* Traditional procedural languages do not provide the necessary constructs for implementing sequence logic. This necessitates one of the following:

*a. Special languages.* The necessary extensions for sequence logic are provided by extending the syntax of the programming language. This is the most common approach within distributed control systems. The early implementations used BASIC as the starting point for the extensions; the later implementations used C as the starting point. A major problem with this approach is portability, especially from one manufacturer to the next but sometimes from one product version to the next within the same manufacturer's product line.

*b. Subroutine or function libraries.* The facilities for sequence logic are provided via subroutines or functions that can be referenced from programs written in FORTRAN or C. This requires a general-purpose program development environment and excellent facilities to trap the inevitable errors in such programs.

3. *State machines.* This technology is commonly applied within the discrete manufacturing industries. However, its migration to process batch applications has been limited.
4. *Graphical implementations.* For sequence logic, the flowchart traditionally used to represent the logic of computer programs must be extended to provide parallel execution paths. Such extensions have been implemented in a graphical representation generally referred to as a *sequential function chart*, which is a derivative of an earlier technology known as *Grafcet*. As process engineers have demonstrated a strong dislike for ladder logic, most PLC manufacturers now provide sequential function charts either in addition to or as an alternative to ladder logic. Many DCS manufacturers also provide sequential function charts either in addition to or as an alternative to special sequence languages.

## INDUSTRIAL APPLICATIONS

An industrial example requiring simple sequence logic is the effluent tank with two sump pumps illustrated in Fig. 8-56. There are two sump

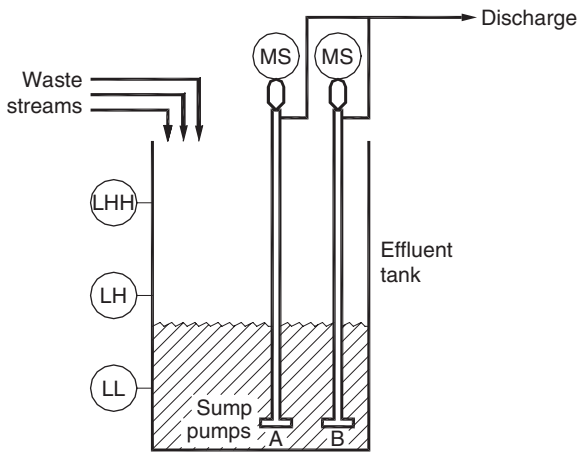

**FIG. 8-56** Effluent tank process.

pumps, A and B. The tank is equipped with three level switches, one for low level (LL), one for high level (LH), and one for high-high level (LHH). All level switches actuate on rising level. The logic is to be as follows:

1. When level switch LH actuates, start one sump pump. This must alternate between the sump pumps. If pump A is started on this occasion, then pump B must be started on the next occasion.
2. When level switch LHH actuates, start the other sump pump.
3. When level switch LL deactuates, stop all sump pumps.

Once a sump pump is started, it is not stopped until level switch LL deactuates. With this logic, one, both, or no sump pump may be running when the level is between LL and LH. Either one or both sump pumps may be running when the level is between LH and LHH.

Figure 8-57*a* presents the ladder logic implementation of the sequence logic. Ladder diagrams were originally developed for representing hardwired logic, but are now widely used in PLCs. The vertical bar on the left provides the source of power; the vertical bar on the right is ground. If a coil is connected between the power source and ground, the coil will be energized. If a circuit consisting of a set of contacts is inserted between the power source and the coil, the coil will be energized only if power can flow through the circuit. This will depend on the configuration of the circuit and the states of the contacts within the circuit. Ladder diagrams are constructed as rungs, with each rung consisting of a circuit of contacts and an output coil.

Contacts are represented as vertical bars. A vertical bar represents a normally open contact; power flows through this contact only if the device with which the contact is associated is actuated (energized). Vertical bars separated by a slash represent a normally closed contact; power flows through this contact only if the device with which the contact is associated is not actuated. The level switches actuate on rising level. If the vessel level is below the location of the switch, the normally open contact is open and the normally closed contact is closed. If the level is above the location of the switch, the normally closed contact is closed and the normally open contact is open.

The first rung in Fig. 8-57*a* is for pump A. It will run if one (or more) of the following conditions is true:

1. Level is above LH and pump A is the lead pump. A coil (designated as LeadIsB) will be subsequently provided to designate the pump to be started next (called the *lead* pump). If this coil is energized, pump B is the lead pump. Hence, pump A is to be started at LH if this coil is not energized, hence the use of the normally closed contact on coil LeadIsB in the rung of ladder logic for pump A.
2. Level is above LHH.
3. Pump A is running and the level is above LL.

The second rung is an almost identical circuit for pump B. The difference is the use of the normally open contact on the coil lead is B.

When implemented as hardwired logic, ladder diagrams are truly parallel logic; i.e., all circuits are active at all instants of time. But when ladder diagrams are implemented in PLCs, the behavior is slightly different. The ladder logic is scanned very rapidly (on the order of 100 times per second), which gives the appearance of parallel logic. But within a scan of ladder logic, the rungs are executed sequentially. This permits constructs within ladder logic for PLCs that make no sense in hardwired circuits.

One such construct is for a "one-shot." Some PLCs provide this as a built-in function, but here it will be presented in terms of separate components. The one-shot is generated by the third rung of ladder logic in Fig. 8-57*a*. But first examine the fourth rung. The input LL drives the output coil LL1. This coil provides the state of level switch LL on the previous scan of ladder logic. This is used in the third rung to produce the one-shot. Output coil OneShot is energized if

1. LL is not actuated on this scan of ladder logic (note the use of the normally closed contact for LL)
2. LL was actuated on the previous scan of ladder logic (note the use of the normally open contact for LL1)

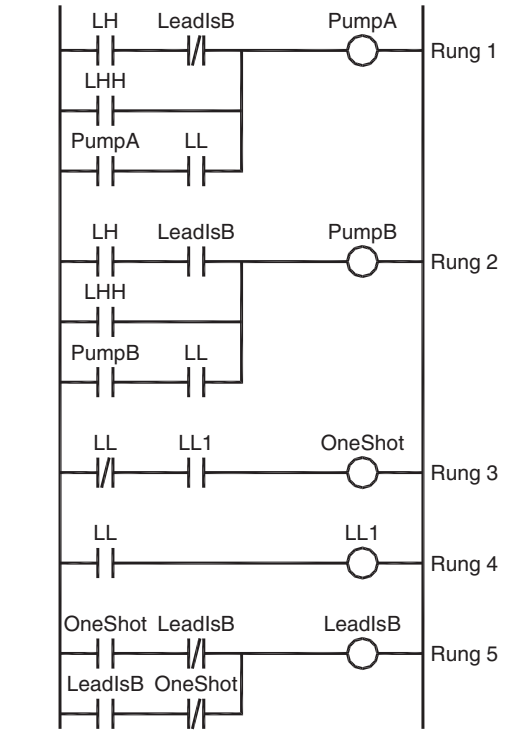
When LL deactuates, coil OneShot is energized for one scan of ladder logic. OneShot does not energize when LL actuates (a slight modification of the circuit would give a one-shot when LL actuates).

The one-shot is used in the fifth rung of ladder logic to toggle the lead pump. The output coil LeadIsB is energized provided that

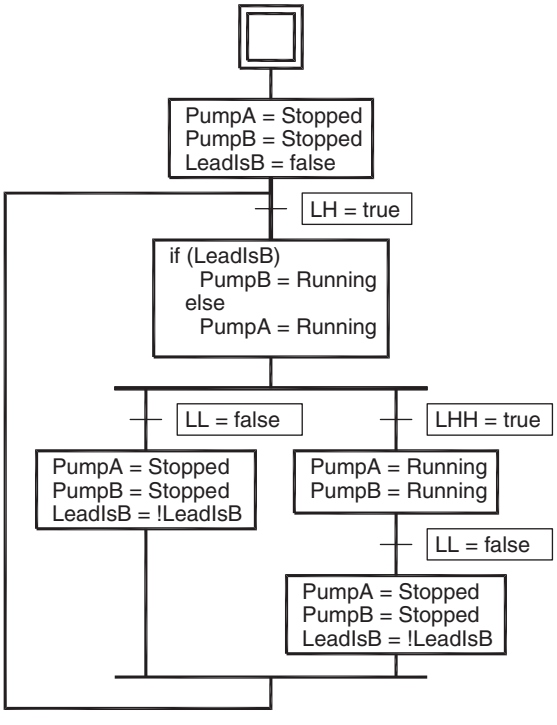
1. LeadIsB is energized and OneShot is not energized. Once LeadIsB is energized, it remains energized until the next "firing" of the one-shot.
2. LeadIsB is not energized and OneShot is energized. This causes coil LeadIsB to change states each time the one-shot fires.

Ladder diagrams are ideally suited for representing discrete logic, such as required for interlocks. Sequence logic can be implemented via ladder logic, but usually with some tricks or gimmicks (the one-shot in Fig. 8-57*a* is such a gimmick). These are well known to those "skilled in the art" of PLC programming. But to others, they can be quite confusing.

Figure 8-57*b* provides a sequential function chart for the pumps. Sequential function charts consist of steps and transitions. A step consists of actions to be performed, as represented by statements. A transition consists of a logical expression. As long as the logical expression is false, the sequence logic remains at the transition. When the logical expression is true, the sequence logic proceeds to the step following the transition.



(*a*)



(*b*)

**FIG. 8-57** (*a*) Ladder logic. (*b*) Sequence logic for effluent tank sump pumps.

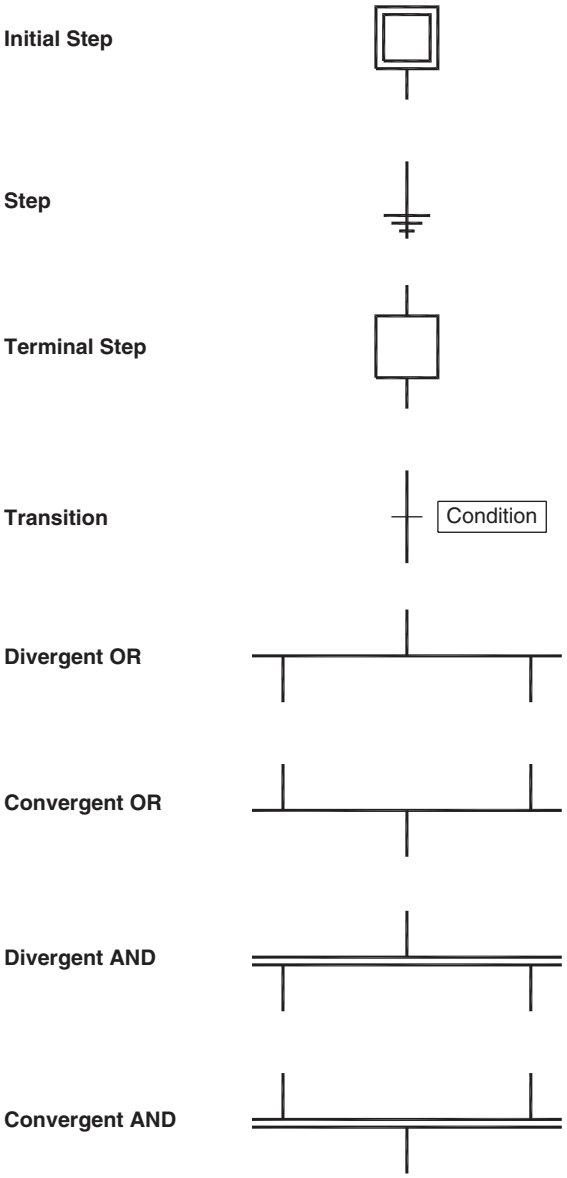


**FIG. 8-58** Elements of sequential function charts.

The basic constructs of sequential function charts are presented in Fig. 8-58. The basic construct of a sequential function chart is the step-transition-step. But also note the constructs for OR and AND. At the divergent OR, the logic proceeds on only one of the possible paths, specifically, the one whose transition is the first to attain the true condition. At the divergent AND, the logic proceeds on all paths simultaneously, and all must complete to proceed beyond the convergent AND. This enables sequential function charts to provide parallel logic.

In the sequential function chart in Fig. 8-57*b* for the pumps, the logic is initiated with both pumps stopped and pump A as the lead pump. When LH actuates, the lead pump is started. A divergent OR is used to create two paths:

1. If LL deactuates, both pumps are stopped and the lead pump is swapped.
2. If LHH actuates, both pumps are started (one is already running). Both remain running until LL deactuates, at which time both are stopped. The logic then loops to the transition for LH actuating.

Although not illustrated here, programming languages (either custom sequence languages or traditional languages extended by libraries of real-time functions) are a viable alternative for implementing the logic for the pumps. Graphical constructs such as ladder logic and sequential function charts are appealing to those uncomfortable with traditional programming languages. But in reality, these are programming methodologies.

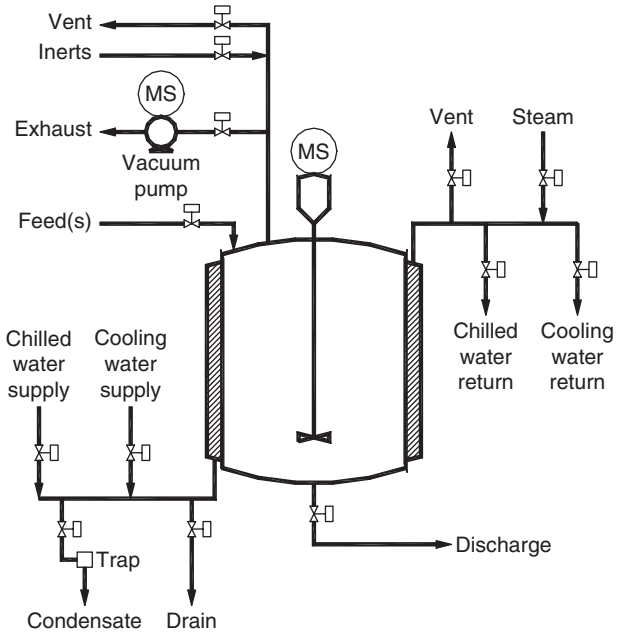

**FIG. 8-59** Chemical reactor schematic.

## BATCH REACTOR CONTROL

The reactors in flexible batch chemical plants usually present challenges. Many reactors have multiple mechanisms for heating and/or cooling. The reactor in Fig. 8-59 has three mechanisms:

1. Heat with steam.
2. Cool with cooling tower water.
3. Cool with chilled water.

Sometimes glycol is an option; occasionally liquid nitrogen is used to achieve even lower temperatures. Some jacket configurations require sequences for switching between the various modes for heating and cooling (the jacket has to be drained or depressurized before another medium can be admitted).

The reactor in Fig. 8-59 has three mechanisms for pressure control:

1. Vacuum
2. Atmospheric (using the vent and inert valves)
3. Pressure

Some reactors are equipped with multiple vacuum pumps, with different operating modes for moderate vacuum versus high vacuum. Sequence logic is usually required to start vacuum pumps and establish vacuum.

With three options for heating/cooling and three options for pressure, the reactor in Fig. 8-59 has nine combinations of operating modes. In practice, this is a low number. This number increases with features such as

1. Recirculation or pump-arounds containing a heater and/or cooler
2. Reflux condensers that can be operated at total reflux (providing only cooling) or such that some component is removed from the reacting system

These further increase the number of possible combinations. Some combinations may not make sense, may not be used in current production operations, or otherwise can be eliminated. However, the net number of combinations that must be supported tends to be large.

The order in which the systems are activated usually depends on the product being manufactured. Sometimes heating/cooling and pressure control are established simultaneously; sometimes heating/cooling is established first and then pressure control, and sometimes pressure control is established first and then heating/cooling. One has to be very careful when imposing restrictions. Suppose no current products establish pressure control first and then establish heating/cooling. But what about the next product to be introduced? After all, this is a flexible batch facility.

Such challenging applications for recipe management and sequence logic require a detailed analysis of the production equipment and the operations conducted within that production equipment. While applications such as the sump pumps in the effluent tank can be pursued without it, a structured approach is essential in flexible batch facilities.

## BATCH PRODUCTION FACILITIES

Especially for flexible batch applications, the batch logic must be properly structured in order to be implemented and maintained in a reasonable manner. An underlying requirement is that the batch process equipment be properly structured. The following structure is appropriate for most batch production facilities.

**Plant** A plant is the collection of production facilities at a geographic site. The production facilities at a site normally share warehousing, utilities, and the like.

**Equipment Suite** An equipment suite is the collection of equipment available for producing a group of products. Normally, this group of products is similar in certain respects. For example, they might all be manufactured from the same major raw materials. Within the equipment suite, material transfer and metering capabilities are available for these raw materials. The equipment suite contains all the necessary types of processing equipment (reactors, separators, and so on) required to convert the raw materials to salable products. A plant may consist of only one suite of equipment, but large plants usually contain multiple equipment suites.

**Process Unit or Batch Unit** A process unit is a collection of processing equipment that can, at least at certain times, be operated in a manner completely independent of the remainder of the plant. A process unit normally provides a specific function in the production of a batch of product. For example, a process unit might be a reactor complete with all associated equipment (jacket, recirculation pump, reflux condenser, and so on). However, each feed preparation tank is usually a separate process unit. With this separation, preparation of the feed for the next batch can be started as soon as the feed tank is emptied for the current batch.

All but the very simplest equipment suites contain multiple process units. The minimum number of process units is one for each type of processing equipment required to make a batch of product. However, many equipment suites contain multiple process units of each type. In such equipment suites, multiple batches and multiple production runs can be in progress at a given time.

**Item of Equipment** An item of equipment is a hardware item that performs a specific purpose. Examples are pumps, heat exchangers, agitators, and the like. A process unit could consist of a single item of equipment, but most process units consist of several items of equipment that must be operated in harmony to achieve the function expected of the process unit.

**Device** A device is the smallest element of interest to batch logic. Examples of devices include measurement devices and final control elements.

## STRUCTURED BATCH LOGIC

Flexible batch applications must be pursued by using a structured approach to batch logic. In such applications, the same processing equipment is used to make a variety of products. In most facilities, little or no proprietary technology is associated with the equipment itself; the proprietary technology is how this equipment is used to produce each of the products.

The primary objective of the structured approach is to separate cleanly the following two aspects of the batch logic:

**Product Technology** This encompasses the technology such as how to mix certain molecules to make other molecules. This technology ultimately determines the chemical and physical properties of the final product. The product recipe is the principal source for the product technology.

**Process Technology** The process equipment permits certain processing operations (e.g., heat to a specified temperature) to be undertaken. Each processing operation will involve certain actions (e.g., opening appropriate valves).

The need to keep these two aspects separated is best illustrated by a situation where the same product is to be made at different plants. While it is possible that the processing equipment at the two plants is identical, this is rarely the case. Suppose one plant uses steam for heating its vessels, but the other uses a hot oil system as the source of heat. When a product recipe requires that material be heated to a specified temperature, each plant can accomplish this objective, but each will go about it in quite different ways. The ideal case for a product recipe is as follows:

1. It contains all the product technology required to make a product.
2. It contains no equipment-dependent information, i.e., no process technology.

In the previous example, such a recipe would simply state that the product must be heated to a specified temperature. Whether heating is undertaken with steam or hot oil is irrelevant to the product technology. By restricting the product recipe to a given product technology, the same product recipe can be used to make products at different sites. At a given site, the specific approach to be used to heat a vessel is important. The traditional approach is for an engineer at each site to expand the product recipe into a document that explains in detail how the product is to be made at the specific site. This document goes by various names, although *standard operating procedure* or *SOP* is a common one. Depending on the level of detail to which it is written, the SOP could specify exactly which valves must be opened to heat the contents of a vessel. Thus, the SOP is site-dependent and contains both product technology and process technology.

In structuring the logic for a flexible batch application, the following organization permits product technology to be cleanly separated from process technology:

- A recipe consists of a formula and one or more processing operations. Ideally, only product technology is contained in a recipe.
- A processing operation consists of one or more phases. Ideally, only product technology is contained in a processing operation.
- A phase consists of one or more actions. Ideally, only process technology is contained in a phase.

In this structure, the recipe and processing operations would be the same at each site that manufactures the product. However, the logic that comprises each phase would be specific to a given site. In the earlier heating example, each site would require a phase to heat the contents of the vessel. However, the logic within the phase at one site would accomplish the heating by opening the appropriate steam valves, while the logic at the other site would accomplish the heating by opening the appropriate hot oil valves.

Usually the critical part of structuring batch logic is the definition of the phases. There are two ways to approach this:

1. Examine the recipes for the current products for commonality, and structure the phases to reflect this commonality.
2. Examine the processing equipment to determine what processing capabilities are possible, and write phases to accomplish each possible processing capability.

There is the additional philosophical issue of whether to have a large number of simple phases with few options each, or a small number of complex phases with numerous options. The issues are analogous to structuring a complex computer program into subprograms. Each possible alternative has advantages and disadvantages.

As the phase contains no product technology, the implementation of a phase must be undertaken by those familiar with the process equipment. Furthermore, they should undertake this on the basis that the result will be used to make a variety of products, not just those that are initially contemplated. The development of the phase logic must also encompass all equipment-related safety issues. The phase should accomplish a clearly defined objective, so the implementers should be able to thoroughly consider all relevant issues in accomplishing this objective. The phase logic is defined in detail, implemented in the control system, and then thoroughly tested. Except when the processing equipment is modified, future modifications to the phase should be infrequent. The result should be a very dependable module that can serve as a building block for batch logic.

Even for flexible batch applications, a comprehensive menu of phases should permit most new products to be implemented by using currently existing phases. By reusing existing phases, numerous advantages accrue:

1. The engineering effort to introduce a new recipe at a site is reduced.
2. The product is more likely to be on-spec the first time, thus avoiding the need to dispose of off-spec product.
3. The new product can be supplied to customers sooner, hopefully before competitors can supply the product.

There is also a distinct advantage in maintenance. When a problem with a phase is discovered and the phase logic is corrected, the correction is effectively implemented in all recipes that use the phase. If a change is implemented in the processing equipment, the affected phases must be modified accordingly and then thoroughly tested. These modifications are also effectively implemented in all recipes that use these phases.

# BIOPROCESS CONTROL

## CHALLENGES OF BIOPROCESS CONTROL

Bioprocesses form a subcategory of processes where the reaction and/or separation is taking place via biological microorganisms such as bacteria, yeasts, or fungi. What distinguishes bioprocesses from other processes from a control point of view is that most of the processes are batch processes and that it is challenging to obtain measurements for many of the process variables of interest. As such, batch process control and model predictive control are often used to control the trajectory of the controlled variables during a batch, and run-to-run control plays a role to counter long-term drifts from one batch to the next. Also, inferential measurements, via observers, Kalman filters, or correlations, play a key role for bioprocess control as important process variables need to be predicted rather than directly measured.

## BIOPROCESSES

Bioprocesses usually require one or more reaction steps in addition to separation processes, similar to what is done for traditional chemical processes. The reaction steps often require microorganisms, and in this case the process is referred to as *fermentation.* Fermentation can be performed as a continuous or a batch process, affecting the dynamics and control of the operation. Separations can include processes found in traditional chemical processes that can handle solids; these unit operations are often found in bioprocesses but can also include operations such as crystallization.

**Fermentation** Fermentation is a unit operation involving biochemical reactions in the presence of microorganisms. The microorganisms convert one or more of the reactants to desired products. Commonly used microorganisms are yeasts, bacteria, or fungi. Controlling operating conditions during fermentation is a key challenge as the microorganisms have a small range of operating conditions where they perform optimally. Furthermore, deviations from the desired operating conditions can lead to die-off of the microorganisms, which stops the fermentation process. Typical controlled variables for fermenters are temperature, pH, nutrient concentration, and dissolved oxygen. Manipulated variables often include sterile airflow, nutrient feed, pressure, cooling water flow, and agitation rate. Operating modes for bioreactors are discontinuous (or batch) mode, semicontinuous (or fed-batch), continuous (or chemostat), or sequencing batch reactors, which is a combination of the aforementioned. As a number of fermentation processes operate in some form of a batch mode, batch control is an important consideration. Batch control can take different forms, such as optimization of the set-point trajectories during a batch or batch-to-batch control from one batch to the next.

One aspect related to modeling and control that sets fermenters apart from regular chemical reactors is that the reaction rates describing the process are in the form of Monod kinetics [Gernaey, Jeppsson, Vanrolleghem, and Copp (eds.), *Benchmarking of Control Strategies for Wastewater Treatment Plants*, IWA Publishing, London, 2014] or modifications thereof, due to the presence of microorganisms.

**Separations** Final product concentration requirements are often greater than 99 percent purity. However, products produced via fermentation are characterized by relatively low yields, often in the 1 to 15 percent range. As such, fermentation is almost always followed by some form of separation process. These separation processes must take into account product size, density, vapor pressure, or solubility. Common separation processes for bioproducts are distillation, solvent extraction, stripping, reverse osmosis, ultrafiltration, centrifugation, flotation, or evaporation. The choice of separation technology used is dependent upon the feedstock and product characteristics.

## CHARACTERISTICS OF BIOPROCESS CONTROL

One key characteristic of bioprocesses is that they are mostly batch processes, which require control of time-varying trajectories of the controlled variables during a batch as well as adjustments from one batch to the next via run-to-run control. Furthermore, bioprocesses are often characterized by a lack of measurement capabilities for controlled variables, which requires the use of inferential measurements.

**Batch Control** As discussed in an earlier section on batch process control, the product is made in discrete batches by sequentially performing a number of processing steps in a defined order on the raw materials and intermediate products. For example, the first step in fermentation is usually an inoculation step where a small number of culture cells are transferred to the fermenter, which is followed by an exponential growth phase until either a component becomes limiting (oxygen, carbon source) or inhibiting (substrate, product, by-products, etc.). Furthermore, many bioprocesses also include a step in which the culture is switched from a "growth" mode to a "product synthesis" mode, often triggered by a programmed shift in temperature or by a chemical addition. Last, batch fermentation involves draining the vessel, product separation, drying, and packaging. Large production runs are achieved by repeating the process. The term *recipe* has a range of definitions in batch processing, but in general a recipe is a procedure with the set of data, operations, and control steps to manufacture a particular grade of product. A formula is the list of recipe parameters, which includes the raw materials, processing parameters, and product outputs. A recipe procedure has operations for both normal and abnormal conditions. Each operation contains resource requests for certain ingredients (and their amounts). The operations in the recipe can adjust set points and turn equipment on and off. The complete production run for a specific recipe is called a *campaign* (multiple batches). A production run consists of a specified number of batches using the same raw materials and making the same product to satisfy customer demand. The accumulated batches are called a *lot* [Smith, *Control of Batch Processes*, Wiley, New York, 2014; Rosenof and Ghosh, *Batch Process Automation: Theory and Practice*, Van Nostrand Reinhold, New York, 1987].

In multigrade batch processing, the instructions remain the same from batch to batch, but the formula can be changed to yield modest variations in the product. In flexible batch processing, both the formula (recipe parameters) and the processing instructions can change from batch to batch. The recipe for each product must specify both the raw materials required and how conditions within the reactor are to be sequenced in order to make the desired product.

Many batch plants, especially those used to manufacture pharmaceuticals, are certified by the International Standards Organization (ISO). ISO 9000 (and related standards 9001–9004) states that every manufactured product should have an established, documented procedure, and the manufacturer should be able to document that the procedure was followed. Companies must pass periodic audits to maintain ISO 9000 status. Both ISO 9000 and the U.S. Food and Drug Administration (FDA) require that only a certified recipe be used. Thus, if the operation of a batch becomes "abnormal," then performing any unusual corrective action to bring it back within the normal limits is not an option. Also, if a slight change in the recipe apparently produces superior batches, the improvement cannot be implemented unless the entire recipe is recertified. The FDA typically requires product and raw material tracking, so that product abnormalities can be traced back to their sources.

**Batch Process Control Hierarchy** Functional control activities for batch process control are summarized below in four categories: batch sequencing and logic control, control during the batch, run-to-run control, and batch production management [Bonvin, "Optimal Operation of Batch Reactors—A Personal View," *Journal of Process Control* **8:** 355 (1998); Pekny and Reklaitis, "Towards the Convergence of Theory and Practice: A Technology Guide for Scheduling/Planning Methodology," Foundations of Computer-Aided Process Operations (FOCAPO) Conference Proceedings, *AIChE Symposium Series* **94:** 91 (1998); Seborg, Edgar, Mellichamp, and Doyle, *Process Dynamics and Control*, 4th ed., Wiley, New York, 2016].

In batch sequencing and logic control, sequencing of control steps that follow the recipe involves, for example, mixing of ingredients, heating, waiting for a reaction to complete, cooling, or discharging the resulting product. Transfer of materials to and from batch tanks or reactors includes metering of materials as they are charged (as specified by each recipe) as well as transfer of materials at the completion of the process operation. In addition to discrete logic for the control steps, logic is needed for safety interlocks to protect personnel, equipment, and the environment from unsafe conditions. Process interlocks ensure that process operations can only occur in the correct time sequence.

Feedback control of flow rate, temperature, pressure, composition, and level, including advanced control strategies, falls under control during the batch, which is also called "within-the-batch" control [Bonvin, "Optimal Operation of Batch Reactors—A Personal View," *Journal of Process Control* **8:** 355 (1998); Pekny and Reklaitis, "Towards the Convergence of Theory and Practice: A Technology Guide for Scheduling/Planning Methodology," Foundations of Computer-Aided Process Operations (FOCAPO) Conference Proceedings, *AIChE Symposium Series* **94:** 91 (1998)]. In sophisticated applications, this requires defining an operating trajectory for the batch (i.e., temperature or flow rate as a function of time). In simpler cases, it involves tracking of set points of the controlled variables, which includes ramping the controlled variables up and down and/or holding them for a prescribed time. Detection of when the batch operations should be terminated (endpoint) may be performed by inferential measurements of product quality, if direct measurement is not feasible.

Run-to-run control (also called *batch-to-batch*) is a supervisory function based on offline product quality measurements at the end of a run. Operating conditions and profiles for the batch are adjusted between runs to improve the product quality by using tools such as optimization. Batch production management entails advising the plant operator of process status and how to interact with the recipes and the sequential, regulatory, and discrete controls. Complete information (recipes) is maintained for manufacturing each product grade, including the names and amounts of ingredients, process variable set points, ramp rates, processing times, and sampling procedures. Other database information includes batches produced on a shift, daily, or weekly basis as well as material and energy balances. Scheduling of process units is based on availability of raw materials and equipment and customer demand.

The ability to handle recipe changes after a recipe has started is a challenging aspect of batch control systems. Often it is desirable to change the grade of the batch to meet product demand, or to change the resources used by the batch after the batch has started. Because not every batch of product is always good, there needs to be special-purpose control recipes to fix, rework, blend, or dispose of bad batches, if that is allowable. It is important to be able to respond to unusual situations by creating special-purpose recipes and still meet the demand. This procedure is referred to as *reactive scheduling*. When ample storage capacity is available, the normal practice has been to build up large inventories of raw materials and ignore the inventory carrying cost. However, improved scheduling can be employed to minimize inventory costs, which implies that supply chain management techniques may be necessary to implement the schedule [Pekny and Reklaitis, "Towards the Convergence of Theory and Practice: A Technology Guide for Scheduling/Planning Methodology," Foundations of Computer-Aided Process Operations (FOCAPO) Conference Proceedings, *AIChE Symposium Series* **94:** 91 (1998)]. More details on batch control can be found in the earlier subsection Batch Process Control.

**Run-to-Run Control** Run-to-run control, also referred to as batch-to-batch control, is a technique that seeks to address slow-moving drifts from one batch to the next. As batch processes are very common for biological production processes, run-to-run control plays an important role for process automation of these systems [Teixeira, Clemente, Cunha, Carrondo, and Oliveira, "Bioprocess Iterative Batch-to-Batch Optimization Based on Hybrid Parametric/Nonparametric Models," *Biotechnology Progress* **22:** 247–258 (2006)].

Although there are many different types of run-to-run controllers, most controllers utilize a similar structure which includes a process model, an observer, and a control law. The process model is used to relate the measurable inputs and states to the desired product qualities. Next, an observer is used to estimate the model parameters while filtering process noise and unmodeled dynamics. Finally, the control law specifies how the input recipe should be modified to keep the process on target. This is usually a plant inversion or a deadbeat control law [Bonvin, Srinivasan, and Ruppen, *Dynamic Optimization in the Batch Chemical Industry*, Proceedings CPC-VI, Tucson, Ariz., 2001; Edgar, Butler, Campbell, Pfeiffer, Bode, Hwang, Balakrishnan, and Hahn, "Automatic Control in Microelectronics Manufacturing: Practices, Challenges, and Possibilities," *Automatica* **36**(11): 1567–1603 (2000); Alford, "Bioprocess Control: Advances and Challenges," *Computers and Chemical Engineering* **30**(10-12): 1464–1475 (2006)].

Two commonly used run-to-run algorithms are the *exponentially weighted moving average* (EWMA) controller and a variation of the *optimizing adaptive quality controller* (OAQC) [Del Castillo and Yey, "An Adaptive Run-to-Run Optimizing Controller for Linear and Nonlinear Semiconductor Processes," *IEEE Transactions on Semiconductor Manufacturing* **11**(2): 285–295 (1996)]. In addition to these two run-to-run controllers, other run-to-run control algorithms include the predictive corrector controller, knowledge-based interactive controller, model predictive run-to-run controller, time-based exponentially weighted moving average controller, and the generic cell controller. For further details on the implementation of these algorithms, see Åström and Wittenmark, *Adaptive Control*, 2d ed., Addison Wesley, Reading, Mass., 1994.

The *single-input single-output* (SISO) EWMA run-to-run controller assumes a linear model with constant gain and a bias that only drifts slowly over time. As the bias can change with time, it is estimated by weighting the most recent observations more heavily than older observations.

In contrast to the EWMA run-to-run controller, the optimizing adaptive quality controller estimates both the gain and the bias recursively [Åström and Wittenmark, *Adaptive Control*, 2d ed., Addison Wesley, Reading, Mass., 1994; Del Castillo and Yey, "An Adaptive Run-to-Run Optimizing Controller for Linear and Nonlinear Semiconductor Processes," *IEEE Transactions on Semiconductor Manufacturing* **11**(2): 285–2950 (1996)].

**Inferential Sensors via Estimation** A small number of online sensors are commonly used in bioprocesses such as temperature, fermenter pressure, gas flow rates, agitation rate, dissolved oxygen, and pH. Some fermentation rates include a few additional probes, e.g., dissolved carbon dioxide, oxidation reduction, and optical density.

The lack of direct measurements of certain controlled variables is one of the challenges of bioprocess control problems [Dochain (ed.), *Automatic Control of Bioprocesses*, Wiley, New York, 2008]. For example, a number of fermentation processes rely on the concentration of active yeast in the fermenter; however, available online measurement techniques cannot distinguish between active yeast and inactive/dead yeast. As such, the concentration of active yeast has to be inferred from other available measurements. Inferring the quantity of one variable by measuring other variables is performed via an inferential sensor, sometimes also called a *soft sensor*. Examples of soft sensors are Kalman filters, moving horizon estimators, Luenberger observers, or, in simpler cases, algebraic relationships. The one aspect that all these inferential sensors have in common is that they are based upon the solution of an inverse problem that computes the variables of interest from available measurements via a model connecting the inferred and measured variables. The quality of this model is very important because an inferential sensor based upon a poor model will result in poor predictions and will degrade control quality.

**Optimization of Set-Point Trajectory during a Batch** Batch control requires that specific trajectories of the controlled variables be followed in order to maximize product yield, minimize cost and use of raw materials, and/or meet environmental requirements. Often the set-point trajectories are determined based upon heuristics and prior knowledge of a process. If a model of the process is available, then the trajectories can be computed in order to meet specific requirements. For example, the trajectory of the temperature set point can be computed for a fermentation process in order to maximize the product concentration at the end of the batch. The implementation of this trajectory can then be performed via batch control, model predictive control, or regular PID control.

**Model Predictive Control** *Model predictive control* (MPC) is a model-based control technique often used for bioprocess control. It is the most popular technique for handling multivariable control problems with multiple inputs and multiple outputs (MIMO) and can also accommodate inequality constraints on the inputs or outputs such as upper and lower limits. All these problems are addressed by MPC by solving an optimization problem, and therefore no complicated override control strategy is required [Seborg, Edgar, Mellichamp, and Doyle, *Process Dynamics and Control*, 4th ed., Wiley, New York, 2016].

Usually, MPC implementations change set points in order to move the plant to a desired steady state; the actual control changes are implemented by PID controllers in response to the set points. MPC is one of the most popular advanced control strategies and, among its other uses, can be used to determine optimal set-point trajectories that should be followed over the course of a batch process.

Complex interactions between different manipulated and controlled variables are common in bioprocesses, which makes MPC a popular control strategy for these types of processes. Furthermore, software packages that implement MPC solutions are now available from a variety of vendors which make their adoption straightforward with adequate engineering personnel. More details on MPC can be found in the earlier subsection Advanced Control Systems.

## BIOPROCESS CONTROL APPLICATIONS

**Biofuels** Fuel-grade ethanol is produced in one of two ways, using either the wet mill or dry mill process. Wet milling involves separating the grain kernel into different components: germ, fiber, protein, and starch. The starch then undergoes the processes of liquifaction, saccharification, and fermentation separately. The focus here is on dry-mill–based plants, where the entire grain kernel is ground into flour, and the flour is transported into the cook tank allowing for complete water penetration. Then, the starch inside the flour is hydrolyzed into dextrin as it passes through the liquifaction tank, as shown in Fig. 8-60. Dextrin, which is a mixture of different

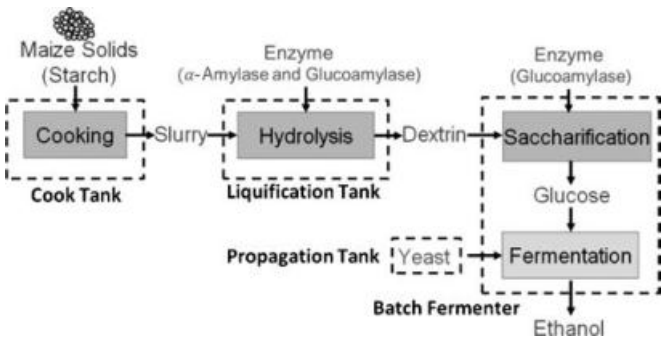

**FIG. 8-60** Ethanol process flowsheet.

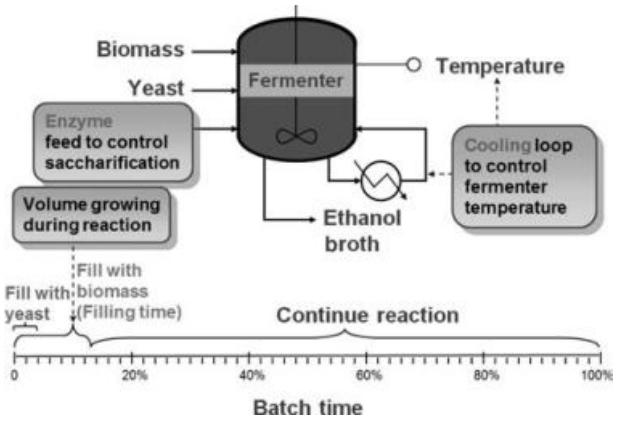

**FIG. 8-61** Ethanol fermentation batch control strategy.

long-chain sugars (maltose, $D_3$, $D_4$ to $D_7$), then enters the batch fermenter and undergoes a *simultaneous saccharification and fermentation* (SSF) process in response to the addition of enzymes and of yeast from the propagation tank [Schweiger, Sayyar-Rodsari, Bartee, and Axelrud, "Plant-wide Optimization of an Ethanol Plant Using Parametric Hybrid Models," *49th IEEE Conference on Decision and Control*, Atlanta, Georgia, pp. 3896–3901, 2010].

A general overview of the SSF process and a timeline describing batch operation are shown in Fig. 8-61 [Dai, Word, and Hahn, "Modeling and Dynamic Optimization of Fuel-grade Ethanol Fermentation Using Fed-batch Process," *Control Eng. Practice* **22:** 231–241, 2014]. Measurements of the SSF process include ethanol and dextrose concentrations at a few regular time intervals and temperatures at a much higher frequency, usually every few minutes. The two key manipulated variables are the cooling water flow rate and the enzyme addition rate. The cooling system is operating during the entire fermentation, while the enzyme is added only during the filling phase, which ranges from the first 10 to 20 percent of the batch time.

The cooling water flow rate is usually controlled by a regular feedback controller, e.g., a PI controller, based upon the temperature measurement. However, note that it is often not the goal of this control scheme to keep the temperature in the fermenter constant over the course of a batch; instead the temperature should follow a preset temperature trajectory where the trajectory is either predetermined to maximize ethanol yield or based upon past experience with the process. In contrast to the temperature control, the enzyme addition rate is often manually controlled, and enzyme is only added during the filling phase. It is not uncommon for the enzyme addition rate to be constant during either part or the entire filling phase. The exact trajectory to follow for the enzyme addition rate is usually determined by experience with a particular plant.

**Pharmaceuticals** Production of pharmaceuticals is one area in which bioprocesses play a key role. There are two major stages involved in pharmaceutical manufacturing: the production of active ingredients and the conversion of active ingredients to drugs suitable for administration. The main manufacturing steps in pharmaceutical processing are (1) preparation of process intermediates, (2) introduction of functional groups, (3) esterification and coupling, (4) separation, and (5) final product purification. Additional production processes can include granulation, drying, tablet pressing/coating, filling, or packaging; however, none of these additional steps involve bioprocesses [Buckbee and Alford, *Automation Applications in Bio-Pharmaceuticals*, ISA, Research Triangle Park, N.C., 2008].

The production of monoclonal antibodies is now the largest product of the pharmaceutical industries with annual sales exceeding $45 billion. Approximately 40 percent of all pharmaceuticals in R&D are now biopharmaceuticals, and the trend is that this number will increase further in the future [Rader and Langer, "Upstream Single-Use Bioprocessing Systems Future Market Trends and Growth Assessment," *BioProcess International Magazine* **10**(2): 1218, 2012].

**Wastewater Treatment** Wastewater treatment plants are needed to meet stringent environmental regulations controlling water quality. Bioprocesses play an important role in wastewater treatment. The key challenges for wastewater treatment facilities are large perturbations in the wastewater flow rate, load, and composition. Most treatment facilities are operated continuously.

A number of models for wastewater treatment plants exist that have been extensively used for developing control strategies. The *activated sludge models* (ASMs) have been developed since the 1980s and applied to full-scale wastewater treatment plants for optimization. These models are quite generic, but can be tailored for particular treatment facilities once parameters related to sludge production and nutrients in the effluent have been estimated [Mogens, Gujer, Mino, and van Loosdrecht, *Activated Sludge Models ASM1, ASM2, ASM2d and ASM3*, IWA Publishing, London, 2000]. ASM1 was the first developed model and formed the foundation for a variety of extensions. The most popular models are ASM2, ASM2d, and ASM3P and they focus on improving prediction of nitrogen and phosphorus removal over ASM1 [Szilveszter, Ráduly, Ábrahám, Lányi, and Niculae, "Mathematical Models for Domestic Wastewater Treatment Process," *Environmental Engineering and Management Journal* **9**(5): 629–636, 2010].

While a number of control strategies have been proposed in the literature for improved and more efficient operation of wastewater treatment plants [Gernaey, Jeppsson, Vanrolleghem, and Copp (Eds.), *Benchmarking of Control Strategies for Wastewater Treatment Plants*, IWA Publishing, London, 2014], the evaluation and comparison of these strategies is nontrivial. Reasons for this are that the influent can vary significantly, but also that the biological/biochemical phenomena are not well characterized, and that time constants of the process range from a few minutes to several days. Nevertheless, a significant amount of work has been done on controlling wastewater treatment plants; see Gernaey, Jeppsson, Vanrolleghem, and Copp (eds.), *Benchmarking of Control Strategies for Wastewater Treatment Plants*, IWA Publishing, London, 2014 for more details.

**Food Processing** Almost all production facilities for food processing require bioprocesses that need to be appropriately operated and controlled. One area where bioprocesses play a critical role is fermentation for the production of beer and other alcoholic beverages. One indicator of the importance of this industry is that brewers in the United States produced 196 million barrels of beer in 2012 [*Brewers Almanac 2013*, The Beer Institute, March 7, 2014], which resulted in sales of over $100 billion. The brewing process consists of several steps which include malting, milling, mashing, lautering, boiling, fermenting, conditioning, filtering, and packaging. The three most commonly used fermentation methods are warm, cool, and spontaneous fermentation, where the fermentation may take place in an open or closed fermenting vessel.

Production of snack foods, which had a worldwide market of $66 billion in 2003 [Nikolaou, "Control of Snack Food Manufacturing Systems: Potato Chips and Micro-Chips are More Similar than Commonly Believed," *IEEE Control Systems Magazine*, Special issue on Process Control, **26**(4): 40–54, 2006], is another area that involves bioprocesses. A relatively small number of processes are used, which include extrusion, frying, baking, and drying. Food processing generally involves serial operations of these unit operations. One of the challenges for control of food processing is a limited number of intermediate variables that assess product quality, which prevents subsequent steps from counteracting disturbances that have occurred at earlier unit operations as the effect of these disturbances on the current state of the (unfinished) product are not known. Similarly, raw materials can vary widely from one batch to the next, which poses a control challenge.

# TELEMETERING AND TRANSMISSION

Digital technology is used for data collection, feedback control, and all other information processing requirements in production facilities. Such systems must acquire data from a variety of measurement devices, and control systems must drive final control elements. Until the turn of this century, digital systems relied on the same technology as their analog predecessors, primarily analog signal transmission in the form of current loops. Digital transmission permits values to be transmitted in engineering units, and it is gradually displacing analog signal transmission.

## FIELDBUS

*Fieldbus* is the generic name of a family of industrial communications networks intended for data acquisition and control applications in industrial facilities, both process and manufacturing. IEC 61158, "Digital Data Communications for Measurement and Control," defines five different communications technologies, each considered to be a fieldbus. Most expect a standard to define one and only one way of doing something, but the

computer industry does things differently. Consequently, one person's "fieldbus" might not be the same as another person's.

The delays in developing the standard led to a slow acceptance of fieldbus technology by the user community. Most plants have preferred suppliers for various technologies, including measurement devices, controllers, valves, variable-frequency drives (VFDs), etc. Users were understandably reluctant to proceed with digital communications until they could be confident that their preferred suppliers could provide as a standard offering an interface to the user's preferred fieldbus technology.

To some extent, the multiple fieldbus technologies reflect the difference in the mixture of I/O points. In the manufacturing industries, 90 percent or more of the I/O points are discrete; *numerical controllers* and *programmable logic controllers* (PLCs) are preferred. In the continuous process industries, 50 percent or more of the I/O points are analog; *distributed control systems* (DCSs) are preferred. In batch facilities, discrete I/O exceeds analog I/O, and both DCSs and PLCs are used as controllers.

In process facilities in the United States, Foundation Fieldbus technology is preferred; in Europe, Profibus technology is preferred. Most manufacturers of smart transmitters, smart valves, VFDs, etc. can supply interfaces for either (and usually a current loop interface as well). Most plants select one technology for their fieldbus, although it is possible to have both Foundation Fieldbus and Profibus interfaces on a given control system.

Eventually fieldbus technology will displace all other forms of data transmission within process facilities. A fieldbus of some type is generally preferred for new construction. Smart transmitters and smart valves gained widespread acceptance long before the fieldbus, so most were installed using current loops. The installed base of electronic current loops is large, but current loop interfaces will gradually disappear.

The major advantages of fieldbus technologies lie in installation and commissioning. With fewer wires and connections, fieldbus installations start with fewer errors that can be located and corrected more rapidly. Once a fieldbus installation is up and running, modifications and additions are much easier, saving both time and money.

Current loop transmission requires dedicated circuits to connect each measurement device and final control element to the controller. Fieldbus permits a single circuit, often called a *segment* or *trunk*, to be used to communicate with a mixture of measurement devices and final control elements, each of which connects to the cable as a "drop" or "node." A fieldbus segment is a shielded twisted-pair wire that serves two purposes: two-way digital signal transmission and DC power for devices with low power requirements. These two-wire fieldbus devices are analogous to two-wire current loop transmitters (explained subsequently). Devices with high power requirements are supported as four-wire fieldbus devices. Wireless communications technology is available for fieldbus, but power must be separately provided.

The fieldbus communications protocols provide for 32 drops or nodes. However, power considerations usually limit the number of devices on a segment to about one-half of this. So that the electronic equipment cannot be a source of ignition, the electrical classifications of most process applications require intrinsically safe circuits (the alternative of explosion-proof or purged enclosures is prohibitively expensive). The approach from current loops of using barriers to limit the amount of energy in the field circuit can also be applied to fieldbus. However, this permits only four devices to be connected to a segment, which increases the number of segments and the costs. Alternate approaches permit a larger number of devices to be connected to a segment, but with some increase in wiring complexity.

Each fieldbus segment must be connected to the data acquisition and control system through an interface card or coupler. These are very different between Foundation Fieldbus and Profibus. For Foundation Fieldbus the power supply is separate from the interface card; for Profibus the power supply is part of the coupler. Communication on Profibus is a master-slave arrangement; the devices (the slaves) can respond only to communications from the data acquisition and control system (the master). Communications on Foundation Fieldbus permit devices to communicate with other devices on the network as well as with the data acquisition and control system.

The data acquisition and control system must be told what devices are on each segment of the fieldbus (not exactly "plug and play"). For each device on a segment, a *device description* (DD) file specifies the input and output variables, the available functions, and other parameters. Originally, Foundation Fieldbus and Profibus used identical text-based files that can be downloaded from a web site. Supporting additional features necessitated the incorporation of extensions into the files, but these are specific to Foundation Fieldbus (EDDL for Electronic Device Description Language) and Profibus (FDT for field device tool). Suppliers of data acquisition and control systems have somewhat insulated the user by supporting both, but the user is responsible for verifying that each field device is compatible with the requirements imposed by the fieldbus in use.

## INDUSTRIAL INTERNET OF THINGS AND CLOUD COMPUTING

The impact of the Internet on retail, banking, and other consumer-oriented industries has been dramatic. Will it similarly impact the process industries? The Industrial Internet of Things (IIoT) envisions connecting the various islands of automation within industrial facilities to each other and to the cloud. Time will tell if this offers real opportunities in the process industries or is largely hype.

Fieldbus technology provides communications between a data acquisition and control system and the various field devices, primarily measurement devices and final control elements. Industrial Ethernet is commonly used in process facilities to communicate from one automation system to another (called *machine-to-machine* or *M2M* communications). Although targeted to distinct layers in the automation hierarchy, the fieldbus and industrial Ethernet technologies overlap and could eventually merge.

An often cited benefit is the application of "big data" analytics to the large quantity of data that can be acquired. The IIoT coupled with the cloud promises to lower the barriers to exploring the potential of such analytics. The analytical programs are available for installation within a company's computing systems. For something that is promising but not proved, a major obstacle is implementing the required software by IT people who already have much to do. The alternative is to prove the worth of the endeavor by using software available through the cloud. Especially at the exploratory stage of an endeavor, purchasing processing and storage from the cloud lowers initial costs and does not incur long-term commitments.

The initial application of the IIoT will be activities that impact operational efficiency, such as dynamic scheduling within a batch facility. Such activities can be pursued with minimal impact on the current structures and practices within the industry. However, the IIoT makes it possible to rethink the industry's approach to many activities. Is it possible to control a process plant using software and computing from the cloud? At the time of this writing, such capability is not available, but with the current processing and communications speeds, all technical issues, including nonstop computing, could be resolved. But providing process control from the cloud is a major departure from the current practice of pushing all processing to the lowest possible level in the hierarchy. Discussions regarding the pros and cons will be lengthy, heated, and possibly more emotional than technical. Process control must stay in the mainstream of computing technology, so the discussions will commence.

## ANALOG SIGNAL TRANSMISSION

For analog signal transmission the transmitter converts the value in engineering units to an analog signal that can be transmitted over some distance. The signal ranges are as follows:

*Pneumatic*: 3 to 15 psi.

*Electronic*: 4 to 20 mA. The result is a circuit, known as a *current loop*, that is less susceptible than voltage to electrical interference from the power equipment present in industrial facilities.

Pneumatic transmission has largely disappeared. Electronic transmission will eventually suffer the same fate, but at the time of this writing the installed base is too large to be ignored.

To transmit a value, the source or transmitter converts the process value (temperature, pressure, valve opening, etc.) to a scaled value that can be transmitted as a signal. The lower range of the signal is 4 mA and corresponds to the lower-range value of the process value in engineering units. The upper range of the signal is 20 mA and corresponds to the upper-range value of the process value in engineering units. The relationship between the process value and the signal value is linear. For modern electronic equipment, the departure from linearity is rarely an issue.

Converting the input signal to an engineering value is a three-step process:

1. *Convert current to voltage.* Current is used for transmission, but all internal signal processing is based on voltages. Inserting a 250-Ω *range resistor* into the circuit converts the 4- to 20-mA signal to a 1- to 5-V input. A nominally more complex circuit can convert the signal to a 0 to 5-V input.

2. *Digitize the voltage input.* The analog-to-digital (A/D) converter translates the input voltage to a short (16-bit) integer known as the *raw value*. A/D converters may be unipolar (voltage input must be positive) or bipolar (voltage input may be positive or negative). Of greater importance in process applications is the resolution, which is the number of data bits in the converted value. A 12-bit bipolar A/D converter provides 11 data bits plus a sign bit. A 12-bit unipolar A/D converter provides 12 data bits. The resolution provided by 11 data bits is 1 part in $2^{11}$ (2048), which is approximately 0.05 percent. Although adequate for older analog or dumb measurement devices, higher resolutions are appropriate for the microprocessor-based smart transmitters. Especially in control applications that use the derivative

mode of control, the resolution should be consistent with the repeatability of the measurement device, which is generally better than its accuracy.

3. *Convert raw value to engineering units.* Digital systems do this in software. The conversion software requires two parameters: the lower-range value (corresponds to 4 mA) and the upper-range value (corresponds to 20 mA). The relationship between the raw value and the engineering value is assumed to be linear, but with one exception. For inputs from head-type flow meters, the lower- and upper-range values are in flow units, but the 4- to 20-mA signal may be the sensed value for the differential pressure. To convert the raw value to flow units, a square root must be incorporated into the computations, and process control systems continue to provide this option. However, most smart differential pressure transmitters can be configured to "transmit in flow units," which means the square root is incorporated into the calculations within the transmitter and the 4- to 20-mA signal is the measured value of the flow.

Some, but not all, "5-V A/D converters" have an input range of 0 to 5.12 V. For an A/D converter with 11 data bits, 5.12 V converts to a raw value of 2047. A 5-V input converts to 2000, giving a resolution of 1 part in 2000 (exactly 0.05 percent) over the 0- to 5-V range. This practice will be assumed in subsequent discussions, but is not universal.

Converting a 4- to 20-mA signal to a 1- to 5-V input has consequences for the resolution. For an A/D converter with 11 data bits, 1 V converts to a digital value of 400. Thus, the range for the digital value is 400 to 2000, making the effective input resolution 1 part in 1600 (0.0625 percent). Sometimes this is expressed as a resolution of 10.6 bits, where $2^{10.6} = 1600$. Using slightly more complex input circuitry to convert the 4- to 20-mA signal to a 0- to 5-V input gives a resolution of 1 part in 2000.

For most measurement devices *two-wire* transmitters are possible. The measurement device is powered over the same circuit used for signal transmission. For measurement devices requiring higher power levels, *four-wire* transmitters (power is separate from the current loop) must be installed.

The electrical classification for most areas of a process entail intrinsically safe circuits (the alternative of explosion-proof or purged enclosures is costly). For two-wire transmitters, the usual practice is to install barriers to limit the amount of power in the field part of the circuit.

Especially when the measured value is the input to a controller, the consequences of a failure known as a "broken wire" must be assessed. For current loops, the result is an open circuit, causing the measured variable to fail to its lower-range value. The consequences may be undesirable. For a fired heater that is heating material to a target temperature, failure of the temperature measurement to its lower-range value drives the output of the combustion control logic to the maximum possible firing rate.

In such applications, the analog transmission signal could be inverted, with the upper range corresponding to 4 mA and the lower range corresponding to 20 mA. On an open circuit, the measured variable fails to its upper range. For the fired heater, failure of the measured variable to its upper range drives the output of the combustion control logic to the minimum firing rate.

An even better approach is for the receiver to distinguish between 4 mA and 0 mA. The former means that the measured value is equal to its lower-range value. The latter is an open circuit, meaning that the measured value is unknown. On an open circuit, the conversion software can be configured to fail to lower-range value, fail to upper-range value, or hold the last value (freeze). If the measured value is the input to a controller, the controller behavior on an invalid value of the measured variable could be to fail to lower output limit, fail to upper output limit, or hold the last value.

## MICROPROCESSOR-BASED SMART TRANSMITTERS

In all aspects of process control the preference is to express everything in engineering units. Although slower than most desired, alternatives to analog signal transmission have become common. Several examples will be presented, beginning with smart transmitters.

Smart transmitters offer several benefits over dumb transmitters:

1. They check on the internal electronics, such as verifying that the voltage levels of internal power supplies are within specifications.
2. They check on environmental conditions within the instruments, such as verifying that the case temperature is within specifications.
3. They perform compensation of the measured value for conditions within the instrument, such as compensating the output of a pressure transmitter for the temperature within the transmitter. Smart transmitters are much less affected by temperature and pressure variations than are conventional transmitters.
4. They perform compensation of the measured value for other process conditions, such as compensating the output of a capacitance level transmitter for variations in process temperature.
5. They linearize the output of the transmitter. Functions such as square root extraction of the differential pressure for a head-type flow meter can be done within the instrument instead of within the control system.
6. They configure the transmitter from a remote location, such as changing the span of the transmitter output.
7. They do automatic recalibration of the transmitter. Although this is highly desired by users, the capabilities, if any, in this respect depend on the type of measurement.

Improved performance is the main incentive to install smart transmitters. With regard to signal transmission, smart transmitters can be purchased with the following:

*Current loop output.* This option permits a smart transmitter to be a direct replacement for a conventional transmitter. The HART (Highway Addressable Remote Transducer) communication protocol can be used over the current loop circuit for remote configuration via a central system or a handheld configuration tool. The value of the measured variable can be retrieved by HART, but the current loop input provides the value for process control, data acquisition, etc.

*Network interface.* Most manufacturers provide a fieldbus interface in the form of Foundation Fieldbus and/or Profibus. Some also support Modbus/TCP, an Ethernet version of the older Modbus serial communications protocol.

The network interface is clearly the preferred option, but can be pursued only where a fieldbus is installed.

## THERMOCOUPLES AND RESISTANCE TEMPERATURE DETECTORS (RTDs)

Input systems that provide temperatures in engineering units have been available for some time. From a marketing perspective, compatibility with systems designed for current loop inputs has been absolutely necessary. However, this will gradually disappear.

Thermocouples present two issues for input signal processing:

*Low-level signals.* Thermocouple outputs rarely exceed 30 mV. In addition, the output could be zero or even negative. Processing such low-level signals requires a bipolar A/D converter front-ended by an amplifier to boost the signal to voltage levels. Such equipment is available, but with increased complexity and cost.

*Reference junction compensation.* The output from a thermocouple depends on the temperatures at the process junction and the reference junction. Either the reference junction temperature must be sensed, or the reference junction must be maintained at a known temperature. Terminal strips with a temperature sensor embedded for the reference junction temperature are manufactured specifically for this purpose.

Although the input equipment for thermocouples is specialized, thermocouples are easily multiplexed. They are ideally suited for applications where a large number of temperatures must be read on a relatively slow scan rate. Consider monitoring the temperature in a cold storage warehouse to ensure it never exceeds a specified value. Uniform temperatures cannot be assumed, so thermocouples must be installed in several locations. Scan rates such as once per minute are acceptable. For such applications, multiplexers that can accept 100 or more points can be purchased. Although the base cost is large, the cost to add one additional thermocouple input is nominal, making the cost per thermocouple very attractive.

RTDs present different issues:

*Bridge network.* Sensing the resistance of the RTD requires a bridge network.

*Three-wire installations.* For plant applications, three-wire RTD installations are the norm. Both complicate multiplexing RTD inputs. Basically, two options are available:

*Temperature transmitter.* The temperature can be transmitted as a 4- to 20-mA current signal or via fieldbus.

*RTD input card.* Such cards typically accept between 4 and 16 RTDs. Usually the cost per point is less than a dedicated transmitter for each RTD. All inputs to the card must be from the same type of RTD, and all must be converted to the same temperature units (degrees Celsius or degrees Fahrenheit), but rarely are these restrictions a problem in an application.

For thermocouples, similar input cards are available. For both thermocouples and RTDs, advancements in electronics permit the conversion of the input to temperature units, including linearization, reference junction compensation (thermocouples), etc., to be performed on the input card. The following approaches permit such cards to be readily integrated into systems designed for current loop inputs:

*Emulate an input from a current loop.* The input card converts the computed value for the temperature to a short integer raw value, using the lower- and upper-range values for the measurement range for the thermocouple (0 to 750°C for type J) or RTD (−200 to 800°C).

*Express temperature as an integer value to 0.1°C or 0.1°F.* For example, a temperature of 123.4°C gives a raw value of 1234. The value of the temperature is provided in engineering units with a resolution of 0.1°. A resolution of 0.1°C is acceptable in most applications, but not all. In aqueous-based processes such as fermentations, a typical measurement range is 0 to 100°C.

Expressing the temperature to 0.1°C gives a resolution of 1 part in 1000 for this measurement range. Using a current loop and an A/D converter with 12 data bits gives a resolution of 1 part in 4000, or 0.025°C. The latter is more consistent with the repeatability of the RTDs normally installed in such processes.

For fieldbus installations, the counterpart to a thermocouple or RTD input card is a multipoint temperature module. The network interface frees the modules from the restrictions (such as expressing the temperature as a short integer value) resulting from being compatible with current loop inputs.

### MULTIVALUE MEASUREMENT DEVICES

Some measurement devices produce more than one value. Here are two examples:

*Chromatographs*. Since it is a sampling instead of a continuous analyzer, the results pertain to a sample withdrawn from the process. Chromatographs occasionally produce a single value such as the ratio of two key components in the sample. But the more common result is a composition analysis for the sample, with the number of values depending on the number of components of interest. The values are associated in that they pertain to a specific sample. In addition, capturing information such as the analysis time (normally the time the sample was injected) is also a requirement.

*Coriolis meters*. If only the mass flow is of interest, a current loop interface is adequate, and most commercial products provide such an option. But in addition to the flow, the Coriolis meter also senses the temperature and density. Coriolis meters can also sense viscosity, provided this option is purchased. Unlike the chromatograph, these are continuous variables. However, providing current loops for all variables is inconvenient, and most manufacturers do not provide such an option.

For chromatographs, the traditional interface was a serial interface, either RS-232 for point-to-point or RS-485 for multidropped. The major issue is the protocol (the character or byte sequence for transmitting the data). Some were proprietary protocols, requiring custom software in the data acquisition or control system. Some use the MODBUS protocol, developed in 1979 for reading and writing the registers in a PLC. In the context of MODBUS, a register is a 16-bit (short integer) storage location. Transmitting values in engineering units as floating-point numbers requires two consecutive registers but eliminates the need to somehow express values as short integers.

Except in legacy systems, serial interfaces have been replaced almost entirely by network interfaces. Most suppliers provide one or more of the following network interfaces:

1. MODBUS/TCP is essentially an Ethernet version of the MODBUS serial protocol.
2. Foundation Fieldbus.
3. Profibus.

### FILTERING AND SMOOTHING

A signal received from a process transmitter generally contains the following components distinguished by their frequency [ frequencies are measured in hertz (Hz), with 60-cycle ac being a 60-Hz frequency):

1. *Low-frequency process disturbances.* The control system is expected to react to these disturbances.
2. *High-frequency process disturbances.* The frequency of these disturbances is beyond the capability of the control system to effectively react.
3. *Measurement noise.*
4. *Stray electrical pickup, primarily 50- or 60-cycle ac.*

The objective of filtering and smoothing is to remove the last three components, leaving only the low-frequency process disturbances. Normally this has to be accomplished by using the proper combination of analog and digital filters. Sampling a continuous signal results in a phenomenon often referred to as *aliasing* or *foldover*. When a signal is sampled at a frequency $\omega_s$, all frequencies higher than $\omega_s/2$ cannot be represented at their original frequency. Instead, they are present in the sampled signal with their original amplitude but at a lower-frequency harmonic. Because of the aliasing or foldover issues, a combination of analog and digital filtering is usually required. The sampler (i.e., the A/D converter) must be preceded by an analog filter that rejects those high-frequency components such as stray electrical pickup that would result in foldover when sampled. In commercial products, analog filters are normally incorporated into the input processing hardware by the manufacturer. The software then permits the user to specify digital filtering to remove any undesirable low-frequency components.

On the analog side, the filter is often the conventional resistor-capacitor or *RC* filter. However, other possibilities exist. For example, one type of A/D converter is called an *integrating A/D* because the converter basically integrates the input signal over a fixed interval of time. By making the interval $\frac{1}{60}$s, this approach provides excellent rejection of any 60-Hz electrical noise.

On the digital side, the input processing software generally provides for smoothing via the exponentially weighted moving average, which is the digital counterpart to the *RC* network analog filter. The smoothing equation is

$$y_i = \alpha x_i + (1 - \alpha) y_{i-1} \tag{8-58}$$

where $x_i$ = current value of input
$y_i$ = current output from filter
$y_{i-1}$ = previous output from filter
$\alpha$ = filter coefficient ($0 \le \alpha \le 1$)

The degree of smoothing is determined by the filter coefficient $\alpha$, with $\alpha = 1$ being no smoothing and $\alpha = 0$ being infinite smoothing (no effect of new measurements). The filter coefficient $\alpha$ is related to the filter time constant $\tau_F$ and the sampling interval $\Delta t$ by

$$\alpha = 1 - \exp\left(\frac{-\Delta t}{\tau_F}\right) \tag{8-59}$$

or by the approximation

$$\alpha = \frac{\Delta t}{\Delta t + \tau_F} \tag{8-60}$$

Another approach to smoothing is to use the arithmetic moving average, which is represented by

$$y_i = \frac{\sum_{j=1}^{n} x_{i+1-j}}{n} \tag{8-61}$$

The term *moving* is used because the filter software maintains a storage array with the previous $n$ values of the input. When a new value is received, the oldest value in the storage array is replaced with the new value, and the arithmetic average is recomputed. This permits the filtered value to be updated each time a new input value is received.

In process applications, determining $\tau_F$ (or $\alpha$) for the exponential filter and $n$ for the moving average filter is often done merely by observing the behavior of the filtered value. If the filtered value is "bouncing," the degree of smoothing (that is, $\tau_F$ or $n$) is increased. This can easily lead to an excessive degree of filtering, which will limit the performance of any control system that uses the filtered value. The degree of filtering is best determined from the frequency spectrum of the measured input, but such information is rarely available for process measurements.

## DIGITAL TECHNOLOGY FOR PROCESS CONTROL

Since the 1970s, process controls have evolved from pneumatic analog technology to electronic analog technology to microprocessor-based controls. Electronic and pneumatic controllers have now virtually disappeared from process control systems, which are dominated by programmable electronic systems based on microprocessor technology.

### HIERARCHY OF INFORMATION SYSTEMS

Coupling digital controls with networking technology permits information to be passed from level to level within a corporation at high rates of speed. This technology is capable of presenting the measured variable from a flow

transmitter installed in a plant in a remote location anywhere in the world to the company headquarters in less than 1 s.

A hierarchical representation of the information flow within a company leads to a better understanding of how information is passed from one layer to the next. Such representations can be developed in varying degrees of detail, and most companies have developed one that describes their specific practices. The following hierarchy consists of five levels, as shown in Fig. 8-24.

**Measurement Devices and Final Control Elements** This lowest layer couples the control and information systems to the process. The measurement devices provide information on the current conditions within the process. The final control elements permit control decisions to be imposed on the process. Although traditionally analog, smart transmitters and smart valves based on microprocessor technology are now beginning to dominate this layer.

**Safety and Environmental/Equipment Protection** The level 2 functions play a critical role by ensuring that the process is operating safely and satisfies environmental regulations. Process safety relies on the principle of multiple protection layers that involve groupings of equipment and human actions. One layer includes process control functions, such as alarm management during abnormal situations, and safety instrumented systems for emergency shutdowns. The safety equipment (including sensors and block valves) operates independently of the regular instrumentation used for regulatory control in level 3. Sensor validation techniques can be employed to confirm that the sensors are functioning properly.

**Regulatory Controls** The objective of this layer is to operate the process at or near the targets supplied by a higher layer in the hierarchy. To achieve consistent process operations, a high degree of automatic control is required from the regulatory layer. The direct result is a reduction in variance in the key process variables. More uniform product quality is an obvious benefit. However, consistent process operation is a prerequisite for optimizing the process operations. To ensure success for the upper-level functions, the first objective of any automation effort must be to achieve a high degree of regulatory control.

**Real-Time Optimization** Determining the most appropriate targets for the regulatory layer is the responsibility of the RTO layer. Given the current production and quality targets for a unit, RTO determines how the process can be best operated to meet them. Usually this optimization has a limited scope, being confined to a single production unit or possibly even a single unit operation within a production unit. RTO translates changes in factors such as current process efficiencies, current energy costs, cooling medium temperatures, and so on to changes in process operating targets so as to optimize process operations.

**Production Controls** The nature of the production control logic differs greatly between continuous and batch plants. A good example of production control in a continuous process is refinery optimization. From the assay of the incoming crude oil, the values of the various possible refined products, the contractual commitments to deliver certain products, the performance measures of the various units within a refinery, and the like, it is possible to determine the mix of products that optimizes the economic return from processing this crude. The solution of this problem involves many relationships and constraints and is solved with techniques such as linear programming.

In a batch plant, production control often takes the form of routing or short-term scheduling. For a multiproduct batch plant, determining the long-term schedule is basically a *manufacturing resource planning* (MRP) problem, where the specific products to be manufactured and the amounts to be manufactured are determined from the outstanding orders, the raw materials available for production, the production capacities of the process equipment, and other factors. The goal of the MRP effort is the long-term schedule, which is a list of the products to be manufactured over a specified time (often one week). For each product on the list, a target amount is also specified. To manufacture this amount usually involves several batches. The term *production run* often refers to the sequence of batches required to make the target amount of product, so in effect the long-term schedule is a list of production runs.

Most multiproduct batch plants have more than one piece of equipment of each type. Routing refers to determining the specific pieces of equipment that will be used to manufacture each run on the long-term production schedule. For example, the plant might have five reactors, eight neutralization tanks, three grinders, and four packing machines. For a given run, a rather large number of routes are possible. Furthermore, rarely is only one run in progress at a given time. The objective of routing is to determine the specific pieces of production equipment to be used for each run on the long-term production schedule. Given the dynamic nature of the production process (equipment failures, insertion/deletion of runs into the long-term schedule, etc.), the solution of the routing problem continues to be quite challenging.

**Corporate Information Systems** Terms such as *management information systems* (MIS), *enterprise resource planning* (ERP), *supply chain management* (SCM), and *information technology* (IT) are frequently used to designate the upper levels of computer systems within a corporation. From a control perspective, the functions performed at this level are normally long-term and/or strategic. For example, in a processing plant, long-term contracts are required with the providers of the feedstocks. A forecast must be developed for the demand for possible products from the plant. This demand must be translated to needed raw materials, and then contracts executed with the suppliers to deliver these materials on a relatively uniform schedule.

## DIGITAL HARDWARE IN PROCESS CONTROL

Digital control technology was first applied to process control in 1959, using a single central computer (and analog backup for reliability). In the mid-1970s, a microcomputer-based process control architecture referred to as a *distributed control system* (DCS) was introduced and rapidly became a commercial success. A DCS consists of some number of microprocessor-based nodes that are interconnected by a digital communications network, often called a *data highway*. Today the DCS is still dominant, but there are other options for carrying out computer control, such as single-loop controllers, programmable logic controllers, and personal computer controllers. A brief review of each type of controller device is given in the following section, Controllers, Final Control Elements, and Regulators, along with more details on controller hardware options.

**Distributed Control System** Figure 8-62 depicts a representative distributed control system. The DCS consists of many commonly used components, including multiplexers (MUXs), single-loop and multiple-loop controllers, PLCs, and smart devices. A system includes some of or all the following components:

1. *Control network.* The control network is the communication link between the individual components of a network. Coaxial cable and, more recently, fiber-optic cable have often been used, with Ethernet protocols becoming more common (100 mbit/s or higher). A redundant pair of cables (dual redundant highway) is normally supplied to reduce the possibility of link failure.
2. *Workstations.* Workstations are the most powerful computers in the system, capable of performing functions not normally available in other units. A workstation acts both as an arbitrator unit to route internodal communications and as the database server. An operator interface is supported, and various peripheral devices are coordinated through the workstations. Computationally intensive tasks, such as real-time optimization or model predictive control, can be implemented in a workstation. Operators supervise and control processes from these workstations. Operator stations may be connected directly to printers for alarm logging, printing reports, or process graphics.
3. *Remote control units (RCUs).* These components are used to implement basic control functions such as PID control. Some RCUs may be configured to acquire or supply set points to single-loop controllers. Radio telemetry (wireless) may be installed to communicate with MUX units located at great distances.
4. *Application stations.* These separate computers run application software such as databases, spreadsheets, financial software, and simulation software via an OPC interface. OPC is an acronym for object linking and embedding for process control, a software architecture based on standard interfaces. These stations can be used for e-mail and as web servers, for remote diagnosis configuration, and even for operation of devices that have an IP (Internet Protocol) address. Applications stations can communicate with the main database contained in online mass storage systems. Typically hard disk drives are used to store active data, including online and historical databases and nonmemory resident programs. Memory resident programs are also stored to allow loading at system start-up.
5. *Fieldbuses and smart devices.* An increasing number of field-mounted devices are available that support digital communication of the process I/O in addition to, or in place of, the traditional 4- to 20-mA current signal. These devices have greater functionality, resulting in reduced setup time, improved control, combined functionality of separate devices, and control valve diagnostic capabilities. Digital communication also allows the control system to become completely distributed where, e.g., a PID control algorithm could reside in a valve positioner or in a sensor/transmitter.

## DISTRIBUTED DATABASE AND THE DATABASE MANAGER

A database is a centralized location for data storage. The use of databases enhances system performance by maintaining complex relations between data elements while reducing data redundancy. A database may be built based on the relational model, the entity relationship model, or some other model. The database manager is a system utility program or programs

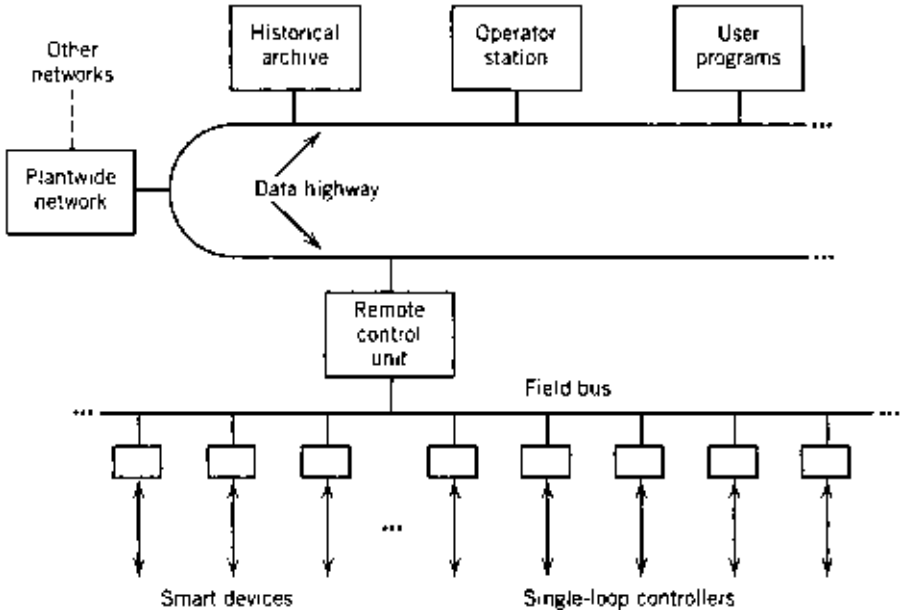

**FIG. 8-62** A DCS using a broadband (high-bandwidth) data highway and fieldbus connected to a single remote control unit that operates smart devices and single-loop controllers.

acting as the gatekeeper to the databases. All functions retrieving or modifying data must submit a request to the manager. Information required to access the database includes the tag name of the database entity, often referred to as a *point*, the attributes to be accessed, and the values, if they are to be modified. The database manager maintains the integrity of the databases by executing a request only when not processing other conflicting requests.

To allow flexibility, the database manager must also perform point addition or deletion. However, the ability to create a point type or to add or delete attributes of a point type is not normally required because, unlike other data processing systems, a process control system normally involves a fixed number of point types and related attributes. For example, analog and binary input and output types are required for process I/O points. Related attributes for these point types include tag names, values, and hardware addresses. Different system manufacturers may define different point types using different data structures.

**Data Historian** An historical database is built similar to an online database. Unlike their online counterparts, the information stored in a historical database is not normally accessed directly by other subsystems for process control and monitoring. Periodic reports and long-term trends are generated based on the archived data. The reports are often used for planning and system performance evaluations such as statistical process (quality) control. The trends may be used to detect process drifts or to compare process variations at different times.

The historical data are sampled at user-specified intervals. A typical process plant contains a large number of data points, but it is not feasible to store data for all points at all times. The user determines if a data point should be included in the list of archived points. Most systems provide archive-point menu displays. The sampling periods are normally some multiple of their base scan frequencies. However, some systems allow historical data sampling of arbitrary intervals. This is necessary when intermediate virtual data points that do not have the scan frequency attribute are involved. The archive point lists are continuously scanned by the historical database software. Online databases are polled for data, and the times of data retrieval are recorded with the data obtained. To conserve storage space, different data compression techniques are employed by various manufacturers, although the greatly reduced costs of data storage make this less critical.

## PROCESS CONTROL LANGUAGES

Originally, software for process control utilized high-level programming languages such as FORTRAN and BASIC. Some companies have incorporated libraries of software routines for these languages, but others have developed specialty languages characterized by natural language statements. The most widely adopted user-friendly approach is the fill-in-the-forms or table-driven *process control languages* (PCLs). Typical PCLs include function block diagrams, ladder logic, and programmable logic. The core of these languages is a number of basic function blocks or software modules, such as analog in, digital in, analog out, digital out, PID, summer, and splitter. Using a module is analogous to calling a subroutine in conventional FORTRAN or C programs.

In general, each module contains one or more inputs and an output. The programming involves connecting outputs of function blocks to inputs of other blocks via the graphical-user interface. Some modules may require additional parameters to direct module execution. Users are required to fill in templates to indicate the sources of input values, the destinations of output values, and the parameters for forms/tables prepared for the modules. The source and destination blanks may specify process I/O channels and tag names when appropriate. To connect modules, some systems require filling in the tag names of modules originating or receiving data.

Many DCSs allow users to write custom code (similar to BASIC) and attach it to data points, so that the code is executed each time the point is scanned. The use of custom code allows many tasks to be performed that cannot be carried out by standard blocks.

All process control languages contain PID control blocks of different forms. Other categories of function blocks include

1. *Logical operators.* AND, OR, and exclusive OR (XOR) functions.
2. *Calculations.* Algebraic operations such as addition, multiplication, square root extraction, or special function evaluation.
3. *Selectors.* Min and max functions, transferring data in a selected input to the output or the input to a selected output.
4. *Comparators.* Comparison of two analog values and transmission of a binary signal to indicate whether one analog value exceeds the other.
5. *Timers.* Delayed activation of the output for a programmed duration after activation by the input signal.
6. *Process dynamics.* Emulation of a first-order process lag (or lead) and time delay.

## GENERAL CONSIDERATIONS

Process measurements encompass the application of the principles of metrology to the process in question. The objective is to obtain values for the current conditions within the process and to make this information available in a form usable by the control system, process operators, or management information systems. The term *measured variable* or *process variable* designates the process condition that is being determined.

Process measurements fall into two categories:

1. *Continuous measurements.* An example of a continuous measurement is a level measurement device that determines the liquid level in a tank (e.g., in meters).
2. *Discrete measurements.* An example of a discrete measurement is a level switch that indicates the presence or absence of liquid at the location at which the level switch is installed.

In continuous processes, most process control applications rely on continuous measurements. In batch processes, many of the process control applications utilize discrete as well as continuous measurements. In both types of processes, the safety interlocks and process interlocks rely largely on discrete measurements.

**Continuous Measurements** In most applications, continuous measurements provide more information than discrete measurements. Basically, discrete measurements involve a yes/no decision, whereas continuous measurements may entail considerable signal processing.

The components of a typical continuous measurement device are as follows:

1. *Sensor.* This component produces a signal that is related in a known manner to the process variable of interest. The sensors in use today are primarily of the electrical analog variety, and the signal is in the form of a voltage, a resistance, a capacitance, or some other directly measurable electrical quantity. Prior to the mid-1970s, instruments tended to use sensors whose signal was mechanical and thus compatible with pneumatic technology. Since that time, the fraction of sensors that are electronic and digital has grown considerably, often eliminating the need for analog-to-digital conversion.
2. *Signal processing.* The signal from a sensor is usually related in a nonlinear fashion to the process variable of interest. For the output of the measurement device to be linear with respect to the process variable of interest, linearization is required. Furthermore, the signal from the sensor might be affected by variables other than the process variable. In this case, additional variables must be sensed, and the signal from the sensor compensated to account for the other variables. For example, reference junction compensation is required for thermocouples (except when used for differential temperature measurements).
3. *Transmitter.* The measurement device output must be a signal that can be transmitted over some distance. Where electronic analog transmission is used, the low range on the transmitter output is 4 mA, and the upper range is 20 mA. Microprocessor-based transmitters (often referred to as *smart transmitters*) are usually capable of transmitting the measured variable digitally in engineering units.

**Accuracy and Repeatability** Definitions of terminology pertaining to process measurements can be obtained from standards available from the Instrumentation, Systems, and Automation Society (ISA) and from the Scientific Apparatus Makers Association [now Measurement, Control, and Automation Association (MCAA)], both of which are updated periodically. An appreciation of accuracy and repeatability is especially important. Some applications depend on the accuracy of the instrument, but other applications depend on repeatability. Excellent accuracy implies excellent repeatability; however, an instrument can have poor accuracy but excellent repeatability. In some applications, this is acceptable, as discussed below.

***Range and Span*** A continuous measurement device is expected to provide credible values of the measured value between a lower range and an upper range. The difference between the upper range and the lower range is the span of the measurement device. The maximum value for the upper range and the minimum value for the lower range depend on the principles on which the measurement device is based and on the design chosen by the manufacturer of the measurement device. If the measured variable is greater than the upper range or less than the lower range, the measured variable is said to be *out of range* or the measurement device is said to be *overranged*.

***Accuracy*** Accuracy refers to the difference between the measured value and the true value of the measured variable. Unfortunately, the true value is never known, so in practice accuracy refers to the difference between the measured value and an accepted standard value for the measured variable.

Accuracy can be expressed in four ways:

1. As an absolute difference in the units of the measured variable
2. As a percentage of the current reading
3. As a percentage of the span of the measured variable
4. As a percentage of the upper range of the span

For process measurements, accuracy as a percentage of span is the most common.

Manufacturers of measurement devices always state the accuracy of the instrument. However, these statements always provide specific or reference conditions at which the measurement device will perform with the stated accuracy, with temperature and pressure most often appearing in the reference conditions. When the measurement device is applied at other conditions, the accuracy is affected. Manufacturers usually also provide some statements on how accuracy is affected when the conditions of use deviate from the referenced conditions in the statement of accuracy. Although appropriate calibration procedures can minimize some of these effects, rarely can they be totally eliminated. It is easily possible for such effects to cause a measurement device with a stated accuracy of 0.25 percent of span at reference conditions to ultimately provide measured values with accuracies of 1 percent or less. Microprocessor-based measurement devices usually provide better accuracy than do the traditional electronic measurement devices.

In practice, most attention is given to accuracy when the measured variable is the basis for billing, such as in custody transfer applications. However, whenever a measurement device provides data to any type of optimization strategy, accuracy is very important.

***Repeatability*** Repeatability refers to the difference between the measurements when the process conditions are the same. This can also be viewed from the opposite perspective. If the measured values are the same, repeatability refers to the difference between the process conditions.

For regulatory control, repeatability is of major interest. The basic objective of regulatory control is to maintain uniform process operation. Suppose that on two different occasions, it is desired that the temperature in a vessel be 800°C. The regulatory control system takes appropriate actions to bring the measured variable to 800°C. The difference between the process conditions at these two times is determined by the repeatability of the measurement device.

In the use of temperature measurement for control of the separation in a distillation column, repeatability is crucial but accuracy is not. Composition control for the overhead product is often based on a measurement of the temperature on one of the trays in the rectifying section. A target would be provided for this temperature. However, at periodic intervals, a sample of the overhead product is analyzed in the laboratory and the information is provided to the process operator. Should this analysis be outside acceptable limits, the operator would adjust the set point for the temperature. This procedure effectively compensates for an inaccurate temperature measurement; however, the success of this approach requires good repeatability from the temperature measurement.

**Dynamics of Process Measurements** Especially where the measurement device is incorporated into a closed-loop control configuration, dynamics are important. The dynamic characteristics depend on the nature of the measurement device, and on the nature of components associated with the measurement device (e.g., thermowells and sample conditioning equipment). The term *measurement system* designates the measurement device and its associated components.

The following dynamics are commonly exhibited by measurement systems:

- *Time constants.* Where there is a capacity and a throughput, the measurement device response will exhibit a time constant. For example, any temperature measurement device has a thermal capacity (mass times heat capacity) and a heat flow term (heat-transfer coefficient and area). Both the temperature measurement device and its associated thermowell will exhibit behavior reflecting its time constants.
- *Dead time.* Probably the best example of a measurement device that exhibits pure dead time (time delay) is the chromatograph, because the analysis is not available for some time after a sample is injected. Additional dead time results from the transportation lag within the sample system. Even continuous analyzer installations can exhibit dead time from the sample system.
- *Underdamped.* Measurement devices with mechanical components often have a natural harmonic and can exhibit underdamped behavior. The displacer type of level measurement device is capable of such behavior.

While the manufacturers of measurement devices can supply some information on the dynamic characteristics of their devices, interpretation is often difficult. Measurement device dynamics are quoted on varying bases,

such as rise time, time to 63 percent response, settling time, etc. Even where the time to 63 percent response is quoted, it might not be safe to assume that the measurement device exhibits first-order behavior.

Where the manufacturer of the measurement device does not supply the associated equipment (thermowells, sample conditioning equipment, etc.), the user must incorporate the characteristics of these components to obtain the dynamics of the measurement system. An additional complication is that most dynamic data are stated for configurations involving reference materials such as water and air. The nature of the process material will affect the dynamic characteristics. For example, a thermowell will exhibit different characteristics when immersed in a viscous organic emulsion versus when immersed in water. It is often difficult to extrapolate the available data to process conditions of interest.

Similarly, it is often impossible, or at least very difficult, to experimentally determine the characteristics of a measurement system under the conditions where it is used. It is certainly possible to fill an emulsion polymerization reactor with water and determine the dynamic characteristics of the temperature measurement system. However, it is not possible to determine these characteristics when the reactor is filled with the emulsion under polymerization conditions.

The primary impact of unfavorable measurement dynamics is on the performance of closed-loop control systems. This explains why most control engineers are very concerned with minimizing measurement dynamics, even though the factors considered in dynamics are often subjective.

**Selection Criteria** The selection of a measurement device entails a number of considerations given below, some of which are almost entirely subjective.

1. *Measurement span.* The measurement span required for the measured variable must lie entirely within the instrument's envelope of performance.
2. *Performance.* Depending on the application, accuracy, repeatability, or perhaps some other measure of performance is appropriate. Where closed-loop control is contemplated, speed of response must be included.
3. *Reliability.* Data available from the manufacturers can be expressed in various ways and at various reference conditions. Often, previous experience with the measurement device within the purchaser's organization is weighted most heavily.
4. *Materials of construction.* The instrument must withstand the process conditions to which it is exposed. This encompasses considerations such as operating temperatures, operating pressures, corrosion, and abrasion. For some applications, seals or purges may be necessary.
5. *Prior use.* For the first installation of a specific measurement device at a site, training of maintenance personnel and purchases of spare parts might be necessary.
6. *Potential for releasing process materials to the environment.* Fugitive emissions are receiving ever-increasing attention. Exposure considerations, both immediate and long-term, for maintenance personnel are especially important when the process fluid is either corrosive or toxic.
7. *Electrical classification.* Article 500 of the National Electric Code provides for the classification of the hazardous nature of the process area in which the measurement device will be installed. If the measurement device is not inherently compatible with this classification, suitable enclosures must be purchased and included in the installation costs.
8. *Physical access.* Subsequent to installation, maintenance personnel must have physical access to the measurement device for maintenance and calibration. If additional structural facilities are required, they must be included in the installation costs.
9. *Invasive or noninvasive.* The insertion of a probe can result in fouling problems and a need for maintenance. Probe location must be selected carefully for good accuracy and minimal fouling.
10. *Cost.* There are two aspects of the cost:
    *a.* Initial purchase and installation (capital cost).
    *b.* Recurring costs (operational expense). This encompasses instrument maintenance, instrument calibration, consumables (e.g., titrating solutions must be purchased for automatic titrators), and any other costs entailed in keeping the measurement device in service.

**Calibration** Calibration entails the adjustment of a measurement device so that the value from the measurement device agrees with the value from a standard. The International Standards Organization (ISO) has developed a number of standards specifically directed to calibration of measurement devices. Furthermore, compliance with the ISO 9000 standards requires that the working standard used to calibrate a measurement device be traceable to an internationally recognized standard such as those maintained by the National Institute of Standards and Technology (NIST).

Within most companies, the responsibility for calibrating measurement devices is delegated to a specific department. Often, this department may also be responsible for maintaining the measurement device. The specific calibration procedures depend on the type of measurement device. The frequency of calibration is normally predetermined, but earlier action may be dictated if the values from the measurement device become suspect.

Calibration of some measurement devices involves comparing the measured value with the value from the working standard. Pressure and differential pressure transmitters are calibrated in this manner. Calibration of analyzers normally involves using the measurement device to analyze a specially prepared sample whose composition is known. These and similar approaches can be applied to most measurement devices.

Flow is an important measurement whose calibration presents some challenges. When a flow measurement device is used in applications such as custody transfer, provision is made to pass a known flow through the meter. However, such a provision is costly and is not available for most in-process flow meters. Without such a provision, a true calibration of the flow element itself is not possible. For orifice meters, calibration of the flow meter normally involves calibration of the differential pressure transmitter, and the orifice plate is usually only inspected for deformation, abrasion, etc. Similarly, calibration of a magnetic flow meter normally involves calibration of the voltage measurement circuitry, which is analogous to calibration of the differential pressure transmitter for an orifice meter.

In the next subsection we cover the major types of measurement devices used in the process industries, principally the "big five" measurements: temperature, flow rate, pressure, level, and composition, along with online physical property measurement techniques. Table 8-7 summarizes the different options under each of the principal measurements.

## TEMPERATURE MEASUREMENTS

Measurement of the hotness or coldness of a body or fluid is commonplace in the process industries. Temperature-measuring devices utilize systems with properties that vary with temperature in a simple, reproducible manner and thus can be calibrated against known references (sometimes called *secondary thermometers*). The three dominant measurement devices used in automatic control are thermocouples, resistance thermometers, and pyrometers, and they are applicable over different temperature regimes.

**Thermocouples** Temperature measurements using thermocouples are based on the discovery by Seebeck in 1821 that an electric current flows in a continuous circuit of two different metallic wires if the two junctions are at different temperatures. Suppose A and B are the two metals, and $T_1$ and $T_2$ are the temperatures of the junctions. Let $T_1$ and $T_2$ be the reference junction (cold junction) and the measuring junction, respectively. If the thermoelectric current $i$ flows from A to B, metal A is customarily referred to as

**TABLE 8-7 Online Measurement Options for Process Control**

| Temperature | Flow | Pressure | Level | Composition |
|---|---|---|---|---|
| Thermocouple | Orifice | Liquid column | Float-activated | Gas-liquid chromatography (GLC) |
| Resistance temperature detector (RTD) | Venturi | Elastic element | Chain gauge | Mass spectrometry (MS) |
| Filled-system thermometer | Rotameter | Bourdon tube | Lever | Magnetic resonance analysis (MRA) |
| Bimetal thermometer | Turbine | Bellow | Magnetically coupled | Infrared (IR) spectroscopy |
| Pyrometer | Vortex-shedding | Diaphragm | Head devices | Raman spectroscopy |
| Total radiation | Ultrasonic | Strain gauges | Bubble tube | Ultraviolet (uv) spectroscopy |
| Photoelectric | Magnetic | Piezoresistive transducers | Electrical (conductivity) | Thermal conductivity |
| Ratio | Thermal mass | Piezoelectric transducers | Sonic | Refractive index (RI) |
| Laser | Coriolis | Optical fiber | Laser | Capacitance probe |
| Surface acoustic wave | Target | | Radiation | Surface acoustic wave |
| Semiconductor | | | Radar | Electrophoresis |
| | | | | Electrochemical |
| | | | | Paramagnetic |
| | | | | Chemi/bioluminescence |
| | | | | Tunable diode laser absorption |

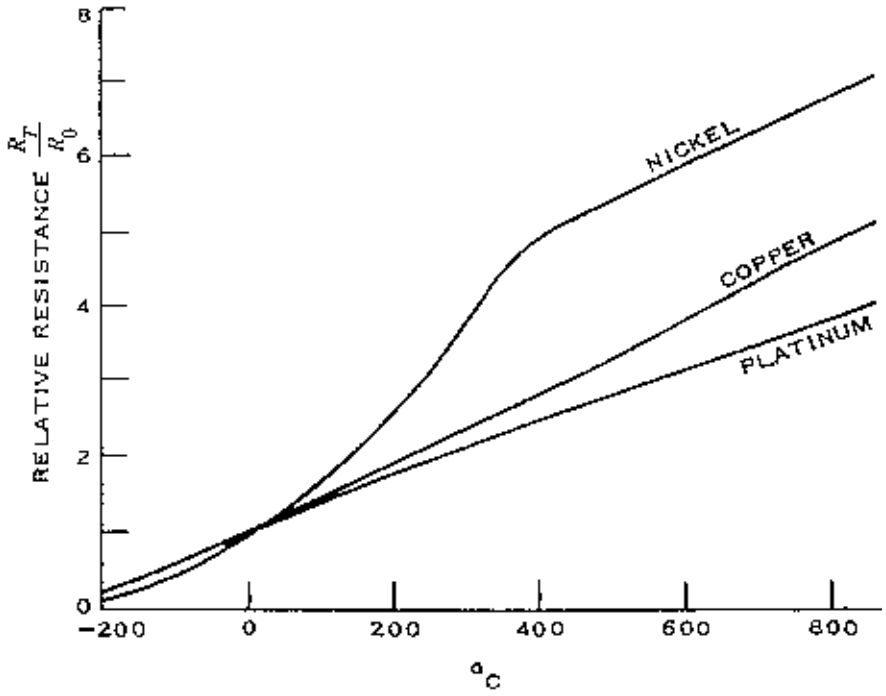

**FIG. 8-63** Typical resistance thermometer curves for platinum, copper, and nickel wire, where $R_T$ = resistance at temperature $T$ and $R_0$ = resistance at 0°C.

thermoelectrically positive to metal B. Metal pairs used for thermocouples include platinum-rhodium (the most popular and accurate), chromel-alumel, copper-constantan, and iron-constantan. The thermal emf is a measure of the difference in temperature between $T_2$ and $T_1$. In control systems the reference junction is usually located at the emf-measuring device. The reference junction may be held at constant temperature such as in an ice bath or a thermostated oven, or it may be at ambient temperature but electrically compensated (cold junction compensated circuit) so that it appears to be held at a constant temperature.

**Resistance Thermometers** The resistance thermometer depends upon the inherent characteristics of materials to change in electrical resistance when they undergo a change in temperature. Industrial resistance thermometers are usually constructed of platinum, copper, or nickel, and more recently semiconducting materials such as thermistors are being used. Basically, a resistance thermometer is an instrument for measuring electrical resistance that is calibrated in units of temperature instead of in units of resistance (typically ohms). Several common forms of bridge circuits are employed in industrial resistance thermometry, the most common being the Wheatstone bridge. A *resistance thermometer detector* (RTD) consists of a resistance conductor (metal) that generally shows an increase in resistance with temperature. The following equation typically represents the variation of resistance with temperature (°C or K):

$$R_T = R_0(1 + a_1T + a_2T^2 + \cdots + a_nT^n) \qquad R_0 = \text{resistance at } 0°\text{C} \tag{8-62}$$

The temperature coefficient of resistance $\alpha_T$ is expressed as

$$\alpha_T = \frac{1}{R_T}\frac{dR_T}{dT} \tag{8-63}$$

For most metals $\alpha_T$ is positive. For many pure metals, the coefficient is essentially constant and stable over large portions of their useful range. Typical resistance versus temperature curves for platinum, copper, and nickel are given in Fig. 8-63, with platinum usually the metal of choice. Platinum has a useful range of −200 to 800°C, while nickel and copper are more limited. Detailed resistance versus temperature tables are available from the National Institute of Standards and Technology (NIST) and suppliers of resistance thermometers. Table 8-8 gives recommended temperature measurement ranges for thermocouples and RTDs. Resistance thermometers are receiving increased usage because they are about 10 times more accurate than thermocouples. Note that Fig. 8-63 shows a temperature region where the change in resistance is nearly linear, a desirable characteristic.

**Thermistors** Thermistors are nonlinear temperature-dependent resistors, and normally only the materials with negative temperature coefficient of resistance (NTC type) are used. The resistance is related to temperature as

$$R_T = R_{T_r} \exp\left[\beta\left(\frac{1}{T} - \frac{1}{T_r}\right)\right] \tag{8-64}$$

where $T_r$ is a reference temperature, which is generally 298 K. Thus

$$\alpha_T = \frac{1}{R_T}\frac{dR_T}{dT} \tag{8-65}$$

The value of $\beta$ is on the order of 4000, so at room temperature (298 K), $\alpha_T = -0.045$ for thermistor and 0.0035 for 100-Ω platinum RTD. Compared with RTDs, NTC-type thermistors are advantageous in that the detector dimension can be made small, the resistance value is higher (less affected by the resistances of the connecting leads), and it has higher temperature sensitivity and low thermal inertia of the sensor. Disadvantages of thermistors to RTDs include nonlinear characteristics and low measuring temperature range.

**TABLE 8-8 Recommended Temperature Measurement Ranges for RTDs and Thermocouples**

| Resistance Thermometer Detectors (RTDs) | |
|---|---|
| 100-V Pt | −200–+800°C |
| 120-V Ni | −80–+320°C |
| **Thermocouples** | |
| Type B | 0–+1700°C |
| Type E | 0–+900°C |
| Type J | 0–+750°C |
| Type K | 0–+1260°C |
| Type N | 0–+1300°C |
| Type R | 870–+1450°C |
| Type S | 960–+1450°C |
| Type T | −170–+350°C |

**Filled-System Thermometers** The filled-system thermometer is designed to provide an indication of temperature some distance removed from the point of measurement. The measuring element (bulb) contains a gas or liquid that changes in volume, pressure, or vapor pressure with temperature. This change is communicated through a capillary tube to a Bourdon tube or other pressure- or volume-sensitive device. The Bourdon tube responds so as to provide a motion related to the bulb temperature. Those systems that respond to volume changes are completely filled with a liquid. Systems that respond to pressure changes either are filled with a gas or are partially filled with a volatile liquid. Changes in gas or vapor pressure with changes in bulb temperatures are carried through the capillary to the Bourdon. The latter bulbs are sometimes constructed so that the capillary is filled with a nonvolatile liquid.

Fluid-filled bulbs deliver enough power to drive controller mechanisms and even directly actuate control valves. These devices are characterized by large thermal capacity, which sometimes leads to slow response, particularly when they are enclosed in a thermal well for process measurements. Filled-system thermometers are used extensively in industrial processes for a number of reasons. The simplicity of these devices allows rugged construction, minimizing the possibility of failure with a low level of maintenance, and inexpensive overall design of control equipment. In case of system failure, the entire unit must be replaced or repaired.

As they are normally used in the process industries, the sensitivity and percentage of span accuracy of these thermometers are generally the equal of those of other temperature-measuring instruments. Sensitivity and absolute accuracy are not the equal of those of short-span electrical instruments used in connection with resistance-thermometer bulbs. Also the maximum temperature is somewhat limited.

**Bimetal Thermometers** *Thermostatic bimetal* can be defined as a composite material made up of strips of two or more metals fastened together. This composite, because of the different expansion rates of its components, tends to change curvature when subjected to a change in temperature. With one end of a straight strip fixed, the other end deflects in proportion to the temperature change, the square of the length, and inversely as the thickness, throughout the linear portion of the deflection characteristic curve. If a bimetallic strip is wound into a helix or a spiral and one end is fixed, the other end will rotate when heat is applied. For a thermometer with uniform scale divisions, a bimetal must be designed to have linear deflection over the desired temperature range. Bimetal thermometers are used at temperatures ranging from 580°C down to −180°C and lower. However, at the low temperatures the rate of deflection drops off quite rapidly. Bimetal thermometers do not have long-time stability at temperatures above 430°C.

**Pyrometers** Planck's distribution law gives the radiated energy flux $q_b(\lambda,T)\,d\lambda$ in the wavelength range $\lambda$ to $\lambda + d\lambda$ from a black surface:

$$q_b(\lambda,T) = \frac{C_1}{\lambda^5}\frac{1}{e^{C_2/\lambda T}-1} \tag{8-66}$$

where $C_1 = 3.7418 \times 10^{10}\ \mu W \cdot \mu m^4 \cdot cm^{-2}$ and $C_2 = 14{,}388\ \mu m \cdot K$.

If the target object is a black body and if the pyrometer has a detector that measures the specific wavelength signal from the object, then the temperature of the object can be accurately estimated from Eq. (8-66). While it is possible to construct a physical body that closely approximates black body behavior, most real-world objects are not black bodies. The deviation from a black body can be described by the spectral emissivity

$$\varepsilon_T = \frac{q(T)}{q_b(T)} \tag{8-67}$$

where $q(\lambda,T)$ is the radiated energy flux from a real body in the wavelength range $\lambda$ to $\lambda + d\lambda$ and $0 < \varepsilon_{\lambda,T} < 1$. Integrating Eq. (8-66) over all wavelengths gives the Stefan-Boltzmann equation

$$q_b(T) = \int_0^\infty q_b(\lambda,T)\,d\lambda = \sigma T^4 \tag{8-68}$$

where $\sigma$ is the Stefan-Boltzmann constant. Similar to Eq. (8-63), the emissivity $\varepsilon_T$ for the total radiation is

$$\varepsilon_T = \frac{q(T)}{q_b(T)} \tag{8-69}$$

where $q(T)$ is the radiated energy flux from a real body with emissivity $\varepsilon_T$.

***Total Radiation Pyrometers*** In total radiation pyrometers, the thermal radiation is detected over a large range of wavelengths from the object at high temperature. The detector is normally a thermopile, which is built by connecting several thermocouples in series to increase the temperature measurement range. The pyrometer is calibrated for black bodies, so the indicated temperature $T_p$ should be converted for non–black body temperature.

***Photoelectric Pyrometers*** Photoelectric pyrometers belong to the class of band radiation pyrometers. The thermal inertia of thermal radiation detectors does not permit the measurement of rapidly changing temperatures. For example, the smallest time constant of a thermal detector is about 1 ms while the smallest time constant of a photoelectric detector can be about 1 or 2 s. Photoelectric pyrometers may use photoconductors, photodiodes, photovoltaic cells, or vacuum photocells. Photoconductors are built from glass plates with thin film coatings of 1-μm thickness, using PbS, CdS, PbSe, or PbTe. When the incident radiation has the same wavelength as the materials are able to absorb, the captured incident photons free photoelectrons, which form an electric current. Photodiodes in germanium or silicon are operated with a reverse-bias voltage applied. Under the influence of the incident radiation, their conductivity as well as their reverse saturation current is proportional to the intensity of the radiation within the spectral response band from 0.4 to 1.7 μm for Ge and from 0.6 to 1.1 μm for Si. Because of the above characteristics, the operating range of a photoelectric pyrometer can be either spectral or in a specific band. Photoelectric pyrometers can be applied for a specific choice of the wavelength.

***Disappearing Filament Pyrometers*** Disappearing filament pyrometers can be classified as spectral pyrometers. The brightness of a lamp filament is changed by adjusting the lamp current until the filament disappears against the background of the target, at which point the temperature is measured. Because the detector is the human eye, it is difficult to calibrate for online measurements.

***Ratio Pyrometers*** The ratio pyrometer is also called the *two-color pyrometer*. Two different wavelengths are utilized for detecting the radiated signal. If one uses Wien's law applicable for small values of $\lambda T$, the detected signals from spectral radiant energy flux emitted at wavelengths $\lambda_1$ and $\lambda_2$ with emissivities $\varepsilon_{\lambda_1}$ and $\varepsilon_{\lambda_2}$ can be calculated, along with their ratio.

$$S_{\lambda_1} = KC_1\varepsilon_{\lambda_1}\lambda_1^{-5}\exp\left(\frac{-C_2}{\lambda_1 T}\right) \tag{8-70}$$

$$S_{\lambda_2} = KC_1\varepsilon_{\lambda_2}\lambda_2^{-5}\exp\left(\frac{-C_2}{\lambda_2 T}\right) \tag{8-71}$$

The ratio of signals $S_{\lambda_1}$ and $S_{\lambda_2}$ is

$$\frac{S_{\lambda_1}}{S_{\lambda_2}} = \frac{\varepsilon_{\lambda_1}}{\varepsilon_{\lambda_2}}\left(\frac{\lambda_2}{\lambda_1}\right)^5 \exp\left[\frac{C_2}{T}\left(\frac{1}{\lambda_2}-\frac{1}{\lambda_1}\right)\right] \tag{8-72}$$

Nonblack or nongray bodies are characterized by the wavelength dependence of their spectral emissivity. Let $T_c$ be defined as the temperature of the body corresponding to the temperature of a black body. If the ratio of its radiant intensities at wavelengths $\lambda_1$ and $\lambda_2$ equals the ratio of the radiant intensities of the nonblack body, whose temperature is to be measured at the same wavelength, then Wien's law gives

$$\frac{\varepsilon_{\lambda_1}\exp(-C_2/\lambda_1 T)}{\varepsilon_{\lambda_2}\exp(-C_2/\lambda_2 T)} = \frac{\exp(-C_2/\lambda_1 T_c)}{\exp(-C_2/\lambda_2 T_c)} \tag{8-73}$$

where $T$ is the true temperature of the body. Rearranging Eq. (8-73) gives

$$T = \left[\frac{\ln(\varepsilon_{\lambda_1}/\varepsilon_{\lambda_2})}{C_2(1/\lambda_1 - 1/\lambda_2)} + \frac{1}{T_c}\right]^{-1} \tag{8-74}$$

For black or gray bodies, Eq. (8-74) reduces to

$$\frac{S_{\lambda_1}}{S_{\lambda_2}} = \left(\frac{\lambda_2}{\lambda_1}\right)^5 \exp\left[\frac{C_2}{T}\left(\frac{1}{\lambda_2}-\frac{1}{\lambda_1}\right)\right] \tag{8-75}$$

Thus by measuring the ratio of $S_{\lambda_1}$ and $S_{\lambda_2}$, temperature $T$ can be estimated.

***Accuracy of Pyrometers*** Most of the temperature estimation methods for pyrometers assume that the object either is a gray body or has known emissivity values. The emissivity of the nonblack body depends on the internal state or the surface geometry of the objects. Also the medium through which the thermal radiation passes is not always transparent. These inherent uncertainties of the emissivity values make the accurate estimation of the temperature of the target objects difficult. Proper selection of the pyrometer and accurate emissivity values can provide a high level of accuracy. The fact that the pyrometer can be protected from the high-temperature environment makes it attractive.

## PRESSURE MEASUREMENTS

*Pressure*, defined as force per unit area, is usually expressed in terms of familiar units of weight-force and area or the height of a column of liquid which produces a like pressure at its base. Process pressure-measuring devices may be

divided into three groups: (1) those based on the measurement of the height of a liquid column, (2) those based on the measurement of the distortion of an elastic pressure chamber, and (3) electrical sensing devices.

**Liquid-Column Methods** Liquid-column pressure-measuring devices are those in which the pressure being measured is balanced against the pressure exerted by a column of liquid. If the density of the liquid is known, the height of the liquid column is a measure of the pressure. Most forms of liquid-column pressure-measuring devices are commonly called *manometers*. When the height of the liquid is observed visually, the liquid columns are contained in glass or other transparent tubes. The height of the liquid column may be measured in length units or calibrated in pressure units. Depending on the pressure range, water and mercury are the liquids most frequently used. Because the density of the liquid used varies with temperature, the temperature must be taken into account for accurate pressure measurements.

**Elastic-Element Methods** Elastic element pressure-measuring devices are those in which the measured pressure deforms some elastic material (usually metallic) within its elastic limit, the magnitude of the deformation being approximately proportional to the applied pressure. These devices may be loosely classified into three types: Bourdon tube, bellows, and diaphragm.

***Bourdon Tube*** Probably the most frequently used process pressure-indicating device is the C-spring Bourdon tube pressure gauge. Gauges of this general type are available in a wide variety of pressure ranges and materials of construction. Materials are selected on the basis of pressure range, resistance to corrosion by the process materials, and effect of temperature on calibration. Gauges calibrated with pressure, vacuum, compound (combination pressure and vacuum), and suppressed-zero ranges are available.

***Bellows*** The bellows element is an axially elastic cylinder with deep folds or convolutions. The bellows may be used unopposed, or it may be restrained by an opposing spring. The pressure to be measured may be applied either to the inside or to the space outside the bellows, with the other side exposed to atmospheric pressure. For measurement of absolute pressure either the inside or the space outside of the bellows can be evacuated and sealed. Differential pressures may be measured by applying the pressures to opposite sides of a single bellows or to two opposing bellows.

***Diaphragm*** Diaphragm elements may be classified into two principal types: those that utilize the elastic characteristics of the diaphragm and those that are opposed by a spring or other separate elastic element. The first type usually consists of one or more capsules, each composed of two diaphragms bonded together by soldering, brazing, or welding. The diaphragms are flat or corrugated circular metallic disks. Metals commonly used in diaphragm elements include brass, phosphor bronze, beryllium copper, and stainless steel. Ranges are available from fractions of an inch of water to over 800 in (200 kPa) gauge. The second type of diaphragm is used for containing the pressure and exerting a force on the opposing elastic element. The diaphragm is a flexible or slack diaphragm of rubber, leather, impregnated fabric, or plastic. Movement of the diaphragm is opposed by a spring which determines the deflection for a given pressure. This type of diaphragm is used for the measurement of extremely low pressure, vacuum, or differential pressure.

**Electrical Methods** Electrical methods for pressure measurement include strain gauges, piezoresistive transducers, and piezoelectric transducers.

***Strain Gauges*** When a wire or other electrical conductor is stretched elastically, its length is increased and its diameter is decreased. Both of these dimensional changes result in an increase in the electrical resistance of the conductor. Devices utilizing resistance-wire grids for measuring small distortions in elastically stressed materials are commonly called *strain gauges*. Pressure-measuring elements utilizing strain gauges are available in a wide variety of forms. They usually consist of one of the elastic elements described earlier to which one or more strain gauges have been attached to measure the deformation. There are two basic strain gauge forms: bonded and unbonded. Bonded strain gauges are bonded directly to the surface of the elastic element whose strain is to be measured. The unbonded strain gauge transducer consists of a fixed frame and an armature that moves with respect to the frame in response to the measured pressure. The strain gauge wire filaments are stretched between the armature and frame. The strain gauges are usually connected electrically in a Wheatstone bridge configuration.

Strain gauge pressure transducers are manufactured in many forms for measuring gauge, absolute, and differential pressures and vacuum. Full-scale ranges from 25.4 mm of water to 10,134 MPa are available. Strain gauges bonded directly to a diaphragm pressure-sensitive element usually have an extremely fast response time and are suitable for high-frequency dynamic pressure measurements.

***Piezoresistive Transducers*** A variation of the conventional strain gauge pressure transducer uses bonded single-crystal semiconductor wafers, usually silicon, whose resistance varies with strain or distortion. Transducer construction and electrical configurations are similar to those using conventional strain gauges. A permanent magnetic field is applied perpendicular to the resonating sensor. An alternating current causes the resonator to vibrate, and the resonant frequency is a function of the pressure (tension) of the resonator. The principal advantages of piezoresistive transducers are a much higher bridge voltage output and smaller size. Full-scale output voltages of 50 to 100 mV/V of excitation are typical. Some newer devices provide digital rather than analog output.

***Piezoelectric Transducers*** Certain crystals produce a potential difference between their surfaces when stressed in appropriate directions. Piezoelectric pressure transducers generate a potential difference proportional to a pressure-generated stress. Because of the extremely high electrical impedance of piezoelectric crystals at low frequency, these transducers are usually not suitable for measurement of static process pressures.

## FLOW MEASUREMENTS

*Flow*, defined as volume per unit of time at specified temperature and pressure conditions, is generally measured by positive displacement or rate meters. The term *positive displacement meter* applies to a device in which the flow is divided into isolated measured volumes when the number of fillings of these volumes is counted in some manner. The term *rate meter* applies to all types of flow meters through which the material passes without being divided into isolated quantities. Movement of the material is usually sensed by a primary measuring element that activates a secondary device. The flow rate is then inferred from the response of the secondary device by means of known physical laws or from empirical relationships.

The principal classes of flow-measuring instruments used in the process industries are variable-head, variable-area, positive-displacement, and turbine instruments; mass flow meters; vortex-shedding and ultrasonic flow meters; magnetic flow meters; and more recently Coriolis mass flow meters. Head meters are covered in detail in Sec. 5.

**Orifice Meter** The most widely used flow meter involves placing a fixed-area flow restriction (an orifice) in the pipe carrying the fluid. This flow restriction causes a pressure drop which can be related to flow rate. The sharp-edge orifice is popular because of its simplicity, low cost, and the large amount of research data on its behavior. For the orifice meter, the flow rate $Q_a$ for a liquid is given by

$$Q_a = \frac{C_d A_2}{\sqrt{1-(A_2/A_1)^2}} \cdot \sqrt{\frac{2(p_1 - p_2)}{\rho}} \tag{8-76}$$

where $p_1 - p_2$ is the pressure drop, $\rho$ is the density, $A_1$ is the pipe cross-sectional area, $A_2$ is the orifice cross-sectional area, and $C_d$ is the discharge coefficient. The discharge coefficient $C_d$ varies with the Reynolds number at the orifice and can be calibrated with a single fluid, such as water (typically $C_d \approx 0.6$). If the orifice and pressure taps are constructed according to certain standard dimensions, quite accurate (about 0.4 to 0.8 percent error) values of $C_d$ may be obtained. Also note that the standard calibration data assume no significant flow disturbances such as elbows and valves for a certain minimum distance upstream of the orifice. The presence of such disturbances close to the orifice can cause errors of as much as 15 percent. Accuracy in measurements limits the meter to a flow rate range of 3:1. The orifice has a relatively large permanent pressure loss that must be made up by the pumping machinery.

**Venturi Meter** The venturi tube operates on exactly the same principle as the orifice [see Eq. (8-76)]. Discharge coefficients of venturis are larger than those for orifices and vary from about 0.94 to 0.99. A venturi gives a definite improvement in power losses over an orifice and is often indicated for measuring very large flow rates, where power losses can become economically significant. The initial higher cost of a venturi over an orifice may thus be offset by reduced operating costs.

**Rotameter** A rotameter consists of a vertical tube with a tapered bore in which a float changes position with the flow rate through the tube. For a given flow rate, the float remains stationary because the vertical forces of differential pressure, gravity, viscosity, and buoyancy are balanced. The float position is the output of the meter and can be made essentially linear with flow rate by making the tube area vary linearly with the vertical distance.

**Turbine Meter** If a turbine wheel is placed in a pipe containing a flowing fluid, its rotary speed depends on the flow rate of the fluid. A turbine can be designed whose speed varies linearly with flow rate. The speed can be measured accurately by counting the rate at which turbine blades pass a given point, using magnetic pickup to produce voltage pulses. By feeding these pulses to an electronic pulse rate meter one can measure the flow rate by summing the pulses during a timed interval. Turbine meters are available with full-scale flow rates ranging from about 0.1 to 30,000 gal/min for liquids and 0.1 to 15,000 $ft^3$/min for air. Nonlinearity can be less than 0.05 percent in the larger sizes. Pressure drop across the meter varies with the square of the flow rate and is about 3 to 10 psi at full flow. Turbine meters can follow flow transients quite accurately since their fluid/mechanical time constant is on the order of 2 to 10 ms.

**Vortex-Shedding Flow Meters** These flow meters take advantage of vortex shedding, which occurs when a fluid flows past a nonstreamlined object (a blunt body). The flow cannot follow the shape of the object and separates from it, forming turbulent vortices or eddies at the object's side surfaces. As the vortices move downstream, they grow in size and are eventually shed or detached from the object. Shedding takes place alternately at either side of the object, and the rate of vortex formation and shedding is directly proportional to the volumetric flow rate. The vortices are counted and used to develop a signal linearly proportional to the flow rate. The digital signals can easily be totaled over an interval of time to yield the flow rate. Accuracy can be maintained regardless of density, viscosity, temperature, or pressure when the Reynolds number is greater than 10,000. There is usually a low flow cutoff point below which the meter output is clamped at zero. This flow meter is recommended for use with relatively clean, low-viscosity liquids, gases, and vapors, and rangeability of 10:1 to 20:1 is typical. A sufficient length of straight-run pipe is necessary to prevent distortion in the fluid velocity profile.

**Ultrasonic Flow Meters** An ultrasonic flow meter is based upon the variable time delays of received sound waves which arise when a flowing liquid's rate of flow is varied. Two fundamental measurement techniques, depending upon liquid cleanliness, are generally used. In the first technique two opposing transducers are inserted in a pipe so that one transducer is downstream from the other. These transducers are then used to measure the difference between the velocity at which the sound travels with the direction of flow and the velocity at which it travels against the direction of flow. The differential velocity is measured either by (1) direct time delays using sound wave burst or (2) frequency shifts derived from beat-together, continuous signals. The frequency measurement technique is usually preferred because of its simplicity and independence of the liquid static velocity. A relatively clean liquid is required to preserve the uniqueness of the measurement path.

In the second technique, the flowing liquid must contain scatters in the form of particles or bubbles which will reflect the sound waves. These scatters should be traveling at the velocity of the liquid. A Doppler method is applied by transmitting sound waves along the flow path and measuring the frequency shift in the returned signal from the scatters in the process fluid. This frequency shift is proportional to liquid velocity.

**Magnetic Flow Meters** The principle behind these flow meters is Faraday's law of electromagnetic inductance. The magnitude of the voltage induced in a conductive medium moving at right angles through a magnetic field is directly proportional to the product of the magnetic flux density, the velocity of the medium, and the path length between the probes. A minimum value of fluid conductivity is required to make this approach viable. The pressure of multiple phases or undissolved solids can affect the accuracy of the measurement if the velocities of the phases are different from that for straight-run pipe. Magmeters are very accurate over wide flow ranges and are especially accurate at low flow rates. Typical applications include metering viscous fluids, slurries, or highly corrosive chemicals. Because magmeters should be filled with fluid, the preferred installation is in vertical lines with flow going upward. However, magmeters can be used in tight piping schemes where it is impractical to have long pipe runs, typically requiring lengths equivalent to five or more pipe diameters.

**Coriolis Mass Flow Meters** Coriolis mass flow meters utilize a vibrating tube in which Coriolis acceleration of a fluid in a flow loop can be created and measured. They can be used with virtually any liquid and are extremely insensitive to operating conditions, with pressure ranges over 100:1. These meters are more expensive than volumetric meters and range in size from $\frac{1}{16}$ to 6 in. Due to the circuitous path of flow through the meter, Coriolis flow meters exhibit higher than average pressure drops. The meter should be installed so that it will remain full of fluid, with the best installation in a vertical pipe with flow going upward. There is no Reynolds number limitation with this meter, and it is quite insensitive to velocity profile distortions and swirl, hence there is no requirement for straight piping upstream. Coriolis flow meters are popular for custody measurement in the pipeline because they are very accurate but are more expensive than other flow meters.

**Thermal Mass Flow Meters** The trend in the chemical process industries is toward increased usage of mass flow meters that are independent of changes in pressure, temperature, viscosity, and density. Thermal mass meters are widely used in semiconductor manufacturing and in bioprocessing for control of low flow rates (called *mass flow controllers*, or MFCs). MFCs measure the heat loss from a heated element, which varies with flow rate, with an accuracy of ±1 percent. Capacitance probes measure the dielectric constant of the fluid and are useful for flow measurements of slurries and other two-phase flows.

## LEVEL MEASUREMENTS

The measurement of *level* can be defined as the determination of the location of the interface between two fluids, separable by gravity, with respect to a fixed reference plane. The most common level measurement is that of the interface between a liquid and a gas. Other level measurements frequently encountered are the interface between two liquids, between a granular or fluidized solid and a gas, and between a liquid and its vapor.

A commonly used basis for classification of level devices is as follows: float-actuated, displacer, and head devices, and a miscellaneous group which depends mainly on fluid characteristics.

**Float-Actuated Devices** Float-actuated devices are characterized by a buoyant member which floats at the interface between two fluids. Because a significant force is usually required to move the indicating mechanism, float-actuated devices are generally limited to liquid-gas interfaces. By properly weighting the float, they can be used to measure liquid-liquid interfaces. Float-actuated devices may be classified on the basis of the method used to couple the float motion to the indicating system, as discussed below.

***Chain or Tape Float Gauge*** In these types of gauges, the float is connected to the indicating mechanism by means of a flexible chain or tape. These gauges are commonly used in large atmospheric storage tanks. The gauge-board type is provided with a counterweight to keep the tape or chain taut. The tape is stored in the gauge head on a spring-loaded reel. The float is usually a pancake-shaped hollow metal float, with guide wires from top to bottom of the tank to constrain it.

***Lever and Shaft Mechanisms*** In pressurized vessels, float-actuated lever and shaft mechanisms are frequently used for level measurement. This type of mechanism consists of a hollow metal float and lever attached to a rotary shaft which transmits the float motion to the outside of the vessel through a rotary seal.

***Magnetically Coupled Devices*** A variety of float-actuated level devices have been developed which transmit the float motion by means of magnetic coupling. Typical of this class of devices are magnetically operated level switches and magnetic-bond float gauges. A typical magnetic-bond float gauge consists of a hollow magnet-carrying float that rides along a vertical nonmagnetic guide tube. The follower magnet is connected and drives an indicating dial similar to that on a conventional tape float gauge. The float and guide tube are in contact with the measured fluid and come in a variety of materials for resistance to corrosion and to withstand high pressures or vacuum. Weighted floats for liquid-liquid interfaces are available.

**Head Devices** A variety of devices utilize hydrostatic head as a measure of level. As in the case of displacer devices, accurate level measurement by hydrostatic head requires an accurate knowledge of the densities of both heavier-phase and lighter-phase fluids. The majority of this class of systems utilize standard pressure and differential pressure measuring devices.

***Bubble Tube Systems*** The commonly used bubble tube system sharply reduces restrictions on the location of the measuring element. To eliminate or reduce variations in pressure drop due to the gas flow rate, a constant differential regulator is commonly employed to maintain a constant gas flow rate. Because the flow of gas through the bubble tube prevents entry of the process liquid into the measuring system, this technique is particularly useful with corrosive or viscous liquids, liquids subject to freezing, and liquids containing entrained solids.

**Electrical Methods** Two electrical characteristics of fluids—conductivity and dielectric constant—are frequently used to distinguish between two phases for level measurement purposes. An application of electrical conductivity is the fixed-point level detection of a conductive liquid such as high and low water levels. A voltage is applied between two electrodes inserted into the vessel at different levels. When both electrodes are immersed in the liquid, current flows. Capacitance-type level measurements are based on the fact that the electrical capacitance between two electrodes varies with the dielectric constant of the material between them. A typical continuous level measurement system consists of a rod electrode positioned vertically in a vessel, the other electrode usually being the metallic vessel wall. The electrical capacitance between the electrodes is a measure of the height of the interface along the rod electrode. The rod is usually conductively insulated from process fluids by a coating of plastic. The dielectric constants of most liquids and solids are markedly higher than those of gases and vapors (by a factor of 2 to 5). The dielectric constant of water and other polar liquids is 10 to 20 times that of hydrocarbons and other nonpolar liquids.

**Thermal Methods** Level-measuring systems may be based on the difference in thermal characteristics between the fluids, such as temperature or thermal conductivity. A fixed-point level sensor based on the difference in thermal conductivity between two fluids consists of an electrically heated thermistor inserted into the vessel. The temperature of the thermistor and consequently its electrical resistance increase as the thermal conductivity of the fluid in which it is immersed decreases. Because the thermal conductivity of liquids is markedly higher than that of vapors, such a device can be used as a point level detector for the liquid-vapor interface.

**Sonic Methods** A fixed-point level detector based on sonic propagation characteristics is available for detection of a liquid-vapor interface. This device uses a piezoelectric transmitter and receiver, separated by a short gap. When the gap is filled with liquid, ultrasonic energy is transmitted

across the gap, and the receiver actuates a relay. With a vapor filling the gap, the transmission of ultrasonic energy is insufficient to actuate the receiver.

**Laser Level Transmitters** These are designed for bulk solids, slurries, and opaque liquids. A laser near the vessel top fires a short pulse of light down to the surface of the process liquid, where it reflects back to a detector at the vessel top. A timing circuit measures the elapsed time and calculates the fluid depth. Lasers are attractive because lasers have no false echoes and can be directed through tight spaces.

**Radar Level Transmitters** Radar systems operate by beaming microwaves downward, from either a horn or parabolic dish located on top of the vessel. The signal reflects off the fluid surface back to the source after it detects a change in dielectric constant from the vapor to the fluid. The round-trip time is proportional to the distance to the fluid level. Guided-wave radar systems provide a rigid probe or flexible cable to guide the microwave down the height of the tank and back. Guided-wave radar is much more efficient than open-air radar because the guide provides a more focused energy path.

## PHYSICAL PROPERTY MEASUREMENTS

Physical property measurements are sometimes equivalent to composition analyzers, because the composition can frequently be inferred from the measurement of a selected physical property.

**Density and Specific Gravity** For binary or pseudo-binary mixtures of liquids or gases or a solution of a solid or gas in a solvent, the density is a function of the composition at a given temperature and pressure. Specific gravity is the ratio of the density of a noncompressible substance to the density of water at the same physical conditions. For nonideal solutions, empirical calibration will give the relationship between density and composition. Several types of measuring devices are described below.

***Liquid Column*** Density may be determined by measuring the gauge pressure at the base of a fixed-height liquid column open to the atmosphere. If the process system is closed, then a differential pressure measurement is made between the bottom of the fixed-height liquid column and the vapor over the column. If vapor space is not always present, the differential pressure measurement is made between the bottom and top of a fixed-height column with the top measurement being made at a point below the liquid surface.

***Displacement*** There are a variety of density measurement devices based on displacement techniques. A hydrometer is a constant-weight, variable-immersion device. The degree of immersion, when the weight of the hydrometer equals the weight of the displaced liquid, is a measure of the density. The hydrometer is adaptable to manual or automatic use. Another modification includes a magnetic float suspended below a solenoid, the varying magnetic field maintaining the float at a constant distance from the solenoid. Change in position of the float, resulting from a density change, excites an electrical system which increases or decreases the current through the solenoid.

***Direct Mass Measurement*** One type of densitometer measures the natural vibration frequency and relates the amplitude to changes in density. The density sensor is a V-shaped tube that is held stationary at its node points and allowed to vibrate at its natural frequency. At the curved end of the V is an electrochemical device that periodically strikes the tube. At the other end of the V, the fluid is continuously passed through the tube. Between strikes, the tube vibrates at its natural frequency. The frequency changes directly in proportion to changes in density. A pickup device at the curved end of the V measures the frequency and electronically determines the fluid density. This technique is useful because it is not affected by the optical properties of the fluid. However, particulate matter in the process fluid can affect the accuracy.

***Radiation-Density Gauges*** Gamma radiation may be used to measure the density of material inside a pipe or process vessel. The equipment is basically the same as for level measurement, except that here the pipe or vessel must be filled over the effective, irradiated sample volume. The source is mounted on one side of the pipe or vessel and the detector on the other side with appropriate safety radiation shielding surrounding the installation. Cesium 137 is used as the radiation source for path lengths under 610 mm (24 in) and cobalt 60 above 610 mm. The detector is usually an ionization gauge. The absorption of the gamma radiation is a function of density. Since the absorption path includes the pipe or vessel walls, an empirical calibration is used. Appropriate corrections must be made for the source intensity decay with time.

**Viscosity** Continuous viscometers generally measure either the resistance to flow or the drag or torque produced by movement of an element (moving surface) through the fluid. Each installation is normally applied over a narrow range of viscosities. Empirical calibration over this range allows use on both newtonian and nonnewtonian fluids. One such device uses a piston inside a cylinder. The hydrodynamic pressure of the process fluid raises the piston to a preset height. Then the inlet valve closes, the piston is allowed to free-fall, and the time of travel (typically a few seconds) is a measure of viscosity. Other geometries include the rotation of a spindle inside a sample chamber and a vibrating probe immersed in the fluid. Because viscosity depends on temperature, the viscosity measurement must be thermostated with a heater or cooler.

**Refractive Index** When light travels from one medium (e.g., air or glass) into another (e.g., a liquid), it undergoes a change of velocity and, if the angle of incidence is not 90°, a change of direction. For a given interface, angle, temperature, and wavelength of light, the amount of deviation or refraction will depend on the composition of the liquid. If the sample is transparent, the normal method is to measure the refraction of light transmitted through the glass-sample interface. If the sample is opaque, the reflectance near the critical angle at a glass-sample interface is measured. In an online refractometer, the process fluid is separated from the optics by a prism material. A beam of light is focused on a point in the fluid which creates a conic section of light at the prism, striking the fluid at different angles (greater than or less than the critical angle). The critical angle depends on the species concentrations; as the critical angle changes, the proportions of reflected and refracted light change. A photodetector produces a voltage signal proportional to the light refracted, when compared to a reference signal. Refractometers can be used with opaque fluids and in streams that contain particulates.

**Dielectric Constant** The dielectric constant of material represents its ability to reduce the electric force between two charges separated in space. This property is useful in process control for polymers, ceramic materials, and semiconductors. Dielectric constants are measured with respect to vacuum (1.0); typical values range from 2 (benzene) to 33 (methanol) to 80 (water). The value for water is higher than that for most plastics. A measuring cell is made of glass or some other insulating material and is usually doughnut-shaped, with the cylinders coated with metal, which constitute the plates of the capacitor.

**Thermal Conductivity** All gases and vapor have the ability to conduct heat from a heat source. At a given temperature and physical environment, radiation and convection heat losses will be stabilized, and the temperature of the heat source will mainly depend on the thermal conductivity and thus the composition of the surrounding gases. Thermal conductivity analyzers normally consist of a sample cell and a reference cell, each containing a combined heat source and detector. These cells are normally contained in a metal block with two small cavities in which the detectors are mounted. The sample flows through the sample cell cavity past the detector. The reference cell is an identical cavity with a detector through which a known gas flows. The combined heat source and detectors are normally either wire filaments or thermistors heated by a constant current. Because their resistance is a function of temperature, the sample detector resistance will vary with sample composition while the reference detector resistance will remain constant. The output from the detector bridge will be a function of sample composition.

## CHEMICAL COMPOSITION ANALYZERS

Chemical composition is generally the most challenging online measurement. Before the era of online analyzers, messengers were required to deliver samples to the laboratory for analysis and to return the results to the control room. The long time delay involved prevented process adjustment from being made, affecting product quality. The development of online analyzers has automated this approach and reduced the analysis time. However, manual sampling is still frequently employed, especially in the specialty chemical industry where few instruments are commercially available. It is not unusual for a chemical composition analysis system to cost over $100,000, so it is important to assess the payback of such an investment versus the cost of manual sampling. Potential quality improvements can be an important consideration.

A number of composition analyzers used for process monitoring and control require chemical conversion of one or more sample components preceding quantitative measurement. These reactions include formation of suspended solids for turbidimetric measurement, formation of colored materials for colorimetric detection, selective oxidation or reduction for electrochemical measurement, and formation of electrolytes for measurement by electrical conductance. Some nonvolatile materials may be separated and measured by gas chromatography after conversion to volatile derivatives.

**Chromatographic Analyzers** These analyzers are widely used for the separation and measurement of volatile compounds and of compounds that can be quantitatively converted to volatile derivatives. The compounds to be measured are separated by placing a portion of the sample in a chromatographic column and carrying the compounds through the column with a gas stream, called *gas chromatography*, or GC. As a result of

the different affinities of the sample components for the column packing, the compounds emerge successively as binary mixtures with the carrier gas. A detector at the column outlet measures a specific physical property that can be related to the concentrations of the compounds in the carrier gas. Both the concentration peak height and the peak height-time integral, i.e., peak area, can be related to the concentration of the compound in the original sample. The two detectors most commonly used for process chromatographs are the thermal conductivity detector and the hydrogen flame ionization detector. Thermal conductivity detectors, discussed earlier, require calibration for the thermal response of each compound. Hydrogen flame ionization detectors are more complicated than thermal conductivity detectors but are capable of 100 to 10,000 times greater sensitivity for hydrocarbons and organic compounds. For ultrasensitive detection of trace impurities, carrier gases must be specially purified.

Typically, all components can be analyzed in a 5- to 10-min time period (although miniaturized GCs are faster). *High-performance liquid chromatography* (HPLC) can be used to measure dissolved solute levels, including proteins.

**Infrared Analyzers** Many gaseous and liquid compounds absorb infrared radiation to some degree. The degree of absorption at specific wavelengths depends on the molecular structure and concentration. There are two common detector types for nondispersive infrared analyzers. These analyzers normally have two beams of radiation, an analyzing and a reference beam. One type of detector consists of two gas-filled cells separated by a diaphragm. As the amount of infrared energy absorbed by the detector gas in one cell changes, the cell pressure changes. This causes movement in the diaphragm, which in turn causes a change in capacitance between the diaphragm and a reference electrode. This change in electrical capacitance is measured as the output. The second type of detector consists of two thermopiles or two bolometers, one in each of the two radiation beams. The infrared radiation absorbed by the detector is measured by a differential thermocouple output or a resistance thermometer (bolometer) bridge circuit.

There are two common detector types for nondispersive analyzers. These analyzers normally have two beams of radiation, an analyzing beam and a reference beam. One type of detector consists of two gas-filled cells separated by a diaphragm. As the amount of infrared energy absorbed by the detector gas in one cell changes, the cell pressure changes. This causes movement in the diaphragm, which in turn causes a change in capacitance between the diaphragm and a reference electrode. This change in electrical capacitance is measured as the output. The second type of detector consists of two thermopiles or two bolometers, one in each of the two radiation beams. The infrared radiation absorbed by the detector is measured by a differential thermocouple output or a resistance thermometer (bolometer) bridge circuit. With gas-filled detectors, a chopped light system is normally used in which one side of the detector sees the source through the analyzing beam and the other side sees through the reference beam, alternating at a frequency of a few hertz.

**Ultraviolet and Visible-Radiation Analyzers** Many gas and liquid compounds absorb radiation in the near-ultraviolet or visible region. For example, organic compounds containing aromatic and carbonyl structural groups are good absorbers in the ultraviolet region. Also many inorganic salts and gases absorb in the ultraviolet or visible region. In contrast, straight-chain and saturated hydrocarbons, inert gases, air, and water vapor are essentially transparent. Process analyzers are designed to measure the absorbance in a particular wavelength band. The desired band is normally isolated by means of optical filters. When the absorbance is in the visible region, the term *colorimetry* is used. A phototube is the normal detector. Appropriate optical filters are used to limit the energy reaching the detector to the desired level and the desired wavelength region. Because absorption by the sample is logarithmic, if a sufficiently narrow wavelength region is used, an exponential amplifier is sometimes used to compensate and produce a linear output.

**Paramagnetism** A few gases including $O_2$, NO, and $NO_2$ exhibit paramagnetic properties as a result of unpaired electrons. In a nonuniform magnetic field, paramagnetic gases, because of their magnetic susceptibility, tend to move toward the strongest part of the field, thus displacing diamagnetic gases. Paramagnetic susceptibility of these gases decreases with temperature. These effects permit measurement of the concentration of the strongest paramagnetic gas, oxygen. An oxygen analyzer uses a dumbbell suspended in the magnetic field which is repelled or attracted toward the magnetic field depending on the magnetic susceptibility of the gas.

**Other Analyzers** *Mass spectroscopy* (MS) determines the partial pressures of gases in a mixture of directing ionized gases into a detector under a vacuum ($10^{-6}$ torr), and the gas-phase composition is then monitored more or less continuously based on the molecular weight of the species (Nichols, 2010). Sometimes GC is combined with MS to obtain a higher level of discrimination of the components present. Fiber-optic sensors are attractive options (although higher-cost) for acquiring measurements in harsh environments such as high temperature or pressure. The transducing technique used by these sensors is optical and does not involve electric signals, so they are immune to electromagnetic interference. Raman spectroscopy uses fiber optics and involves pulsed light scattering by molecules. It has a wide variety of applications in process control [Workman, Koch, and Veltkamp, *Anal. Chem.* **75:** 2859 (2003)].

Significant advances have occurred during the past decade to miniaturize the size of the measurement system in order to make online analysis economically feasible and to reduce time delays that often are present in analyzers. Recently, chemical sensors have been placed on microchips, even those requiring multiple physical, chemical, and biochemical steps (such as electrophoresis) in the analysis. This device has been called *lab-on-a-chip*. The measurements of chemical composition can be direct or indirect, the latter case referring to applications in which some property of the process stream is measured (such as refractive index) and then related to composition of a particular component.

## ELECTROANALYTICAL INSTRUMENTS

**Conductometric Analysis** Solutions of electrolytes in ionizing solvents (e.g., water) conduct current when an electrical potential is applied across electrodes immersed in the solution. Conductance is a function of ion concentration, ionic charge, and ion mobility. Conductance measurements are ideally suited for measurement of the concentration of a single strong electrolyte in dilute solutions. At higher concentrations conductance becomes a complex, nonlinear function of concentration requiring suitable calibration for quantitative measurements.

**Measurement of pH** The primary detecting element in pH measurement is the glass electrode. A potential is developed at the pH-sensitive glass membrane as a result of differences in hydrogen ion activity in the sample and a standard solution contained within the electrode. This potential measured relative to the potential of the reference electrode gives a voltage which is expressed as pH. Instrumentation for pH measurement is among the most widely used process measurement devices. Rugged electrode systems and highly reliable electronic circuits have been developed for this use.

After installation, the majority of pH measurement problems are sensor-related, mostly on the reference side, including junction plugging, poisoning, and depletion of electrolyte. For the glass (measuring electrode), common difficulties are broken or cracked glass, coating, and etching or abrasion. Symptoms such as drift, sluggish response, unstable readings, and inability to calibrate are indications of measurement problems. Online diagnostics such as impedance measurements, wiring checks, and electrode temperature are now available in most instruments. Other characteristics that can be measured offline include efficiency or slope and asymmetry potential (offset), which indicate whether the unit should be cleaned or changed [McMillan and Cameron, *Advanced Measurement and Control*, 3d ed., ISA, Research Triangle Park, N.C., 2005].

**Specific-Ion Electrodes** In addition to the pH glass electrode specific for hydrogen ions, a number of electrodes that are selective for the measurement of other ions have been developed. This selectivity is obtained through the composition of the electrode membrane (glass, polymer, or liquid-liquid) and the composition of the electrode. These electrodes are subject to interference from other ions, and the response is a function of the total ionic strength of the solution. However, electrodes have been designed to be highly selective for specific ions, and when properly used, these provide valuable process measurements.

## MOISTURE MEASUREMENT

Moisture measurements are important in the process industries because moisture can foul products, poison reactions, damage equipment, or cause explosions. Moisture measurements include both absolute moisture methods and relative-humidity methods. The absolute methods provide a primary output that can be directly calibrated in terms of dew point temperature, molar concentration, or weight concentration. Loss of weight on heating is the most familiar of these methods. The relative-humidity methods provide a primary output that can be more directly calibrated in terms of percentage of saturation of moisture.

**Dew Point Method** For many applications the dew point is the desired moisture measurement. When concentration is desired, the relation between water content and dew point is well known and available. The dew point method requires an inert surface whose temperature can be adjusted and measured, a sample gas stream flowing past the surface, a manipulated variable for adjusting the surface temperature to the dew point, and a means of detecting the onset of condensation.

Although the presence of condensate can be detected electrically, the original and most often used method is the optical detection of change in light reflection from an inert metallic-surface mirror. Some instruments measure the attenuation of reflected light at the onset of condensation. Others measure

the increase of light dispersed and scattered by the condensate instead of, or in addition to, the reflected-light measurement. Surface cooling is obtained with an expendable refrigerant liquid, conventional mechanical refrigeration, or thermoelectric cooling. Surface-temperature measurement is usually made with a thermocouple or a thermistor.

**Piezoelectric Method** A piezoelectric crystal in a suitable oscillator circuit will oscillate at a frequency dependent on its mass. If the crystal has a stable hygroscopic film on its surface, the equivalent mass of the crystal varies with the mass of water sorbed in the film. Thus the frequency of oscillation depends on the water in the film. The analyzer contains two such crystals in matched oscillator circuits. Typically, valves alternately direct the sample to one crystal and a dry gas to the other on a 30-s cycle. The oscillator frequencies of the two circuits are compared electronically, and the output is the difference between the two frequencies. This output is then representative of the moisture content of the sample. The output frequency is usually converted to a variable dc voltage for meter readout and recording. Multiple ranges are provided for measurement from about 1 ppm to near saturation. The dry reference gas is preferably the same as the sample except for the moisture content of the sample. Other reference gases which are adsorbed in a manner similar to the dried sample gas may be used. The dry gas is usually supplied by an automatic dryer. The method requires a vapor sample to the detector. Mist striking the detector destroys the accuracy of measurement until it vaporizes or is washed off the crystals. Water droplets or mist may destroy the hygroscopic film, thus requiring crystal replacement. Vaporization or gas-liquid strippers may sometimes be used for the analysis of moisture in liquids.

**Capacitance Method** Several analyzers utilize the high dielectric constant of water for its detection in solutions. The alternating electric current through a capacitor containing all or part of the sample between the capacitor plates is measured. Selectivity and sensitivity are enhanced by increasing the concentration of moisture in the cell by filling the capacitor sample cell with a moisture-specific sorbent as part of the dielectric. This both increases the moisture content and reduces the amount of other interfering sample components. Granulated alumina is the most frequently used sorbent. These detectors may be cleaned and recharged easily and with satisfactory reproducibility if the sorbent itself is uniform.

**Oxide Sensors** Aluminum oxide can be used as a sensor for moisture analysis. A conductivity call has one electrode node of aluminum, which is anodized to form a thin film of aluminum oxide, followed by coating with a thin layer of gold (the opposite electrode). Moisture is selectively adsorbed through the gold layer and into the hygroscopic aluminum oxide layer, which in turn determines the electrical conductivity between gold and aluminum oxide. This value can be related to ppm water in the sample. This sensor can operate between near vacuum to several hundred atmospheres, and it is independent of flow rate (including static conditions). Temperature, however, must be carefully monitored. A similar device is based on phosphorous pentoxide. Moisture content influences the electric current between two inert metal electrodes, which are fabricated as a helix on the inner wall of a tubular nonconductive sample cell. For a constant dc voltage applied to the electrodes, current flow is proportional to moisture. The moisture is absorbed into the hygroscopic phosphorous pentoxide, where the current electrolyzes the water molecules into hydrogen and oxygen. This sensor will handle moisture up to 1000 ppm and 6-atm pressure. As with the aluminum oxide ion, temperature control is very important.

**Photometric Moisture Analysis** This analyzer requires a light source, a filter wheel rotated by a synchronous motor, a sample cell, a detector to measure the light transmitted, and associated electronics. Water has two absorption bands in the near-infrared region at 1400 and 1900 nm. This analyzer can measure moisture in liquid or gaseous samples at levels from 5 ppm up to 100 percent, depending on other chemical species in the sample. Response time is less than 1 s, and samples can be run up to 300°C and 400 psig.

## OTHER TRANSDUCERS

Other types of transducers used in process measurements include mechanical drivers such as gear trains and electrical drivers such as a differential transformer or a Hall effect (semiconductor-based) sensor.

**Gear Train** Rotary motion and angular position are easily transduced by various types of gear arrangements. A gear train in conjunction with a mechanical counter is a direct and effective way to obtain a digital readout of shaft rotations. The numbers on the counter can mean anything desired, depending on the gear ratio and the actuating device used to turn the shaft. A pointer attached to a gear train can be used to indicate a number of revolutions or a small fraction of a revolution for any specified pointer rotation.

**Differential Transformer** These devices produce an ac electrical output from linear movement of an armature. They are very versatile in that they can be designed for a full range of output with any range of armature travel up to several inches. The transformers have one or two primaries and two secondaries connected to oppose each other. With an ac voltage applied to the primary, the output voltage depends on the position of the armature and the coupling. Such devices produce accuracies of 0.5 to 1.0 percent of full scale and are used to transmit forces, pressures, differential pressures, or weights up to 1500 m. They can also be designed to transmit rotary motion.

**Hall Effect Sensors** Some semiconductor materials exhibit a phenomenon in the presence of a magnetic field which is adaptable to sensing devices. When a current is passed through one pair of wires attached to a semiconductor, such as germanium, another pair of wires properly attached and oriented with respect to the semiconductor will develop a voltage proportional to the magnetic field present and the current in the other pair of wires. Holding the exciting current constant and moving a permanent magnet near the semiconductor produce a voltage output proportional to the movement of the magnet. The magnet may be attached to a process variable measurement device, which moves the magnet as the variable changes. Hall effect devices provide high speed of response, excellent temperature stability, and no physical contact.

## SAMPLING SYSTEMS FOR PROCESS ANALYZERS

The sampling system consists of all the equipment required to present a process analyzer with a clean representative sample of a process stream and to dispose of that sample. When the analyzer is part of an automatic control loop, the reliability of the sampling system is as important as the reliability of the analyzer or the control equipment. Sampling systems have several functions. The sample must be withdrawn from the process, transported, conditioned, introduced to the analyzer, and disposed. Probably the most common problem in sample system design is the lack of realistic information concerning the properties of the process material at the sampling point. Another common problem is the lack of information regarding the conditioning required so that the analyzer may utilize the sample without malfunction for long periods. Some samples require enough conditioning and treating that the sampling systems become equivalent to miniature online processing plants. These systems possess many of the same fabrication, reliability, and operating problems as small-scale pilot plants except that the sampling system must generally operate reliably for much longer periods.

**Selecting the Sampling Point** The selection of the sampling point is based primarily on supplying the analyzer with a sample whose composition or physical properties are pertinent to the control function to be performed. Other considerations include selecting locations that provide representative homogeneous samples with minimum transport delay, locations which collect a minimum of contaminating material, and locations that are accessible for test and maintenance procedures.

**Sample Withdrawal from Process** A number of considerations are involved in the design of sample withdrawal devices which will provide representative samples. For example, in a horizontal pipe carrying process fluid, a sample point on the bottom of the pipe will collect a maximum count of rust, scale, or other solid materials being carried along by the process fluid. In a gas stream, such a location will also collect a maximum amount of liquid contaminants. A sample point on the top side of a pipe will, for liquid streams, collect a maximum amount of vapor contaminants being carried along. Bends in the piping that produce swirls or cause centrifugal concentration of the denser phase may cause maximum contamination to be at unexpected locations. Two-phase process materials are difficult to sample for a total-composition representative sample.

A typical method for obtaining a sample of process fluid well away from vessel or pipe walls is an eduction tube inserted through a packing gland. This sampling method withdraws a liquid sample and vaporizes it for transport to the analyzer location. The transport lag time from the end of the probe to the vaporizer is minimized by using tubing having a small internal volume compared with pipe and valve volumes.

This sample probe may be removed for maintenance and reinstalled without shutting down the process. The eduction tube is made of material that will not corrode so that it will slide through the packing gland even after long periods of service. There may be a small amount of process fluid leakage until the tubing is withdrawn sufficiently to close the gate valve. A swaged ferrule on the end of the tube prevents accidental ejection of the eduction tube prior to removal of the packing gland. The section of pipe surrounding the eduction tube and extending into the process vessel provides mechanical protection for the eduction tube.

**Sample Transport** Transport time—the time elapsed between sample withdrawal from the process and its introduction into the analyzer—should be minimized, particularly if the analyzer is an automatic analyzer-controller. Any sample transport time in the analyzer-controller loop must be treated as equivalent to process dead time in determining conventional feedback controller settings or in evaluating controller performance. Reduction in transport time usually means transporting the sample in the vapor state.

Design considerations for sample lines are as follows:

1. The structural strength or protection must be compatible with the area through which the sample line runs.
2. Line size and length must be small enough to meet transport time requirements without excessive pressure drop or excessive bypass of sample at the analyzer input.
3. Line size and internal surface quality must be adequate to prevent clogging by the contaminants in the sample.
4. The prevention of a change of state of the sample may require installation, refrigeration, or heating of the sample line.
5. Sample line material must be such as to minimize corrosion due to the sample or the environment.

**Sample Conditioning** Sample conditioning usually involves the removal of contaminants or some deleterious component from the sample mixture and/or the adjustment of temperature, pressure, and flow rate of the sample to values acceptable to the analyzer. Some of the more common contaminants that must be removed are rust, scale, corrosion products, deposits due to chemical reactions, and tar. In sampling some process streams, the material to be removed may include the primary process product such as a polymer or the main constituent of the stream such as oil. In other cases, the material to be removed is present in trace quantities, e.g., water in an online chromatograph sample that can damage the chromatographic column packing. When contaminants or other materials that will hinder analysis represent a large percentage of the stream composition, their removal may significantly alter the integrity of the sample. In some cases, removal must be done as part of the analysis function so that removed material can be accounted for. In other cases, proper calibration of the analyzer output will suffice.

# CONTROLLERS, FINAL CONTROL ELEMENTS, AND REGULATORS

External control of the process is achieved by devices that are specially designed, selected, and configured for the intended process control application. The text that follows covers three very common function classifications of process control devices: controllers, final control elements, and regulators.

The process controller is the "master" of the process control system. It accepts a set point and other inputs and generates an output or outputs that it computes from a rule or set of rules that is part of its internal configuration. The controller output serves as an input to another controller or, more often, as an input to a final control element. The final control element typically is a device that affects the flow in the piping system of the process. The final control element serves as an interface between the process controller and the process. Control valves and adjustable-speed pumps are the principal types discussed.

Regulators, though not controllers or final control elements, perform the combined function of these two devices (controller and final control element) along with the measurement function commonly associated with the process variable transmitter. The uniqueness, control performance, and widespread use of the regulator make it deserving of a functional grouping of its own.

## PNEUMATIC, ELECTRONIC, AND DIGITAL CONTROLLERS

**Pneumatic Controllers** The pneumatic controller is an automatic controller that uses variable air pressure as input and output signals. An air supply is also required to "power" the mechanical components of the controller and provide an air source for the controller output signal. Pneumatic controllers were first available in the early 1940s but are now rarely used for large-scale industrial control projects. Pneumatic controllers are still used where cost, ruggedness, or the installation requires an all-pneumatic solution.

Pneumatic process transmitters are used to produce a pressure signal that is proportional to the calibrated range of the measuring element. Of the transmitter range 0 to 100 percent is typically represented by a 0.2- to 1.0-bar (3- to 15-psig) pneumatic signal. This signal is sent through tubing to the pneumatic controller process variable feedback connection. The process variable feedback can also be sensed directly in cases where the sensing element has been incorporated into the controller design. Controllers with integral sensing elements are available that sense pressure, differential pressure, temperature, and level.

The pneumatic controller is designed so that 0 to 100 percent output is also represented by 0.2 to 1.0 bar (3 to 15 psig). The output signal is sent through tubing to the control valve or other final control element. Most pneumatic controllers provide a manual control mode where the output pressure is manually set by operating personnel. The controller design also provides a mechanism to adjust the set point.

Early controller designs required "balancing" of the controller output prior to switching to or from automatic and manual modes. This procedure minimized inadvertent disturbance to the process caused by potentially large differences between the automatic and manual output levels. Later designs featured "bumpless" or "procedureless" automatic-to-manual transfer.

Although the pneumatic controller is often used in single-loop control applications, cascade strategies can be implemented where the controller design supports input of external or remote set-point signals. A balancing procedure is typically required to align the remote set point with the local set point before the controller is switched into cascade mode.

Almost all pneumatic controllers include indicators for process variable, set point, and output. Many controller designs also feature integral chart recorders. There are versions of the pneumatic controller that support combinations of proportional, integral, and derivative actions.

The pneumatic controller can be installed into panel boards that are adjacent to the process being controlled or in a centrally located control room. Field-mountable controllers can be installed directly onto the control valve, a nearby pipe stand, or wall in close proximity to the control valve and/or measurement transmitter.

If operated on clean, dry plant air, pneumatic controllers offer good performance and are extremely reliable. In many cases, however, plant air is neither clean nor dry. A poor-quality air supply will cause unreliable performance of pneumatic controllers, pneumatic field measurement devices, and final control elements. The main shortcoming of the pneumatic controller is its lack of flexibility when compared to modern electronic controller designs. Increased range of adjustability, choice of alternative control algorithms, the communication link to the control system, and other features and services provided by the electronic controller make it a superior choice in most of today's applications. Controller performance is also affected by the time delay induced by pneumatic tubing runs. For example, a 100-m run of 6.35-mm ($\frac{1}{4}$-in) tubing will typically cause 5 s of apparent process dead time, which will limit the control performance of fast processes such as flows and pressures.

Pneumatic controllers continue to be used in areas where it would be hazardous to use electronic equipment, such as locations with flammable or explosive atmospheres or other locations where compressed air is available but where access to electrical services is limited or restricted.

**Electronic (Digital) Controllers** Almost all the electronic process controllers used today are microprocessor-based, digital devices. In the transition from pneumatic to electronic controllers, a number of analog controller designs were available. Due to the inflexible nature of the analog designs, these controllers have been almost completely replaced by digital designs. The microprocessor-based controllers contain, or have access to, input/output (I/O) interface electronics that allow various types of signals to enter and leave the controller's processor.

The resolution of the analog I/O channels of the controller varies by manufacturer and age of the design. The 12- to 14-bit conversion resolution of the analog input channels is quite common. Conversion resolution of the analog output channels is typically 10- to 12-bit. Newer designs support up to 16-bit input and output resolution. Although 10-bit output resolution

had been considered satisfactory for many years, it has recently been identified as a limitation of control performance. This limitation has emerged as the performance of control valve actuators has improved and the use of other high-resolution field devices, such as variable-speed pump drives, has become more prevalent. These improvements have been driven by the need to deliver higher operating efficiencies and improved product specifications through enhanced process control performance.

Sample rates for the majority of digital controllers are adjustable and range from 1 sample every 5 s to 10 samples per second. Some controller designs have fixed sample rates that fall within the same range. Hardwired low-pass filters are usually installed on the analog inputs to the controller to help protect the sampler from aliasing errors.

The real advantage of digital controllers is the substantial flexibility offered by a number of different configuration schemes. The simplest form of configuration is seen in a controller design that features a number of user-selectable control strategies. These strategies are customized by setting "tunable" parameters within the strategy. Another common configuration scheme uses a library of function blocks that can be selected and combined to form the desired control strategy. Each function block has adjustable parameters. Additional configuration schemes include text-based scripting languages, higher-level languages such as BASIC or C, and ladder logic.

Some digital controller designs allow the execution rates of control strategy elements to be set independently of one another and independently of the I/O subsystem sample rate. Data passed from control element to subsystems that operate at slower sample or execution rates present additional opportunities for timing and aliasing errors.

***Distributed Control Systems*** Some knowledge of the *distributed control system* (DCS) is useful in understanding electronic controllers. A DCS is a process control system with sufficient performance to support large-scale, real-time process applications. The DCS has (1) an operations workstation with input devices, such as a keyboard, mouse, track ball, or other similar device, and a display device, such as a CRT or LCD panel; (2) a controller subsystem that supports various types of controllers and controller functions; (3) an I/O subsystem for converting analog process input signals to digital data and digital data back to analog output signals; (4) a higher-level computing platform for performing process supervision, historical data trending and archiving functions, information processing, and analysis; and (5) communication networks to tie the DCS subsystems, plant areas, and other plant systems together. The component controllers used in the controller subsystem portion of the DCS can be of various types and include multiloop controllers, programmable logic controllers, personal computer controllers, single-loop controllers, and fieldbus controllers. The type of electronic controller utilized depends on the size and functional characteristics of the process application being controlled. Personal computers are increasingly being used as DCS operation workstations or interface stations in place of custom-built machines. This is due to the low cost and high performance of the PC. See the earlier subsection Digital Technology for Process Control.

***Multiloop Controllers*** The multiloop controller is a DCS network device that uses a single 32-bit microprocessor to provide control functions to many process loops. The controller operates independently of the other devices on the DCS network and can support from 20 to 500 loops. Data acquisition capability for 1000 analog and discrete I/O channels or more can also be provided by this controller. The I/O is typically processed through a subsystem that is connected to the controller through a dedicated bus or network interface. The multiloop controller contains a variety of function blocks (for example, PID, totalizer, lead/lag compensator, ratio control, alarm, sequencer, and boolean) that can be "soft-wired" together to form complex control strategies. The multiloop controller also supports additional configuration schemes including text-based scripting languages, higher-level languages such as BASIC or C, and, to a limited extent, ladder logic. The multiloop controller, as part of a DCS, communicates with other controllers and human/machine interface (HMI) devices also on the DCS network.

***Programmable Logic Controllers*** The *programmable logic controller* (PLC) originated as a solid-state, and far more flexible, replacement for the hardwired relay control panel and was first used in the automotive industry for discrete manufacturing control. Today, PLCs are primarily used to implement boolean logic functions, timers, and counters. Some PLCs offer a limited number of math functions and PID control. PLCs are often used with on/off input and output devices such as limit or proximity switches, solenoid-actuated process control valves, and motor switch gear. PLCs vary greatly in size with the smallest supporting less than 128 I/O channels and the largest supporting more than 1023 I/O channels. Very small PLCs combine processor, I/O, and communications functions into a single, self-contained unit. For larger PLC systems, hardware modules such as the power supply, processor module, I/O modules, communication module, and backplane are specified based on the application. These systems support multiple I/O backplanes that can be chained together to increase the I/O count available to the processor. Discrete I/O modules are available that support high-current motor loads and general-purpose voltage and current loads. Other modules support analog I/O and special-purpose I/O for servomotors, stepping motors, high-speed pulse counting, resolvers, decoders, displays, and keyboards. PLC I/O modules often come with indicators to determine the status of key I/O channels. When used as an alternative to a DCS, the PLC is programmed with a handheld or computer-based loader. The PLC is typically programmed with ladder logic or a high-level computer language such as BASIC, FORTRAN, or C. Programmable logic controllers use 16- or 32-bit microprocessors and offer some form of point-to-point serial communications such as RS-232C, RS-485, or networked communication such as Ethernet with proprietary or open protocols. PLCs typically execute the boolean or ladder logic configuration at high rates; 10-ms execution intervals are common. This does not necessarily imply that the analog I/O or PID control functions are executed at the same rate. Many PLCs execute the analog program at a much slower rate. Manufacturers' specifications must be consulted.

***Personal Computer Controller*** Because of its high performance at low cost and its unexcelled ease of use, application of the personal computer (PC) as a platform for process controllers is growing. When configured to perform scan, control, alarm, and data acquisition (SCADA) functions and combined with a spreadsheet or database management application, the PC controller can be a low-cost, basic alternative to the DCS or PLC. Using the PC for control requires installation of a board into the expansion slot in the computer, or the PC can be connected to an external I/O module by using a standard communication port on the PC. The communication is typically achieved through a serial interface (RS-232, RS-422, or IEEE-488), universal serial bus (USB), or Ethernet. The controller card/module supports 16- or 32-bit microprocessors. Standardization and high volume in the PC market have produced a large selection of hardware and software tools for PC controllers.

The PC can also be interfaced to a DCS to perform advanced control or optimization functions that are not available within the standard DCS function library.

***Single-Loop Controller*** The *single-loop controller* (SLC) is a process controller that produces a single output. SLCs can be pneumatic, analog electronic, or microprocessor-based. Pneumatic SLCs are discussed in the pneumatic controller section, and analog electronic SLC is not discussed because it has been virtually replaced by the microprocessor-based design. The microprocessor-based SLC uses an 8- or 16-bit microprocessor with a small number of digital and analog process input channels with control logic for the I/O incorporated within the controller. Analog inputs and outputs are available in the standard ranges (1 to 5 V dc and 4 to 20 mA dc). Direct process inputs for temperature sensors (thermistor RTD and thermocouple types) are available. Binary outputs are also available. The face of the SLC has some form of visible display and pushbuttons that are used to view or adjust control values and configuration. SLCs are available for mounting in panel openings as small as $48 \times 48$ mm ($1.9 \times 1.9$ in).

The processor-based SLC allows the user to select from a set of predefined control strategies or to create a custom control strategy by using a set of control function blocks. Control function blocks include PID, on/off, lead/lag, adder/subtractor, multiply/divide, filter functions, signal selector, peak detector, and analog track. SLCs feature auto/manual transfer switching, multi-set-point self-diagnostics, gain scheduling, and perhaps also time sequencing. Most processor-based SLCs have self-tuning or auto-tuning PID control algorithms. Sample times for the microprocessor-based SLCs vary from 0.1 to 0.5 s. Low-pass analog electronic filters are usually installed on the process inputs to minimize aliasing errors caused by high-frequency content in the process signal. Input filter time constants are typically in the range of 0.1 to 1 s. Microprocessor-based SLCs may be made part of a DCS by using the communication port (RS-488 is common) on the controller or may be operated in a stand-alone mode independently of the DCS.

***Fieldbus Controller*** Fieldbus technology is a network-based communications system that interconnects measurement and control equipment such as sensors, actuators, and controllers. Advanced fieldbus systems, intended for process control applications, such as Foundation Fieldbus, enable digital interoperability among these devices and have a built-in capability to distribute the control application across the network. Several manufacturers have made available Foundation Fieldbus devices that support process controller functionality. These controllers, known as fieldbus controllers, typically reside in the final control element or measurement transmitter, but can be designed into any fieldbus device. A suitable communications interface connects the fieldbus segment to the distributed control system. When the control strategy is configured, all or part of the strategy may be loaded into the fieldbus devices. The remaining part of the control strategy would reside in the DCS itself. The distribution of the control function depends on the processing capacity of the fieldbus devices, the control strategy, and where it makes sense to perform these functions. Linearization of a control valve could be performed in the digital valve

positioner (controller), for example. Temperature and pressure compensation of a flow measurement could be performed in the flow transmitter processor. The capability of fieldbus devices varies greatly. Some devices will allow instances of control system function blocks to be loaded and executed, while other devices allow the use of only preconfigured function blocks. Fieldbus controllers are typically configured as single-loop PID controllers, but cascade or other complex control strategies can be configured depending on the capability of the fieldbus device. Fieldbus devices that have native support for process control functions do not necessarily implement the PID algorithm in the same way. It is important to understand these differences so that the controller tuning will deliver the desired closed-loop characteristics. The functionality of fieldbus devices is projected to increase as the controller market develops.

***Controller Reliability and Application Trends*** Critical process control applications demand a high level of reliability from the electronic controller. Some methods that improve the reliability of electronic controllers include (1) focusing on robust circuit design using quality components; (2) using redundant circuits, modules, or subsystems where necessary; (3) using small backup systems when needed; (4) reducing repair time and using more powerful diagnostics; and (5) distributing functionality to more independent modules to limit the impact of a failed module. Currently, the trend in process control is away from centralized process control and toward an increased number of small distributed control or PLC systems. This trend will put emphasis on the evolution of the fieldbus controller and continued growth of the PC-based controller. Also, as hardware and software improve, the functionality of the controller will increase, and the supporting hardware will be physically smaller. Hence, the traditional lines between the DCS and the PLC will become less distinct as systems become capable of supporting either function set.

***Controller Performance and Process Dynamics*** The design of a control loop must take the control objectives into account. What do you want this loop to do? And under what operating conditions? There may be control applications that require a single control objective and others that have several control objectives. Control objectives may include such requirements as minimum variance control at steady state, maximum speed of recovery from a major disturbance, maximum speed of set-point response where overshoot and ringing are acceptable, critically damped set-point response with no overshoot, robustness issues, and special start-up or shutdown requirements. The control objectives will define not only the tuning requirements of the controller, but also, to a large extent, the allowable dynamic parameters of the field instruments and process design. Process dynamics alone can prevent control objectives from being realized. Tuning of the controller cannot compensate for an incompatible process or unrealistic control objectives. For most controllers, the difference between the set-point and process feedback signal—the error—is the input to the PID algorithm. The calculated PID output is sent back to the final control element. Every component between the controller output and the process feedback is considered by the controller as the "process" and will directly affect the dynamics and ultimately the performance of the system. This includes not only the dynamics of the physical process, but also the dynamics of the field instruments, signal conditioning equipment, and controller signal processing elements such as filters, scaling, and linearization routines. The choice of final control element can significantly affect the dynamics of the system. If the process dynamics are relatively slow, with time constants of a few minutes or longer, most control valves are fast enough that their contribution to the overall process time response will be negligible. In cases where the process time constants are only a few seconds, the control valve dynamics may become the dominant lag in the overall response. Excessive filtering in the field-sensing devices may also mask the true process dynamics and potentially limit control performance. Often, the design of a control loop and the tuning of the controller are a compromise between a number of different control objectives. When a compromise is unacceptable, gain scheduling or other adaptive tuning routine may be necessary to match the controller response to the most appropriate control objective.

When one is tuning a controller, the form of the PID algorithm must be known. The three common forms of the PID algorithm are parallel or noninteracting, classical or interacting, and the ISA Standard form. In *most* cases, a controller with any of these PID forms can be tuned to produce the desired closed-loop response. The actual tuning parameters will be different. The units of the tuning parameters also affect their value. The controller gain parameter is typically represented as a pure gain ($K_c$), acting on the error, or as *proportional band* (PB). In cases where the proportional band parameter is used, the equivalent controller gain is equal to 100 divided by the proportional band and represents the percent span that the error must traverse to produce a 100 percent change in controller output. The proportional band is always applied to the controller error in terms of percent of span and percent of output. Controllers that use a gain tuning parameter commonly scale the error into percent span and use a percent output basis. In some controllers, the error is scaled by using a separate parameter into percent span prior to the PID algorithm. The gain parameter can also be applied to the error in engineering units. Even though most controller outputs are scaled as a percent, in cascade strategies the controller output may need to be scaled to the same span at the slave loop set point. In this case, the controller gain may in fact be required to calculate the controller output in terms of the slave loop engineering units.

The execution rate of a digital controller should be sufficiently fast, compared to the process dynamics, to produce a response that closely approximates that of an analog controller with the same tuning. A general rule of thumb is that the execution interval should be at least 3 times faster than the dominant lag of the process or about 10 times faster than the closed-loop time constant. The controller can be used when the sample rates are slower than this recommendation, but the controller output will consist of a series of coarse steps as compared to a smooth response. This may create stability problems. Some integral and derivative algorithms may not be accurate when the time-based tuning parameters approach the controller execution interval. The analog inputs of the controller are typically protected from aliasing errors through the use of one- or two-pole analog filters. Faster sample rates allow a smaller antialiasing filter and improved input response characteristics. Some controllers or I/O subsystems oversample the analog inputs with respect to the controller execution interval and then process the input data through a digital filter. This technique can produce a more representative measurement with less quantization noise.

Differences in the PID algorithm, controller parameters, units, and other fundamental control functions highlight the importance of understanding the structure of the controller and the requirement of sufficiently detailed documentation. This is especially important for the controller but is also important for the field instruments, final control elements, and devices that have the potential to affect the signal characteristics.

## CONTROL VALVES

A control valve consists of a valve, an actuator, and usually one or more valve control devices. The valves discussed in this section are applicable to throttling control (i.e., where flow through the valve is regulated to any desired amount between maximum and minimum limits). Other valves such as check, isolation, and relief valves are addressed in the next subsection. As defined, control valves are automatic control devices that modify the fluid flow rate as specified by the controller.

**Valve Types** Types of valves are categorized according to their design style. These styles can be grouped into type of stem motion—linear or rotary. The valve stem is the rod, shaft, or spindle that connects the actuator with the closure member (i.e., a movable part of the valve that is positioned in the flow path to modify the rate of flow). Movement of either type of stem is known as *travel*. The major categories are described briefly below.

***Globe and Angle*** The most common linear stem-motion control valve is the *globe valve*. The name comes from the globular cavities around the port. In general, a port is any fluid passageway, but often the reference is to the passage that is blocked off by the closure member when the valve is closed. In globe valves, the closure member is called a *plug*. A popular construction is a cage-guided plug, as illustrated in Fig. 8-64. In many such designs, openings in the cage provide the flow control orifices. The valve seat is the zone of contact between the moving closure member and the stationary valve body, which shuts off the flow when the valve is closed. Often the seat in the body is on a replaceable part known as a *seat ring*. This stationary seat can also be designed as an integral part of the cage. Plugs may also be port-guided by wings or a skirt that fits snugly into the seat-ring bore.

One distinct advantage of cage guiding is the use of balanced plugs in single-port designs. In the balanced design (Fig. 8-64), note that both the top and bottom of the plug are subjected to the same downstream pressure when the valve is closed. Leakage via the plug-to-cage clearance is prevented by a plug seal.

The plug, cage, seat ring, and associated seals are known as the *trim*. A key feature of globe valves is that they allow maintenance of the trim via a removable bonnet without removing the valve body from the line. Bonnets are typically bolted on but may be threaded in smaller sizes.

Angle valves are an alternate form of the globe valve. They often share the same trim options and have the top-entry bonnet style. Angle valves can eliminate the need for an elbow but are especially useful when direct impingement of the process fluid on the body wall is to be avoided. Sometimes it is not practical to package a long trim within a globe body, so an angle body is used. Some angle bodies are self-draining, which is an important feature for dangerous fluids.

***Butterfly*** The classic design of butterfly valves is shown in Fig. 8-65. Its chief advantage is high capacity in a small package and a very low initial cost. Much of the size and cost advantage is due to the wafer body design, which is clamped between two pipeline flanges. In the simplest design,

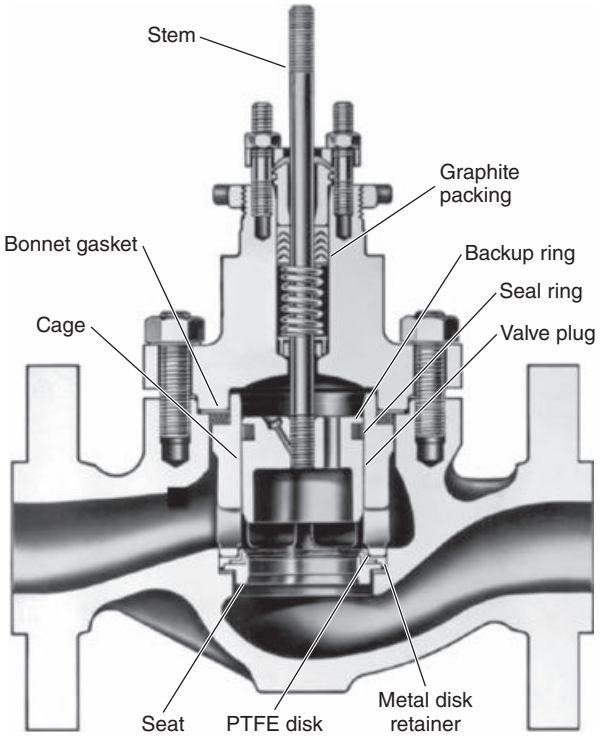

**FIG. 8-64** Cage-guided balanced plug globe valve with polymer seat and plug seal. (*Courtesy Fisher Controls International LLC.*)

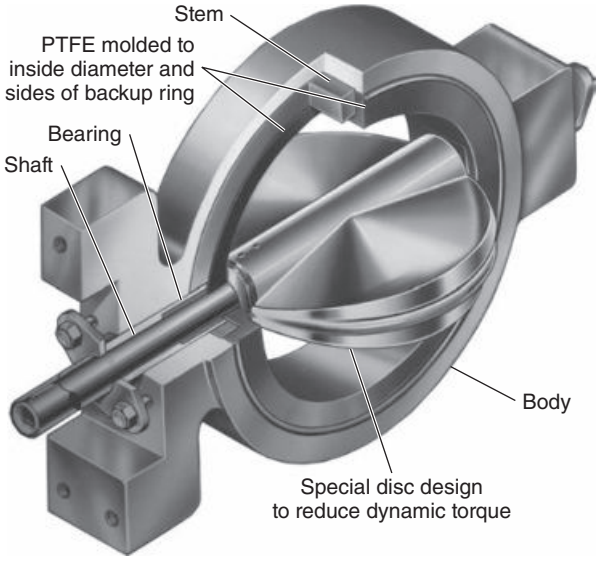

**FIG. 8-65** Partial cutaway of wafer-style lined butterfly valve. (*Courtesy Fisher Controls International LLC.*)

there is no seal as such, merely a small clearance gap between the disc OD and the body ID. Often a true seal is provided by a resilient material in the body that is engaged via an interference fit with the disc. In a lined butterfly valve, this material covers the entire body ID and extends around the body ends to eliminate the need for pipeline joint gaskets. In a fully lined valve, the disc is also coated to minimize corrosion or erosion.

A high-performance butterfly valve has a disc that is offset from the shaft centerline. This eccentricity causes the seating surface to move away from the seal once the disc is out of the closed position, reducing friction and seal wear. It is also known as an *eccentric disc valve*; the advantage of the butterfly valve is improved shutoff while maintaining high ultimate capacity at a reasonable cost. This cost advantage relative to other design styles is particularly true in sizes above 6-in nominal pipe size (NPS). Improved shutoff is due to advances in seal technologies, including polymer, flexing metal, combination metal with polymer inserts, and so on, many utilizing pressure assist.

***Ball*** Ball valves get their name from the shape of the closure member. One version uses a full spherical member with a cylindrical bore through it. The ball is rotated one-quarter turn from the full-closed to the full-open position. If the bore is the same diameter as the mating-pipe fitting ID, the valve is referred to as *full-bore*. If the hole is undersized, the ball valve is considered to be a venturi style. A segmented ball is a portion of a hollow sphere that is large enough to block the port when closed. Segmented balls often have a V-shaped contour along one edge, which provides a desirable flow characteristic (see Fig. 8-66). Both full ball and segmented ball valves are known for their low resistance to flow when full open. Shutoff leakage is minimized through the use of flexing or spring-loaded elastomeric or metal seals. Bodies are usually in two or three pieces or have a removable retainer to facilitate installing seals. End connections are usually flanged or threaded in small sizes, although segmented ball valves are offered in wafer style also.

***Plug*** There are two substantially different rotary valve design categories referred to as *plug valves*. The first consists of a cylindrical or slightly conical plug with a port through it. The plug rotates to vary the flow much as a ball valve does. The body is top-entry but is geometrically simpler than a globe valve and thus can be lined with fluorocarbon polymer to protect against corrosion. These plug valves have excellent shutoff but are generally not for modulating service due to high friction. A variation of the basic design (similar to the eccentric butterfly disc) only makes sealing contact in the closed position and is used for control.

The other rotary plug design is portrayed in Fig. 8-67. The seating surface is substantially offset from the shaft, producing a ball-valve-like motion with the additional cam action of the plug into the seat when closing. In reverse flow, high-velocity fluid motion is directed inward, impinging on itself and only contacting the plug and seat ring.

***Multiport*** This term refers to any valve or manifold of valves with more than one inlet or outlet. For throttling control, the three-way body is used for blending (two inlets, one outlet) or as a diverter (one inlet, two outlets). A three-way valve is most commonly a special globelike body with special trim that allows flow both over and under the plug. Two rotary valves and a pipe tee can also be used. Special three-, four-, and five-way ball valve designs are used for switching applications.

**Special Application Valves**

***Digital Valves*** True digital valves consist of discrete solenoid-operated flow ports that are sized according to binary weighing. The valve can be designed with sharp-edged orifices or with streamlined nozzles that can be used for flow metering. Precise control of the throttling control orifice is the strength of the digital valve. Digital valves are mechanically complicated and expensive, and they have considerably reduced maximum flow capacities compared to the globe and rotary valve styles.

***Cryogenic Service*** Valves designed to minimize heat absorption for throttling liquids and gases below 80 K are called *cryogenic service valves*. These valves are designed with small valve bodies to minimize heat absorption and long bonnets between the valve and actuator to allow for extra layers of insulation around the valve. For extreme cases, vacuum jacketing can be constructed around the entire valve to minimize heat influx.

***High Pressure*** Valves used for pressures nominally above 760 bar (11,000 psi, pressures above ANSI Class 4500) are often custom-designed for specific applications. Normally, these valves are of the plug type and use specially hardened plug and seat assemblies. Internal surfaces are polished, and internal corners and intersecting bores are smoothed to reduce high localized stresses in the valve body. Steam loops in the valve body are available to raise the body temperature to increase the ductility and impact strength of the body material.

***High-Viscous Process*** Used most extensively by the polymer industry, the valve for high-viscous fluids is designed with smooth finished internal passages to prevent stagnation and polymer degradation. These valves are available with integral body passages through which a heat-transfer fluid is pumped to keep the valve and process fluid heated.

***Pinch*** The industrial equivalent of controlling flow by pinching a soda straw is the pinch valve. Valves of this type use fabric-reinforced elastomer sleeves that completely isolate the process fluid from the metal parts in the valve. The valve is actuated by applying air pressure directly to the outside of the sleeve, causing it to contract or pinch. Another method is to pinch the sleeve with a linear actuator with a specially attached foot. Pinch valves are used extensively for corrosive material service and erosive slurry service. This type of valve is used in applications with pressure drops up to 10 bar (145 psi).

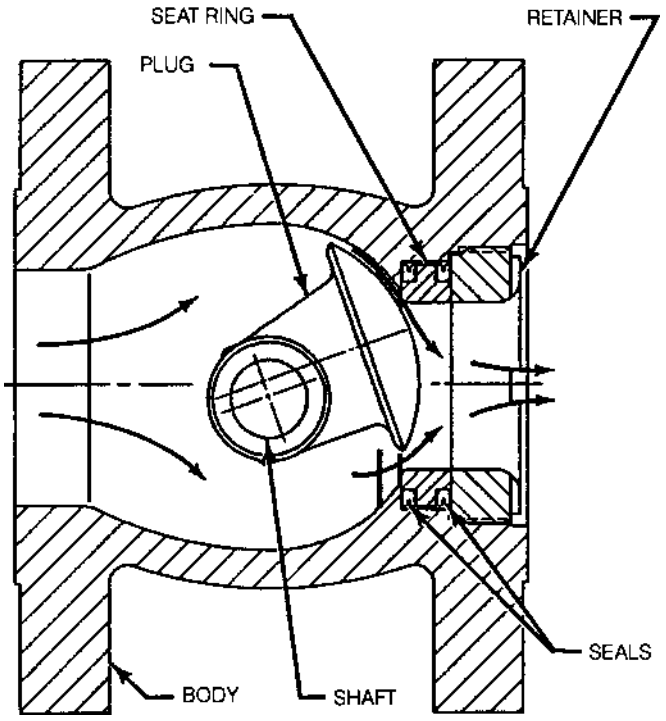

**FIG. 8-67** Eccentric plug valve shown in erosion-resistant reverse-flow direction. Shaded components can be made of hard metal or ceramic materials. (*Courtesy Fisher Controls International LLC.*)

***Fire-Rated*** Valves that handle flammable fluids may have additional safety-related requirements for minimal external leakage, minimal internal (downstream) leakage, and operability during and after a fire. Being fire-rated does not mean being totally impervious to fire, but a sample valve must meet particular specifications such as those of the American Petroleum Institute (API) 607, Factory Mutual Research Corp. (FM) 7440, or the British Standard 5146 under a simulated fire test. Due to very high flame temperature, metal seating (either primary or as a backup to a burned-out elastomer) is mandatory.

***Solids Metering*** The control valves described earlier are primarily used for the control of fluid (liquid or gas) flow. Sometimes these valves, particularly the ball, butterfly, or sliding gate valves, are used to throttle dry or slurry solids. More often, special throttling mechanisms such as venturi ejectors, conveyers, knife-type gate valves, or rotating vane valves are used. The particular solids-metering valve hardware depends on the volume, density, particle shape, and coarseness of the solids to be handled.

**Actuators** An actuator is a device that applies the force (torque) necessary to cause a valve's closure member to move. Actuators must overcome pressure and flow forces as well as friction from packing, bearings or guide surfaces, and seals; and must provide the seating force. In rotary valves, maximum friction occurs in the closed position, and the moment necessary to overcome it is referred to as *breakout torque*. The rotary valve shaft torque generated by steady-state flow and pressure forces is called *dynamic torque*. It may tend to open or close the valve depending on valve design and travel. Dynamic torque per unit pressure differential is largest in butterfly valves at roughly 70° open. In linear stem-motion valves, the flow forces should not exceed the available actuator force, but this is usually accounted for by default when the seating force is provided.

Actuators often provide a fail-safe function. In the event of an interruption in the power source, the actuator will place the valve in a predetermined safe position, usually either full-open or full-closed. Safety systems are often designed to trigger local fail-safe action at specific valves to cause a needed action to occur, which may not be a complete process or plant shutdown.

Actuators are classified according to their power source. The nature of these sources leads naturally to design features that make their performance characteristics distinct.

***Pneumatic*** Despite the availability of more sophisticated alternatives, the pneumatically driven actuator is still by far the most popular type. Historically the most common has been the spring and diaphragm design (Fig. 8-68). The compressed air input signal fills a chamber sealed by an elastomeric diaphragm. The pressure force on the diaphragm plate causes a spring to be compressed and the actuator stem to move. This spring provides the fail-safe function and contributes to the dynamic stiffness of the actuator. If the accompanying valve is "push down to close," the actuator depicted in Fig. 8-68 will be described as "air to close" or synonymously as fail-open. A slightly different design yields "air to open" or fail-closed action. The spring is typically precompressed to provide a significant available force in the failed position (e.g., to provide seating load). The spring also provides a proportional relationship between the force generated by air pressure and the stem position. The pressure range over which a spring and diaphragm actuator strokes in the absence of valve forces is known as the *bench set*. The chief advantages of spring and diaphragm actuators are their high reliability, low cost, adequate dynamic response, and fail-safe action—all of which are inherent in their simple design.

***Motion Conversion*** Actuator power units with translational output can be adapted to rotary valves that generally need 90° or less rotation. A lever is attached to the rotating shaft, and a link with pivoting means on the end connects to the linear output of the power unit, an arrangement similar to an internal combustion engine crankshaft, connecting rod, and piston. When the actuator piston, or more commonly the diaphragm plate, is designed to tilt, one pivot can be eliminated. Scotch yoke and rack-and-pinion arrangements are also commonly used, especially with piston power units. Friction and the changing mechanical advantage of these motion conversion mechanisms mean the available torque may vary greatly with travel. One notable exception is vane-style rotary actuators whose offset "piston" pivots, giving direct rotary output.

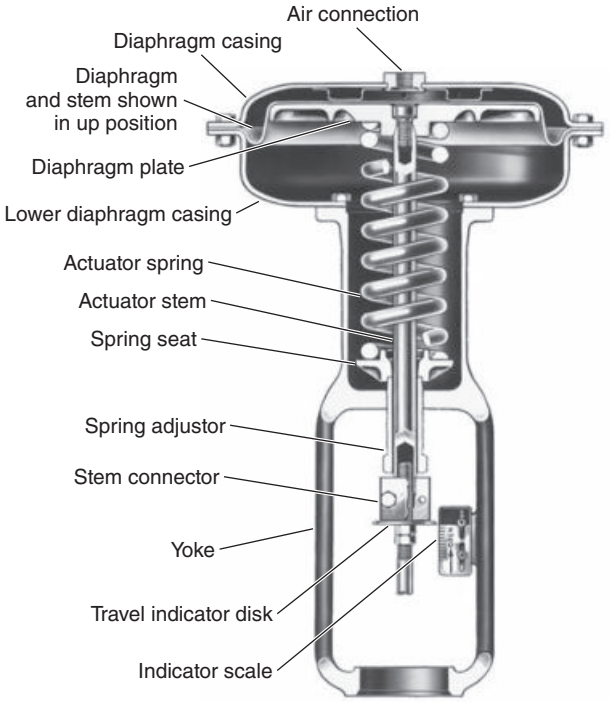

**FIG. 8-68** Spring and diaphragm actuator with an "up" fail-safe mode. Spring adjuster allows slight alteration of bench set. (*Courtesy Fisher Controls International LLC.*)

***Hydraulic*** The design of typical hydraulic actuators is similar to that of double-acting piston pneumatic types. One key advantage is the high pressure [typically 35 to 70 bar (500 to 1000 psi)], which leads to high thrust in a smaller package. The incompressible nature of the hydraulic oil means these actuators have very high dynamic stiffness. The incompressibility and small chamber size connote fast stroking speed and good frequency response. The disadvantages include high initial cost, especially when considering the hydraulic supply. Maintenance is much more difficult than with pneumatics, especially on the hydraulic positioner.

Electrohydraulic actuators have similar performance characteristics and cost/maintenance ramifications. The main difference is that they contain their own electric-powered hydraulic pump. The pump may run continuously or be switched on when a change in position is required. Their main application is remote sites without an air supply when a fail-safe spring return is needed.

***Electric*** The most common electric actuators use a typical motor—three-phase ac induction, capacitor-start split-phase induction, or dc. Normally the motor output passes through a large gear reduction and, if linear motion output is required, a ball screw or thread. These devices can provide large thrust, especially given their size. Lost motion in the gearing system does create backlash, but if not operating across a thrust reversal, this type of actuator has very high stiffness. Usually the gearing system is self-locking, which means that forces on the closure member cannot move it by spinning a nonenergized motor. This behavior is called a *lock-in-last-position fail-safe mode*. Some gear systems (e.g., low-reduction spur gears) can be back-driven. A solenoid-activated mechanical brake or locking current to motor field coils is added to provide lock-in-last-position fail-safe mode. A battery backup system for a dc motor can guard against power failures. Otherwise, an electric actuator is not acceptable if fail-open/closed action is mandatory. Using electric power requires environmental enclosures and explosion protection, especially in hydrocarbon processing facilities; see the full discussion in the subsection Valve Control Devices.

Unless sophisticated speed control power electronics is used, position modulation is achieved via bang-zero-bang control. Mechanical inertia causes overshoot, which is (1) minimized by braking and/or (2) hidden by adding dead band to the position control. Without these provisions, high starting currents would cause motors to overheat from constant "hunting" within the position loop. Travel is limited with power interruption switches or with force (torque) electromechanical cutouts when the closed position is against a mechanical stop (e.g., a globe valve). Electric actuators are often used for on/off service. Stepper motors can be used instead, and they, as their name implies, move in fixed incremental steps. Through gear reduction, the typical number of increments for 90° rotation ranges from 5000 to 10,000; hence positioning resolution at the actuator is excellent.

An electromagnetic solenoid can be used to directly actuate the plug on very small linear stem-motion valves. A solenoid is usually designed as a two-position device, so this valve control is on/off. Special solenoids with position feedback can provide proportional action for modulating control. Force requirements of medium-sized valves can be met with piloted plug designs, which use process pressure to assist the solenoid force. Piloted plugs are also used to minimize the size of common pneumatic actuators, especially when there is need for high seating load.

***Manual*** A manually positioned valve is by definition not an automatic control valve, but it may be involved with process control. For rotary valves, the manual operator can be as simple as a lever, but a wheel driving a gear reduction is necessary in larger valves. Linear motion is normally created with a wheel turning a screw-type device. A manual override is usually available as an option for the powered actuators listed above. For spring-opposed designs, an adjustable travel stop will work as a one-way manual input. In more complex designs, the handwheel can provide loop control override via an engagement means. Some gear reduction systems of electric actuators allow the manual positioning to be independent of the automatic positioning without declutching. In practice, most control valves have a bypass line with a manual valve that can be adjusted when the control valve fails or is taken out of service, as shown in Fig. 8-69.

## OTHER PROCESS VALVES

In addition to the throttling control valve, other types of process valves can be used to manipulate a process.

**Valves for On/Off Applications** Valves are often required for service that is primarily nonthrottling. Valves in this category, depending on the service requirements, may be of the same design as the types used for throttling control or, as in the case of gate valves, different in design. Valves in this category usually have tight shutoff when they are closed and low pressure drops when they are wide open. The on/off valve can be operated manually, such as by handwheel or lever; or automatically, with pneumatic or electric actuators.

***Batch*** Batch process operation is an application requiring on/off valve service. Here the valve is opened and closed to provide reactant, catalyst, or product to and from the batch reactor. Like the throttling control valve, the valve used in this service must be designed to open and close thousands of times. For this reason, valves used in this application are often the same valves used in continuous throttling applications. Ball valves are especially useful in batch operations. The ball valve has a straight-through flow passage that reduces pressure drop in the wide-open state and provides tight shutoff capability when closed. In addition, the segmented ball valve provides for shearing action between the ball and the ball seat that promotes closure in slurry service.

***Isolation*** A means for pressure-isolating control valves, pumps, and other piping hardware for installation and maintenance is another common application for an on/off valve. In this application, the valve is required to have tight shutoff so that leakage is stopped when the piping system is under repair. As the need to cycle the valve in this application is far less than that of a throttling control valve, the wear characteristics of the valve are less important. Also, because many are required in a plant, the isolation valve needs to be reliable, simple in design, and simple in operation.

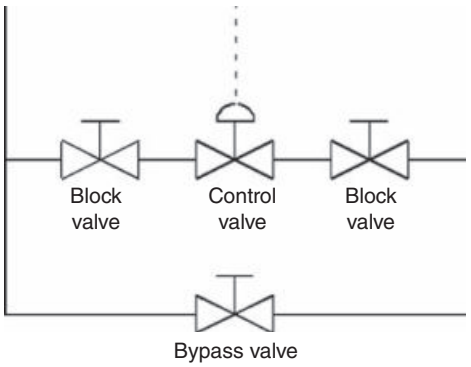

**FIG. 8-69** Control valve bypass.

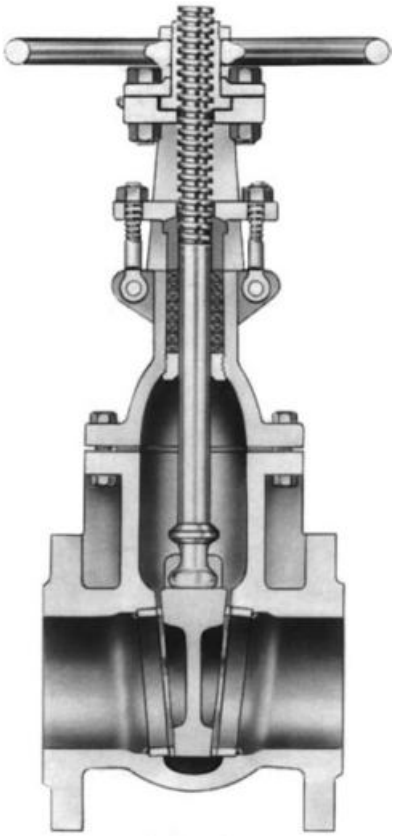

**FIG. 8-70** Gate valve. (*Courtesy Crane Valves.*)

The gate valve, shown in Fig. 8-70, is the most widely used valve in this application. The gate valve is composed of a gatelike disc that moves perpendicular to the flow stream. The disc is moved up and down by a threaded screw that is rotated to effect disc movement. Because the disc is large and at right angles to the process pressure, a large seat loading for tight shutoff is possible. Wear produced by high seat loading during the movement of the disc prohibits the use of the gate valve for throttling applications.

**Pressure Relief Valves** The pressure relief valve is an automatic pressure-relieving device designed to open when normal conditions are exceeded and to close again when normal conditions are restored. Within this class there are relief valves, pilot-operated pressure relief valves, and safety valves. Relief valves (see Fig. 8-71) have spring-loaded discs that close a main orifice against a pressure source. As pressure rises, the disc begins to rise off the orifice and a small amount of fluid passes through the valve. Continued rise in pressure above the opening pressure causes the disc to open the orifice in a proportional fashion. The main orifice reduces and closes when the pressure returns to the set pressure. Additional sensitivity to overpressure conditions can be improved by adding an auxiliary pressure relief valve (pilot) to the basic pressure relief valve. This combination is known as a *pilot-operated pressure relief valve*.

The safety valve is a pressure relief valve that is designed to open fully, or pop, with only a small amount of pressure over the rated limit. Where conventional safety valves are sensitive to downstream pressure and may have unsatisfactory operating characteristics in variable backpressure applications, pressure-balanced safety relief valve designs are available to minimize the effect of downstream pressure on performance.

Application and sizing of pressure relief valves, pilot-operated pressure relief valves, and safety valves for use on pressure vessels are found in the ASME Boiler and Pressure Vessel Code, Section VIII, Division 1, "Rules for Construction of Pressure Vessels," Paragraphs UG-125 through UG-137.

**Check Valves** The purpose of a check valve is to allow relatively unimpeded flow in the desired direction but to prevent flow in the reverse direction. Two common designs are swing-type and lift-type check valves, the names of which denote the motion of the closure member. In the forward direction, flow forces overcome the weight of the member or a spring to open the flow passage. With reverse pressure conditions, flow forces drive the closure member into the valve seat, thus providing shutoff.

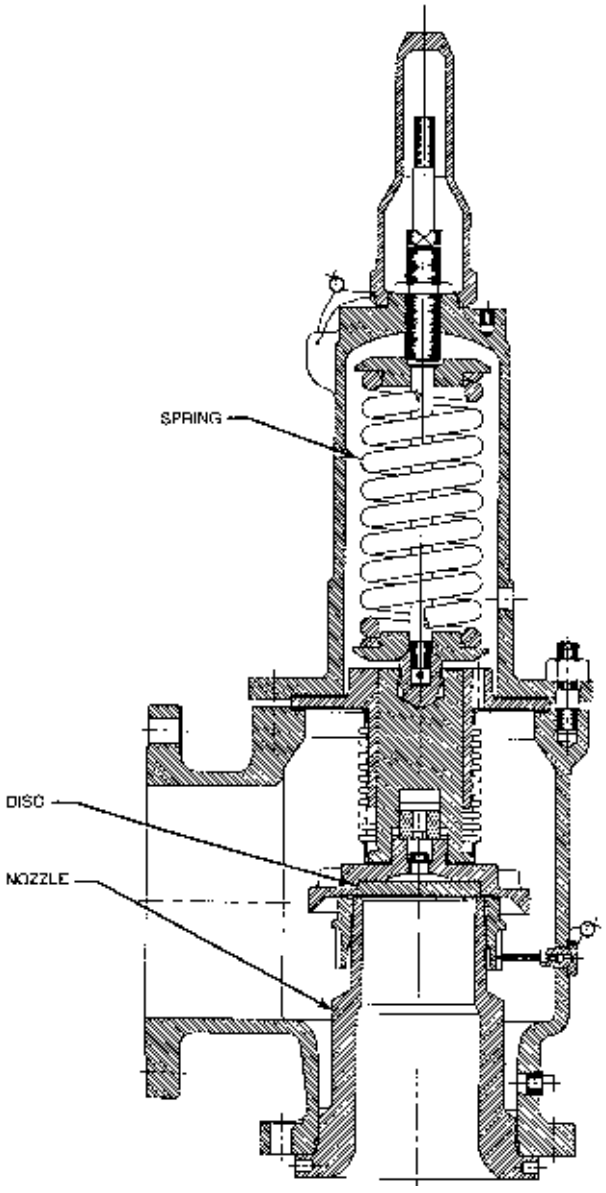

**FIG. 8-71** Relief valve. (*Courtesy Teledyne Fluid Systems, Farris Engineering.*)

## VALVE DESIGN CONSIDERATIONS

Functional requirements and the properties of the controlled fluid determine which valve and actuator types are best for a specific application. If demands are modest and no unique valve features are required, the valve design style selection may be determined solely by cost. If so, general-purpose globe or angle valves provide exceptional value, especially in sizes less than 3-in NPS and hence are very popular. Beyond type selection, there are many other valve specifications that must be determined properly to ultimately yield improved process control.

**Materials and Pressure Ratings** Valves must be constructed from materials that are sufficiently immune to corrosive or erosive action by the process fluid. Common body materials are cast iron, steel, stainless steel, high-nickel alloys, and copper alloys such as bronze. Trim materials need better corrosion and erosion resistance due to the higher fluid velocity in the throttling region. High hardness is desirable in erosive and cavitating applications. Heat-treated and precipitation-hardened stainless steels are common. High hardness is also good for guiding, bearing, and seating surfaces; cobalt-chromium alloys are utilized in cast or wrought form and frequently as welded overlays called *hard facing*. In less stringent situations,

chrome plating, heat-treated nickel coatings, and nitriding are used. Tungsten carbide and ceramic trim are warranted in extremely erosive services. See Sec. 25, Materials of Construction, for specific material properties.

Since the valve body is a pressurized vessel, it is usually designed to comply with a standardized system of pressure ratings. Two common systems are described in the standards ASME B16.34 and EN 12516. Internal pressure limits under these standards are divided into broad classes, with specific limits being a function of material and temperature. Manufacturers also assign their own pressure ratings based on internal design rules. A common insignia is *250 WOG*, which means a pressure rating of 250 psig (~17 bar) in water, oil, or gas at ambient temperature. The subsection Storage and Process Vessels in Sec. 10 provides introductory information on compliance of pressure vessel design to industry codes (e.g., ASME Boiler and Pressure Vessel Code, Section VIII; ASME B31.3 Chemical Plant and Petroleum Refinery Piping).

Valve bodies are also standardized to mate with common piping connections: flanged, butt-welded end, socket-welded end, and screwed end. Dimensional information for some of these joints and class pressure-temperature ratings are included in Sec. 10, Process Plant Piping. Control valves have their own standardized face-to-face dimensions that are governed by ANSI/ISA Standards S75.08 and S75.22. Butterfly valves are also governed by API 609 and Manufacturers Standardization Society (MSS) SP-67 and SP-68.

**Sizing** Throttling control valves must be selected to pass the required flow rate, given expected pressure conditions. Sizing is not merely matching the end connection size with surrounding piping; it is a key step in ensuring that the process can be properly controlled. Sizing methods range from simple models based on elementary fluid mechanics to very complex models when unusual thermodynamics or nonideal behaviors occur. Basic sizing practices have been standardized (for example, ANSI-75.01.01) and are implemented as PC-based programs by manufacturers. The following is a discussion of very basic sizing equations and the associated physics.

Regardless of the particular process variable being controlled (e.g., temperature, level, pH), the output of a control valve is the flow rate. The throttling valve performs its function of manipulating the flow rate by virtue of being an adjustable resistance to flow. Flow rate and pressure conditions are normally known when a process is designed, and the valve resistance range must be matched accordingly. In the tradition of orifice and nozzle discharge coefficients, this resistance is embodied in the valve flow coefficient $C_V$. By applying the principles of conservation of mass and energy, the mass flow rate $w$ kg/h is given for a liquid by

$$w = 27.3 C_V \sqrt{\rho(p_1 - p_2)} \tag{8-77}$$

where $p_1$ and $p_2$ are upstream and downstream static pressures, in bar, respectively. The density of the fluid ρ is expressed in kilograms per cubic meter. This equation is valid for nonvaporizing, turbulent flow conditions for a valve with no attached fittings.

While Eq. (8-77) gives the relationship between pressure and flow from a macroscopic point of view, it does not explain what is going on inside the valve. Valves create a resistance to flow by restricting the cross-sectional area of the flow passage and by forcing the fluid to change direction as it passes through the body and trim. The conservation of mass principle dictates that, for steady flow, the product of density, average velocity, and cross-sectional area remains a constant. The average velocity of the fluid stream at the minimum restriction in the valve is therefore much higher than that at the inlet. Note that due to the abrupt nature of the flow contraction that forms the minimum passage, the main fluid stream may separate from the passage walls and form a jet that has an even smaller cross section, the so-called vena contracta. The ratio of minimum stream area to the corresponding passage area is called the *contraction coefficient*. As the fluid expands from the minimum cross-sectional area to the full passage area in the downstream piping, large amounts of turbulence are generated. Direction changes can also induce significant amounts of turbulence.

Figure 8-72 is an illustration of how the mean pressure changes as fluid moves through a valve. Some of the potential energy that was stored in the fluid by pressurizing it (e.g., the work done by a pump) is first converted to the kinetic energy of the fast-moving fluid at the vena contracta. Some of that kinetic energy turns into the kinetic energy of turbulence. As the turbulent eddies break down into smaller and smaller structures, viscous effects ultimately convert all the turbulent energy to heat. Therefore, a valve converts fluid energy from one form to another.

For many valve constructions, it is reasonable to approximate the fluid transition from the valve inlet to the minimum cross section of the flow stream as an isentropic or lossless process. Using this approximation, the minimum pressure $p_{VC}$ can be estimated from the Bernoulli relationship. See Sec. 6, Fluid and Particle Dynamics, for more background information. Downstream of the vena contracta, the flow is definitely not lossless due to

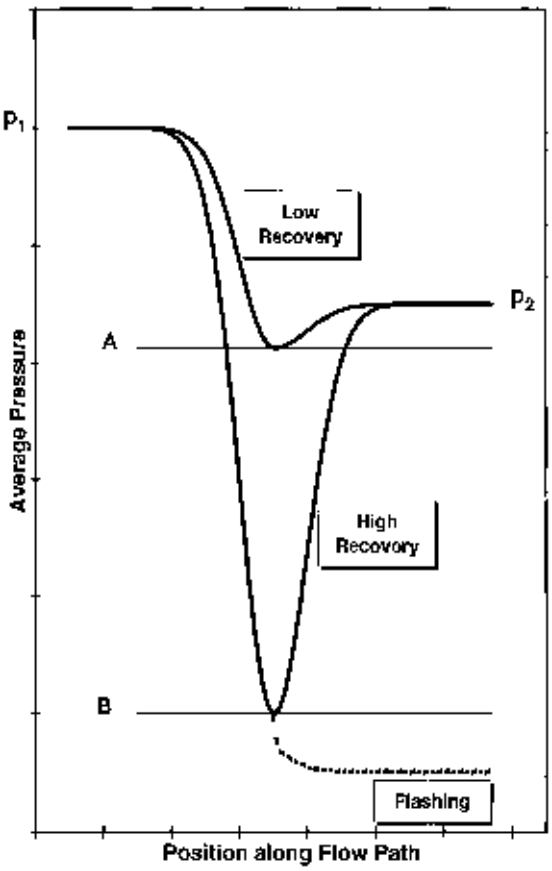

**FIG. 8-72** Generic depictions of average pressure at subsequent cross sections throughout a control valve. The $F_L$ values selected for illustration are 0.9 and 0.63 for low and high recovery, respectively. Internal pressure in the high-recovery valve is shown as a dashed line for flashing conditions ($p_2 < p_v$) with $p_v = B$.

all the turbulence that is generated. As the flow passage area increases and the fluid slows down, some of the kinetic energy of the fluid is converted back to pressure energy as pressure recovers. The energy that is permanently lost via turbulence accounts for the permanent pressure or head loss of the valve. The relative amount of pressure that is recouped determines whether the valve is considered to be high- or low-recovery. The flow passage geometry at and downstream of the vena contracta primarily determines the amount of recovery. The amount of recovery is quantified by the liquid pressure recovery factor $F_L$

$$F_L = \sqrt{\frac{p_1 - p_2}{p_1 - p_{vc}}} \tag{8-78}$$

Under some operating conditions, sufficient pressure differential may exist across the valve to cause the vena contracta pressure to drop to the saturation pressure (also known as the *vapor pressure*) of the liquid. If this occurs, a portion of the liquid will vaporize, forming a two-phase, compressible mixture within the valve. If sufficient vapor forms, the flow may *choke*. When a flow is choked, any increase in pressure differential across the valve no longer produces an increase in flow through the valve.

The vena contracta condition at choked flow for pure liquids has been shown to be

$$p_{vc} = F_F p_v \tag{8-79}$$

where

$$F_F = 0.96 - 0.28\sqrt{\frac{p_v}{p_c}} \tag{8-80}$$

and $p_{vc}$ is the absolute vena contracta pressure under choked conditions, $F_F$ is the liquid critical pressure ratio factor, $p_v$ is the absolute vapor pressure

of the liquid at inlet temperature, and $p_c$ is the absolute thermodynamic critical pressure of the fluid.

Equations (8-78) and (8-79) can be used together to determine the pressure differential across the valve at the point where the flow chokes.

$$\Delta p_{\text{choked}} = F_L^2 (p_1 - F_F p_v) \tag{8-81}$$

The pressure recovery factor is a constant for any given valve at a given opening. The value of this factor can be established by flow test and is published by the valve manufacturer. If the actual pressure differential across the valve is greater than the choked pressure differential of Eq. (8-81), then $\Delta p_{\text{choked}}$ should be used in Eq. (8-77) to determine the correct valve size. A more complete presentation of sizing relationships is given in ANSI 75.01.01, including provisions for pipe reducers and Reynolds number effects.

Equations (8-77) to (8-81) are restricted to incompressible fluids. For gases and vapors, the fluid density is dependent on pressure. For convenience, compressible fluids are often assumed to follow the ideal gas law model. Deviations from ideal behavior are corrected for, to first order, with nonunity values of compressibility factor $Z$ (see Sec. 2, Physical and Chemical Data, for definitions and data for common fluids). For compressible fluids

$$w = 94.8 C_v p_1 Y \sqrt{\frac{x M_w}{T_1 Z}} \tag{8-82}$$

where $p_1$ is in bar absolute, $T_1$ is inlet temperature in K, $M_w$ is the molecular weight, and $x$ is the dimensionless pressure drop ratio $(p_1 - p_2)/p_1$. The expansion factor $Y$ accounts for changes in the fluid density as the fluid passes through the valve. It is dependent on pressure drop and valve geometry. Experimental data have shown that for small departures in the ratio of specific heat from that of air (1.4), a simple linear relationship can be used to represent the expansion factor:

$$Y = 1 - \frac{1.4x}{3x_T \gamma} \quad \text{for} \quad x \le \frac{x_T \gamma}{1.4} \tag{8-83}$$

where $\gamma$ is the ratio of specific heats and $x_T$ is an experimentally determined factor for a specific valve and is the largest value of $x$ that contributes to flow (i.e., values of $x$ greater than $x_T$ do not contribute to flow).

The terminal value of $x$, $x_T$, results from a phenomenon known as *choking*. Given a nozzle geometry with fixed inlet conditions, the mass flow rate will increase as $p_2$ is decreased up to a maximum amount at the critical pressure drop. The velocity at the vena contracta has reached sonic, and a standing shockwave has formed. This shock causes a step change in pressure as flow passes through it, and further reduction in $p_2$ does not increase mass flow. Thus $x_T$ relates to the critical pressure drop ratio and also accounts for valve geometry effects. The value of $x_T$ varies with flow path geometry and is supplied by the valve manufacturer. In the choked case,

$$x > \frac{x_T Y}{1.4} \quad \text{and} \quad Y = 0.67 \tag{8-84}$$

**Noise Control** Sound is a fluctuation of air pressure that can be detected by the human ear. Sound travels through any fluid (e.g., the air) as a compression/expansion wave. This wave travels radially outward in all directions from the sound source. The pressure wave induces an oscillating motion in the transmitting medium that is superimposed on any other net motion it may have. These waves are reflected, refracted, scattered, and absorbed as they encounter solid objects. Sound is transmitted through solids in a complex array of types of elastic waves. Sound is characterized by its amplitude, frequency, phase, and direction of propagation.

Sound strength is therefore location-dependent and is often quantified as a sound pressure level $L_p$ in decibels based on the root mean square (rms) sound pressure value $p_s$, where

$$L_p = 10 \log \left( \frac{p_s}{p_{\text{reference}}} \right)^2 \tag{8-85}$$

For airborne sound, the reference pressure is $2 \times 10^{-5}$ Pa ($29 \times 10^{-1}$ psi), which is nominally the human threshold of hearing at 1000 Hz. The corresponding sound pressure level is 0 dB. A voice in conversation is about 50 dB, and a jackhammer operator is subject to 100 dB. Extreme levels such as a jet engine at takeoff might produce 140 dB at a distance of 3 m, which is a pressure amplitude of 200 Pa ($29 \times 10^{-3}$ psi). These examples demonstrate both the sensitivity and the wide dynamic range of the human ear.

Traveling sound waves carry energy. Sound intensity $I$ is a measure of the power passing through a unit area in a specified direction and is related to $p_s$. Measuring sound intensity in a process plant gives clues to the location of the source. As one moves away from the source, the fact that the energy is spread over a larger area requires that the sound pressure level decrease. For example, doubling one's distance from a point source reduces $L_p$ by 6 dB. Viscous action from the induced fluid motion absorbs additional acoustic energy. However, in free air, this viscous damping is negligible over short distances (on the order of 1 m).

Noise is a group of sounds with many nonharmonic frequency components of varying amplitudes and random phase. The turbulence generated by a throttling valve creates noise. As a valve converts potential energy to heat, some of the energy becomes acoustic energy as an intermediate step. Valves handling large amounts of compressible fluid through a large pressure change create the most noise because more total power is being transformed. Liquid flows are noisy only under special circumstances, as will be seen in the next subsection. Due to the random nature of turbulence and the broad distribution of length and velocity scales of turbulent eddies, valve-generated sound is usually random, broad-spectrum noise. The total sound pressure level from two such statistically uncorrelated sources is (in decibels)

$$L_p = 10 \log \frac{(p_{s1})^2 + (p_{s2})^2}{(p_{\text{reference}})^2} \tag{8-86}$$

For example, two sources of equal strength combine to create an $L_p$ that is 3 dB higher.

While noise is annoying to listen to, the real reasons for being concerned about noise relate to its impact on people and equipment. Hearing loss can occur due to long-term exposure to moderately high—or even short exposure to very high—noise levels. The U.S. Occupational Safety and Health Act (OSHA) has specific guidelines for permissible levels and exposure times. The human ear has a frequency-dependent sensitivity to sound. When the effect on humans is the criterion, $L_p$ measurements are weighted to account for the ear's response. This so-called A-weighted scale is defined in ANSI S1.4 and is commonly reported as $L_{pA}$.

There are two approaches to fluid-generated noise control—source or path treatment. Path treatment means absorbing or blocking the transmission of noise after it has been created. The pipe itself is a barrier. The sound pressure level inside a standard schedule pipe is roughly 40 to 60 dB higher than on the outside. Thicker-walled pipe reduces levels somewhat more, and adding acoustical insulation on the outside of the pipe reduces ambient levels up to 10 dB per inch of thickness. Since noise propagates relatively unimpeded inside the pipe, barrier approaches require the entire downstream piping system to be treated in order to be totally effective. In-line silencers place absorbent material inside the flow stream, thus reducing the level of the internally propagating noise. Noise reductions up to 25 dB can be achieved economically with silencers.

The other approach to valve noise problems is the use of quiet trim. Two basic strategies are used to reduce the initial production of noise—dividing the flow stream into multiple paths and using several flow resistances in series. Sound pressure level $L_p$ is proportional to mass flow and is dependent on vena contracta velocity. If each path is an independent source, it is easy to show from Eq. (8-86) that $p_s^2$ is inversely proportional to the number of passages; additionally, smaller passage size shifts the predominant spectral content to higher frequencies, where structural resonance may be less of a problem. Series resistances or multiple stages can reduce maximum velocity and/or produce backpressure to keep jets issuing from multiple passages from acting independently. While some of the basic principles are understood, predicting noise for a particle flow passage requires some empirical data as a basis. Valve manufacturers have developed noise prediction methods for the valves they build. ANSI/ISA-75.17 is a public-domain methodology for standard (non–low-noise) valve types, although treatment of some multistage, multipath types is underway. Low-noise hardware consists of special cages in linear stem valves, perforated domes or plates and multichannel inserts in rotary valves, and separate devices that use multiple fixed restrictions.

**Cavitation and Flashing** From the discussion of pressure recovery it was seen that the pressure at the vena contracta can be much lower than the downstream pressure. If the pressure on a liquid falls below its vapor pressure $p_v$, the liquid will vaporize. Due to the effect of surface tension, this vapor phase will first appear as bubbles. These bubbles are carried downstream with the flow, where they collapse if the pressure recovers to a value above $p_v$. This pressure-driven process of vapor bubble formation and collapse is known as *cavitation*.

Cavitation has three negative side effects in valves—noise and vibration, material removal, and reduced flow. The bubble collapse process is a violent asymmetric implosion that forms a high-speed microjet and induces pressure waves in the fluid. This hydrodynamic noise and the mechanical vibration that it can produce are far stronger than other noise generation sources in liquid flows. If implosions occur adjacent to a solid component, minute pieces of material can be removed, which, over time, will leave a rough, cinderlike surface.

The presence of vapor in the vena contracta region puts an upper limit on the amount of liquid that will pass through a valve. A mixture of vapor

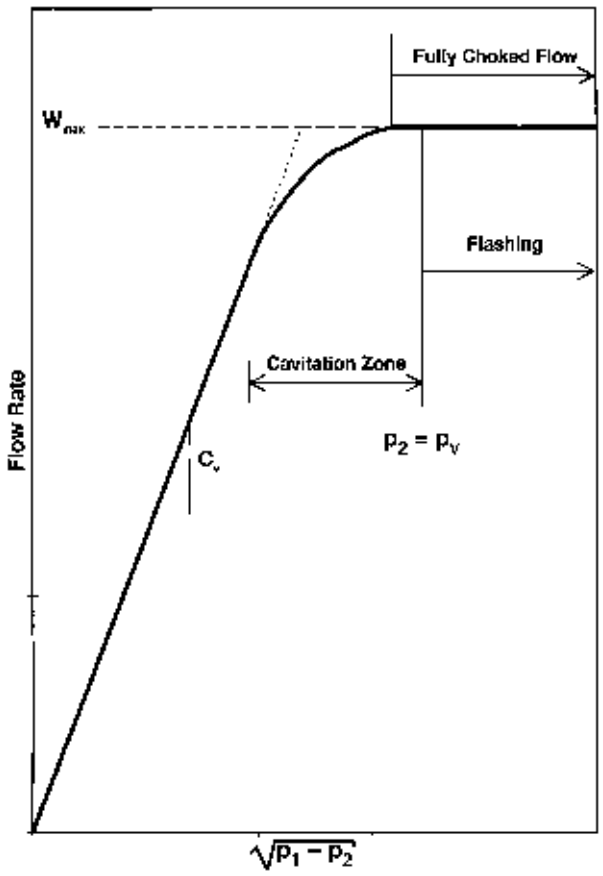

**FIG. 8-73** Liquid flow rate versus pressure drop (assuming constant $p_1$ and $p_v$).

and liquid has a lower density than that of the liquid alone. While Eq. (8-77) is not applicable to two-phase flows because pressure changes are redistributed due to varying density and the two phases do not necessarily have the same average velocity, it does suggest that lower density reduces the total mass flow rate. Figure 8-73 illustrates a typical flow rate/pressure drop relationship. As with compressible gas flow at a given $p_1$, flow increases as $p_2$ is decreased until the flow chokes (i.e., no additional fluid will pass). The transition between incompressible and choked flow is gradual because, within the convoluted flow passages of valves, the pressure is actually an uneven distribution at each cross section and consequently vapor formation zones increase gradually. In fact, isolated zones of bubble formation or incipient cavitation often occur at pressure drops well below that at which a reduction in flow is noticeable. The similarity between liquid and gas choking is not serendipitous; it is surmised that the two-phase fluid is traveling at the mixture's sonic velocity in the throat when choked. Complex fluids with components having varying vapor pressures and/or entrained noncondensable gases (e.g., crude oil) will exhibit soft vaporization/implosion transitions.

There are several methods to reduce cavitation or at least its negative side effects. Material damage is slowed by using harder materials and by directing the cavitating stream away from passage walls (e.g., with an angle body flowing down). Sometimes the system can be designed to place the valve in a higher $p_2$ location or add downstream resistance, which creates backpressure. A low recovery valve has a higher minimum pressure for a given $p_2$ and so is a means to eliminate the cavitation itself, not just its side effects. In Fig. 8-72, if $p_v < B$, neither valve will cavitate substantially. For $p_v > B$ but $p_v < A$, the high recovery valve will cavitate substantially, but the low recovery valve will not. Special anticavitation trims are available for globe and angle valves and more recently for some rotary valves. These trims use multiple contraction/expansion stages or other distributed resistances to boost $F_L$ to values sometimes near unity.

If $p_2$ is below $p_v$, the two-phase mixture will continue to vaporize in the body outlet and/or downstream pipe until all liquid phase is gone, a condition known as *flashing*. The resulting huge increase in specific volume leads to high velocities, and any remaining liquid droplets acquire much of the higher vapor-phase velocity. Impingement of these droplets can produce material damage, but it differs from cavitation damage because it exhibits a smooth surface. Hard materials and directing the two-phase jets away from solid surfaces are means to avoid this damage.

**Seals, Bearings, and Packing Systems** In addition to their control function, valves often need to provide shutoff. FCI 70-2-1998 and IEC 60534-4 recognize six standard classifications and define their as-shipped qualification tests. Class I is an amount agreed to by user and supplier with no test needed. Classes II, III, and IV are based on an air test with maximum leakage of 0.5 percent, 0.1 percent, and 0.01 percent of rated capacity, respectively. Class V restricts leakage to $5 \times 10^{-6}$ mL of water per second per millimeter of port diameter per bar differential. Class VI allows 0.15 to 6.75 mL/min of air to escape depending on port size; this class implies the need for interference-fit elastomeric seals. With the exception of class V, all classes are based on standardized pressure conditions that may not represent actual conditions. Therefore, it is difficult to estimate leakage in service. Leakage normally increases over time as seals and seating surfaces become nicked or worn. Leak passages across the seat-contact line, known as *wire drawing*, may form and become worse over time—even in hard metal seats under sufficiently high pressure differentials.

Polymers used for seat and plug seals and internal static seals include PTFE (polytetrafluoroethylene) and other fluorocarbons, polyethylene, nylon, polyether-ether-ketone, and acetal. Fluorocarbons are often carbon- or glass-filled to improve mechanical properties and heat resistance. Temperature and chemical compatibility with the process fluid are the key selection criteria. Polymer-lined bearings and guides are used to decrease friction, which lessens dead band and reduces actuator force requirements. See Sec. 25, Materials of Construction, for properties.

Packing forms the pressure-tight seal, where the stem protrudes through the pressure boundary. Packing is typically made from PTFE or, for high temperature, a bonded graphite. If the process fluid is toxic, more sophisticated systems such as dual packing, live-loaded, or a flexible metal bellows may be warranted. Packing friction can significantly degrade control performance. Pipe, bonnet, and internal-trim joint gaskets are typically a flat sheet composite. Gaskets intended to absorb dimensional mismatch are typically made from filled spiral-wound flat stainless-steel wire with PTFE or graphite filler. The use of asbestos in packing and gaskets has been largely eliminated.

**Flow Characteristics** The relationship between valve flow and valve travel is called the *valve flow characteristic*. The purpose of flow characterization is to make loop dynamics independent of load, so that a single controller tuning remains optimal for all loads. Valve gain is one factor affecting loop dynamics. In general, gain is the ratio of change in output to change in input. The input of a valve is travel $y$, and the output is flow $w$. Since pressure conditions at the valve can depend on flow (hence travel), valve gain is

$$\frac{dw}{dy} = \frac{\partial w}{\partial C_V}\frac{dC_V}{dy} + \frac{\partial w}{\partial p_1}\frac{dp_1}{dy} + \frac{\partial w}{\partial p_2}\frac{dp_2}{dy} \tag{8-87}$$

An inherent valve flow characteristic is defined as the relationship between flow rate and travel, under constant-pressure conditions. Since the rightmost two terms in Eq. (8-87) are zero in this case, the inherent characteristic is necessarily also the relationship between flow coefficient and travel.

Figure 8-74 shows three common inherent characteristics. A linear characteristic has a constant slope, meaning the inherent valve gain is a constant. The most popular characteristic is equal-percentage ("=%" in the Fig. 8-74), which gets its name from the fact that equal changes in travel produce equal-percentage changes in the existing flow coefficient. In other words, the slope of the curve is proportional to $C_V$, or equivalently that inherent valve gain is proportional to flow. The equal-percentage characteristic can be expressed mathematically by

$$C_V(y) = (\text{rated } C_V)\exp\left[\left(\frac{y}{\text{rated } y} - 1\right)\ln R\right] \tag{8-88}$$

This expression represents a set of curves parameterized by $R$. Note that $C_V(y = 0)$ equals (rated $C_V$)/$R$ rather than zero; real equal-percentage characteristics deviate from theory at some small travel to meet shutoff requirements. An equal-percentage characteristic provides perfect compensation for a process where the gain is inversely proportional to flow (e.g., liquid pressure). *Quick opening* does not have a standardized mathematical definition. Its shape arises naturally from high-capacity plug designs used in on/off service globe valves. Frequently, pressure conditions at the valve will change with flow rate. This so-called *process influence* [the rightmost two terms on the right-hand side of Eq. (8-87)] combines with inherent gain to express the installed valve gain. The flow versus travel relationship for a specific set of conditions is called the *installed flow characteristic*. Typically, valve $\Delta p$ decreases with load, since pressure losses in the piping system

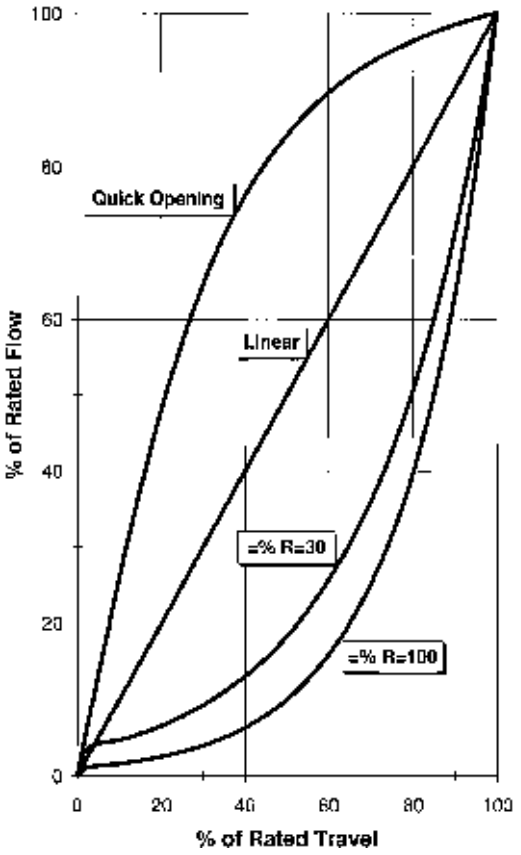

**FIG. 8-74** Typical inherent flow characteristics.

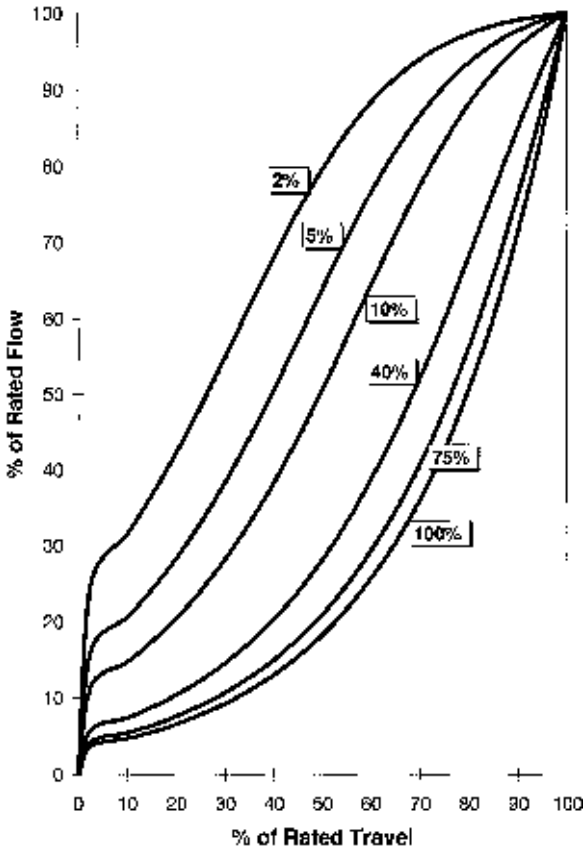

**FIG. 8-75** Installed flow characteristic as a function of percent of total system head allocated to the control valve (assuming constant-head pump, no elevation head loss, and an $R$ equal to 30 equal-percentage inherent characteristic).

increase with flow. Figure 8-75 illustrates how allocation of total system head to the valve influences the installed flow characteristics. For a linear or quick-opening characteristic, this transition toward a concave down shape would be more extreme. This effect of typical process pressure variation, which causes equal-percentage characteristics to have fairly constant installed gain, is one reason the equal-percentage characteristic is the most popular.

Due to clearance flow, flow force gradients, seal friction, and the like, flow cannot be throttled to an arbitrarily small value. Installed rangeability is the ratio of maximum to minimum controllable flow. The actuator and positioner, as well as the valve, influence the installed rangeability. *Inherent rangeability* is defined as the ratio of the largest to the smallest $C_V$ within which the characteristic meets specified criteria (see ISA 75.11). The $R$ value in the equal-percentage definition is a theoretical rangeability only. While high installed rangeability is desirable, it is also important not to oversize a valve; otherwise, turndown (ratio of maximum normal to minimum controllable flow) will be limited.

Sliding stem valves are characterized by altering the contour of the plug when the port and plug determine the minimum (controlling) flow area. Passage area versus travel is also easily manipulated in characterized cage designs. Inherent rangeability varies widely, but typical values are 30 for contoured plugs and 20 to 50 for characterized cages. While these types of valves can be characterized, the degree to which manufacturers conform to the mathematical ideal is revealed by plotting measured $C_V$ versus travel. Note that ideal equal-percentage will plot as a straight line on a semilog graph. Custom characteristics that compensate for a specific process are possible.

Rotary stem-valve designs are normally offered only in their naturally occurring characteristic, since it is difficult to appreciably alter this. If additional characterization is required, the positioner or controller may be characterized. However, these approaches are less direct, since it is possible for device nonlinearity and dynamics to distort the compensation.

## VALVE CONTROL DEVICES

Devices mounted on the control valve that interface various forms of input signals, monitor and transmit valve position, or modify valve response are valve control devices. In some applications, several auxiliary devices are used together on the same control valve. For example, mounted on the control valve, one may find a current-to-pressure transducer, a valve positioner, a volume booster relay, a solenoid valve, a trip valve, a limit switch, a process controller, and/or a stem position transmitter. Figure 8-76 shows a valve positioner mounted on the yoke leg of a spring and diaphragm actuator.

As most throttling control valves are still operated by pneumatic actuators, the control valve device descriptions that follow relate primarily to devices that are used with pneumatic actuators. The functions of hydraulic and electrical counterparts are very similar. Specific details on a particular valve control device are available from the vendor of the device.

**Valve Positioners** The valve positioner, when combined with an appropriate actuator, forms a complete closed-loop valve position control system. This system makes the valve stem conform to the input signal coming from the process controller in spite of force loads that the actuator may encounter while moving the control valve. Usually, the valve positioner is contained in its own enclosure and is mounted on the control valve.

The key parts of the positioner/actuator system, shown in Fig. 8-77*a*, are (1) an input conversion network, (2) a stem position feedback network, (3) a summing junction, (4) an amplifier network, and (5) an actuator.

The input conversion network shown is the interface between the input signal and the summer. This block converts the input current or pressure (from an I/P transducer or a pneumatic process controller) to a voltage, electric current, force, torque, displacement, or other particular variable that can be directly used by the summer. The input conversion usually contains a means to adjust the slope and offset of the block to provide for a means of spanning and zeroing the positioner during calibration. In addition, means for changing the sense (known as "action") of the input/output characteristic are often addressed in this block. Also exponential, logarithmic, or other predetermined characterization can be put in this block to provide a characteristic that is useful in offsetting or reinforcing a nonlinear valve or process characteristic.

The stem position feedback network converts stem travel to a useful form for the summer. This block includes the feedback linkage which varies with

**FIG. 8-76** Valve and actuator with valve positioner attached. (*Courtesy Fisher Controls International LLC.*)

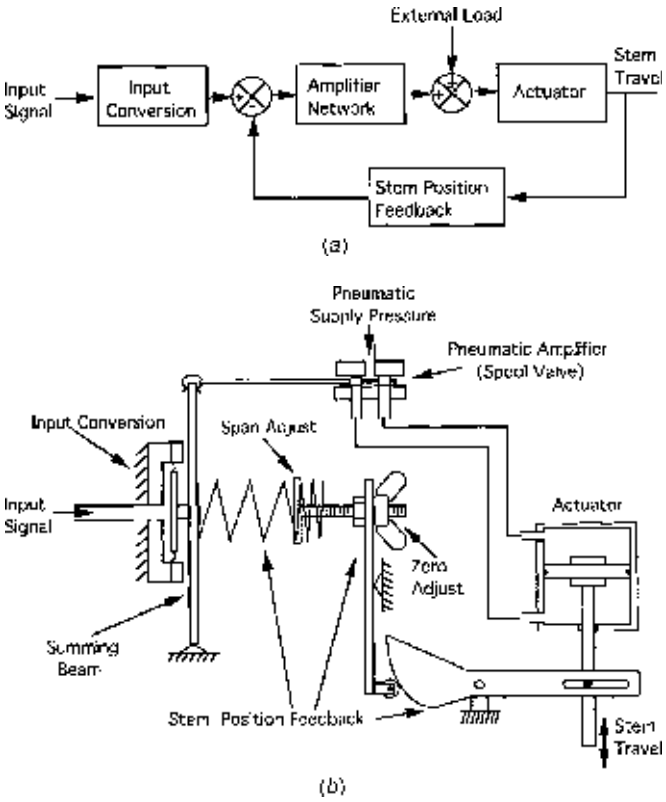

**FIG. 8-77** Positioner/actuators. (*a*) Generic block diagram. (*b*) Example of a pneumatic positioner/actuator.

actuator type. Depending on positioner design, the stem position feedback network can provide span and zero and characterization functions similar to that described for the input conversion block.

The amplifier network provides signal conversion and suitable static and dynamic compensation for good positioner performance. Control from this block usually reduces to a form of proportional or proportional plus derivative control. The output from this block in the case of a pneumatic positioner is a single connection to the spring and diaphragm actuator or two connections for push/pull operation of a springless piston actuator. The action of the amplifier network and the action of the stem position feedback can be reversed together to provide for reversed positioner action.

By design, the gain of the amplifier network shown in Fig. 8-77*a* is made very large. Large gain in the amplifier network means that only a small proportional deviation will be required to position the actuator through its active range of travel. This means that the signals into the summer track very closely and that the gain of the input conversion block and the stem position feedback block determine the closed-loop relationship between the input signal and the stem travel.

Large amplifier gain also means that only a small amount of additional stem travel deviation will result when large external force loads are applied to the actuator stem. For example, if the positioner's amplifier network has a gain of 50 (and assuming that high packing box friction loads require 25 percent of the actuator's range of thrust to move the actuator), then only 25 percent/50 (or 0.5 percent deviation) between input signal and output travel will result due to valve friction.

Figure 8-77*b* is an example of a pneumatic positioner/actuator. The input signal is a pneumatic pressure that (1) moves the summing beam, which (2) operates the spool valve amplifier, which (3) provides flow to and from the piston actuator, which (4) causes the actuator to move and continue moving until (5) the feedback force returns the beam to its original position and stops valve travel at a new position. Typical positioner operation is thereby achieved.

Static performance measurements related to positioner/actuator operation include the conformity, measured accuracy, hysteresis, dead band, repeatability, and locked stem pressure gain. Definitions and standardized test procedures for determining these measurements can be found in ISA-S75.13, "Method of Evaluating the Performance of Positioners with Analog Input Signals and Pneumatic Output."

***Dynamics of Positioner-Based Control Valve Assemblies*** Control valve assemblies are complete, functional units that include the valve body, actuator, positioner, if so equipped, associated linkages, and any auxiliary equipment such as current to pneumatic signal transducers and air supply pressure regulators. Although performance information such as frequency response, sensitivity, and repeatability data may be available for a number of these components individually, it is the performance of the entire assembly that will ultimately determine how well the demand signal from the controller output is transferred through the control valve to the process. The valve body, actuator, and positioner combination is typically responsible for the majority of the control valve assembly's dynamic behavior. On larger actuators, the air supply pressure regulator capacity or other airflow restrictions may limit the control valve assembly's speed of response.

The control valve assembly response can usually be characterized quite well by using a first-order plus dead-time response model. The control valve assembly will also exhibit backlash, stiction, and other nonlinear behavior. During normal operation of a control loop, the controller usually makes small output changes from one second to the next. Typically this change is less than 1 percent. With very small controller output changes, e.g., less than 0.1 percent, the control valve assembly may not move at all. As the magnitude of the controller output change increases, eventually the control valve will move. At the threshold of movement, the positional accuracy and repeatability of the control valve are usually quite poor. The speed of response may be quite slow and may occur after a number of seconds of dead time. This poor performance is due to the large backlash and stiction effects relative to the requested movement and the small output change of the positioner. With a further increase in the magnitude of the controller output steps, the behavior of the control valve typically becomes more repeatable and "linear." Dead time usually drops to only a fraction of a second, and the first-order time constant becomes faster. For much larger steps in

the controller output, e.g., over 10 percent, the positioner and air supply equipment may be unable to deliver the necessary air volume to maintain the first-order response. In this case, the control valve will exhibit very little dead time, but will be rate-limited and will ramp toward the requested position. It is within the linear region of motion that the potential for the best control performance exists.

When one is specifying a control valve for process control applications, in addition to material, style, and size information, the dynamic response characteristics and maximum allowable dead band (sum of backlash, stiction, and hysteresis effects) *must* be stated. The requirement for the control valve assembly's speed of response is ultimately determined by the dynamic characteristics of the process and the control objectives. Typically, the equivalent first-order time constant specified for the control valve assembly should be at least 5 times faster than the desired controller closed-loop time constant. If this requirement is not met, the tuning of the control loop must be slowed down to accommodate the slow control valve response; otherwise, control robustness and stability may be compromised. The dead band of the control valve assembly is typically the determining factor for control resolution and frequently causes control instability in the form of a "limit" cycle. The controller output will typically oscillate across a range that is one to two times the magnitude of the control valve dead band. This is very dependent on the nature of the control valve nonlinearities, the process dynamics, and the controller tuning. The magnitude of the process limit cycle is determined by the size of the control valve dead band multiplied by the installed gain of the control valve. For this reason, a high-performance control valve assembly, e.g., with only 0.5 percent dead band, may cause an unacceptably large process limit cycle if the valve is oversized and has a high installed gain. For typical process control applications, the installed gain of the control valve should be in the range of 0.5 to 2 percent of the process variable span per percent of controller output. The total dead band of the control valve assembly should be less than 1 percent. For applications that require more precise control, the dead band and possibly the installed gain of the control valve must be reduced. Specialized actuators are available that are accurate down to 0.1 percent or less. At this level of performance, however, the design of the valve body, bearings, linkages, and seals starts to become a significant source of dead band.

***Positioner/Actuator Stiffness*** Minimizing the effect of dynamic loads on valve stem travel is an important characteristic of the positioner/actuator. Stem position must be maintained in spite of changing reaction forces caused by valve throttling. These forces can be random (buffeting force) or can result from a negative-slope force/stem travel characteristic (negative gradient); either could result in valve stem instability and loss of control. To reduce and eliminate the effect of these forces, the effective stiffness of the positioner/actuator must be made sufficiently high to maintain stationary control of the valve stem.

The air spring effect is added to the spring stiffness and results from adiabatic expansion and compression of air in the actuator casing. Numerically, the small perturbation value for air spring stiffness in newtons per meter is given by

$$\text{Air spring rate} = \frac{\gamma p_a A_a^2}{V} \tag{8-89}$$

where $\gamma$ is the ratio of specific heats (1.4 for air), $p_a$ is the actuator pressure in pascals absolute, $A_a$ is the actuator pressure area in square meters, and $V$ is the internal actuator volume in cubic meters.

***Positioner Application*** Positioners are widely used on pneumatic valve actuators. Often they provide improved process loop control because they reduce valve-related nonlinearity. Dynamically, positioners maintain their ability to improve control valve performance for sinusoidal input frequencies up to about one-half of the positioner bandwidth. At input frequencies greater than this, the attenuation in the positioner amplifier network increases, and valve nonlinearity begins to affect final control element performance more significantly. Because of this, the most successful use of the positioner occurs when the positioner response bandwidth is greater than twice that of the most dominant time lag in the process loop.

Some typical examples in which the dynamics of the positioner are sufficiently fast to improve process control are the following:

1. *In a distributed control system (DCS) process loop with an electronic transmitter.* The DCS controller and the electronic transmitter have time constants that are dominant over the positioner response. Positioner operation is therefore beneficial in reducing valve-related nonlinearity.

2. *In a process loop with a pneumatic controller and a large process time constant.* Here the process time constant is dominant, and the positioner will improve the linearity of the final control element. Some common processes with large time constants that benefit from positioner application are liquid level, temperature, large-volume gas pressure, and mixing.

3. *Additional situations in which valve positioners are used:*

*a.* On springless actuators where the actuator is not usable for throttling control without position feedback.

*b.* When split ranging is required to control two or more valves sequentially. In the case of two valves, the smaller control valve is calibrated to open in the lower half of the input signal range, and a larger valve is calibrated to open in the upper half of the input signal range. Calibrating the input command signal range in this way is known as *split-range operation* and increases the practical range of throttling process flows over that of a single valve.

*c.* In open-loop control applications best static accuracy is needed. On occasion, positioner use can degrade process control. Such is the case when the process controller, process, and process transmitter have time constants that are similar to or smaller than that of the positioner/actuator. This situation is characterized by low process controller proportional gain (gain < 0.5), and hunting or limit cycling of the process variable is observed. Improvements here can be made by doing one of the following:

1. Install a dominant first-order, low-pass filter in the loop ahead of the positioner and retune the process loop. This should allow increased proportional gain in the process loop and reduce hunting. Possible means for adding the filter include adding it to the firmware of the DCS controller, by adding an external *RC* network on the output of the process controller or by enabling the filter function in the input of the positioner, if it is available. Also, some transducers, when connected directly to the actuator, form a dominant first-order lag that can be used to stabilize the process loop.
2. Select a positioner with a faster response characteristic.

***Processor-Based Positioners*** When designed around an electronic microcontroller, the valve positioner [now commonly referred to as a *digital valve controller* (DVC)] takes on additional functionality that provides convenience and performance enhancements over the traditional design. The most common form of processor-based positioner, shown in Fig. 8-77, is a digitally communicating stem position controller that operates by using the fundamental blocks shown in Fig. 8-77*a*. A local display is part of the positioner and provides tag information, command input and travel, servo tuning parameters, and diagnostic information. Often auxiliary sensors are integrated into the device to provide increased levels of functionality and performance. Sensed variables can include actuator pressure, relay input pressure, relay valve position, board temperature, or a discrete input. A 4- to 20-mA valve travel readback circuit is also common. The travel sensor is based on a potentiometer or can be a noncontacting type such as a variable capacitance sensor, Hall effect sensor, or GMR device. Some positioners require a separate connection to an ac or dc supply voltage, but the majority of the designs are "loop-powered," which means that they receive power either through the current input ( for positioners that require a 4- to 20-mA analog input signal) or through the digital communications link when the control signal is a digital signal.

Processor-based positioners support automatic travel calibration and automatic response tuning for quick commissioning of the final control element. Features of this type of valve positioner include compensators for improved static and dynamic travel response; diagnostics for evaluating positioner, actuator, and valve health; and the capability to be polled from remote locations through a PC-based application or through a handheld communicator attached to the field wiring. Capability to support custom firmware for special valve applications, such as emergency safety shutdown, is also a characteristic of the processor-based design.

***Digital Field Communications*** To provide increased data transmission capability between valve-mounted devices and the host control system, manufacturers are providing digital network means in their devices. The field networks, commonly known as fieldbuses, compete fiercely in the marketplace and have varying degrees of flexibility and specific application strengths. A prospective fieldbus customer is advised to study the available bus technologies and to make a selection based on needs, and not be seduced by the technology itself.

Generally, a fieldbus protocol must be nonproprietary ("open") so that different vendors of valve devices can design their bus interface to operate properly on the selected fieldbus network. Users demand that the devices be "interoperable" so that the device will work with other devices on the same segment or can be substituted with a device from an alternate manufacturer. International standardization of some of the protocols is currently underway ( for example, IEC 61158), whereas others are sponsored by user groups or foundations that provide democratic upgrades to the standard as well as network compliance testing.

The physical wiring typically used is the plant standard twisted-pair wiring for 4- to 20-mA instrumentation. Because of the networking capability of the bus, more than one device can be supported on a single pair of wires, and thus wiring requirements are reduced. Compared to a host level bus such as Ethernet, fieldbuses exhibit slower communication rates, have longer transmission distance capability (1 to 2 km), use standard two-wire installation, are capable of multidrop busing, can support bus-powered devices, do not have redundant modes of bus operation, and are available for intrinsically safe installations. Devices on the fieldbus network may be either powered by the bus itself or powered separately.

The simplest digital networks available today support discrete sensors and on/off actuators, including limit switches and motor starters. Networks of this type have fast cycle times and are often used as an alternative to PLC discrete I/O. More sophisticated field networks are designed to support process automation, more complex process transmitters, and throttling valve actuators. These process-level networks are fundamentally continuous and analoglike in operation, and data computation is floating-point. They support communication of materials of construction, calibration and commissioning, device and loop level diagnostics (including information displays outlining corrective action), and unique manufacturer-specific functionality. Some process networks are able to automatically detect, identify, and assign an address to a new device added to the network, thus reducing labor, eliminating addressing errors, and indicating proper network function immediately after the connection is made. Final control elements operated by the process-level network include I/P transducers, motorized valves, digital valve controllers, and transmitters.

A particular field network protocol known as HART (highway addressable remote transducer) is the most widely used field network protocol. It is estimated that as of 2004 there are more than 14 million HART-enabled devices installed globally and that 70 percent of all processor-based process measurement and control instruments installed each year use HART communications. HART's popularity is based on its similarity to the traditional 4- to 20-mA field signaling and thus represents a safe, controlled transition to digital field communications without the risk often associated with an abrupt change to a totally digital fieldbus. With this protocol, the digital communications occur over the same two wires that provide the 4- to 20-mA process control signal without disrupting the process signal. The protocol uses the frequency-shift keying (FSK) technique (see Fig. 8-78) where two individual frequencies, one representing the mark and the other representing the space, are superimposed on the 4- to 20-mA current signal. As the average value of the signals used is zero, there is no dc offset value added to the 4- to 20-mA signal. The HART protocol is principally a master/slave protocol which means that a field device (slave) speaks only when requested by a master device. In this mode of operation, the slave can update the master at a rate of twice per second. An optional communication mode, *burst mode*, allows a HART slave device to continuously broadcast updates without stimulus requests from the master device. Update rates of 3 to 4 updates per second are typical in the burst mode of operation.

HART-enabled devices are provided by the valve device manufacturer at little or no additional cost. The HART network is compatible with existing 4- to 20-mA applications using current plant personnel and practices, provides for a gradual transition from analog to fully digital protocols, and is provided by the valve device manufacturer at little or no additional cost. Contact the HART Communication Foundation for additional information.

Wireless digital communication to and from the final control element is not yet commercially available but is presently being investigated by more than one device manufacturer. The positive attribute of a wireless field network is the reduced cost of a wireless installation compared to a wired installation. Hurdles for wireless transmissions include security from non-network sources, transmission reliability in the plant environment, limited bus speed, and the conservative nature of the process industry relative to change. Initial installations of wireless networks are supporting secondary variables and diagnostics; in the future primary control of processes with large time constants and finally general application to process control are expected. Both point-to-point and mesh architectures are commercialized at the device level. Mesh architectures rely on the other transmitting devices in the area to receive and then pass on any data transmission, thus rerouting communications around sources of interference. Two unlicensed spread spectrum radio bands are the main focus for current wireless development: 900 MHz and 2.4 GHz. The 900-MHz band is unique to North America and has better propagation and penetrating properties than the 2.4-GHz band. The 2.4-GHz band is a worldwide band and has wider channels, allowing much higher data rates. The spread spectrum technique uses multiple frequencies within the radio band to transmit data. Spread spectrum is further divided into the direct sequence technique, where the device changes frequency many times per data bit, and the frequency-hopping technique, where the device transmits a data packet on one frequency and then changes to a different frequency. Because of the rapid growth expected in this decade, the prospective wireless customer is encouraged to review up-to-date literature to determine the state of field wireless commercialization as it applies to her or his specific application.

***Diagnostic Capability*** The rapid proliferation of communicating, processor-based digital valve controllers over the last decade has led to a corresponding rise in diagnostic capability at the control valve. Diagnosing control valve health is critical to plant operation as maintenance costs can be reduced by identifying the valves that are candidates for repair. Less time is spent during plant shutdown repairing valves that do not need repair, which ultimately results in increased online operating time. Valve diagnostics can detect and flag a failed valve more quickly than by any other means, and they can be configured to cause the valve to move to its fail-safe position on detection of specified fault conditions. The diagnostic-enabled positioner, when used with its host-based software application, can pinpoint exact components in a given final control element that have failed and can recommend precise maintenance procedures to follow to remedy the fault condition.

The state variables that provide valve position control are used to diagnose the health of the final control element. In addition, some digital valve controller designs integrate additional sensors into their construction to provide increased diagnostic capability. For example, pressure sensors are provided to detect supply pressure, actuator pressure (upper and lower cylinder pressures in the case of a springless piston actuator), and internal pilot pressure. Also, the position of the pneumatic relay valve is available in some designs to provide quiescent flow data used for leak detection in the actuator.

Valve diagnostics are divided into two types: online and offline. Offline diagnostics are those diagnostics that occur when the control valve is bypassed or otherwise isolated from the process. The offline diagnostic routine manipulates the travel command to the valve and records the corresponding valve travel, actuator pressure, and servo drive value. These parameters are plotted in various combinations to provide hysteresis plus dead-band information, actuator operating pressure as a function of travel, valve friction, servo drive performance, valve seating load, positioner calibration endpoints, and dynamic response traces. Small- and large-amplitude step inputs as well as large slow ramps (exceeding 100 percent of the input range) are common offline test waveforms generated by the diagnostic as command inputs for

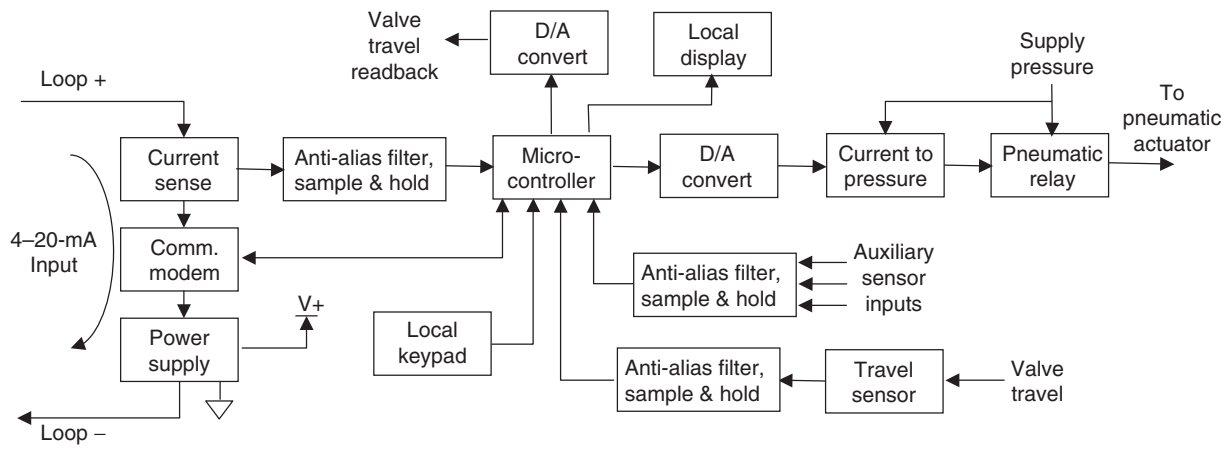

**FIG. 8-78** Generic loop-powered digital valve controller.

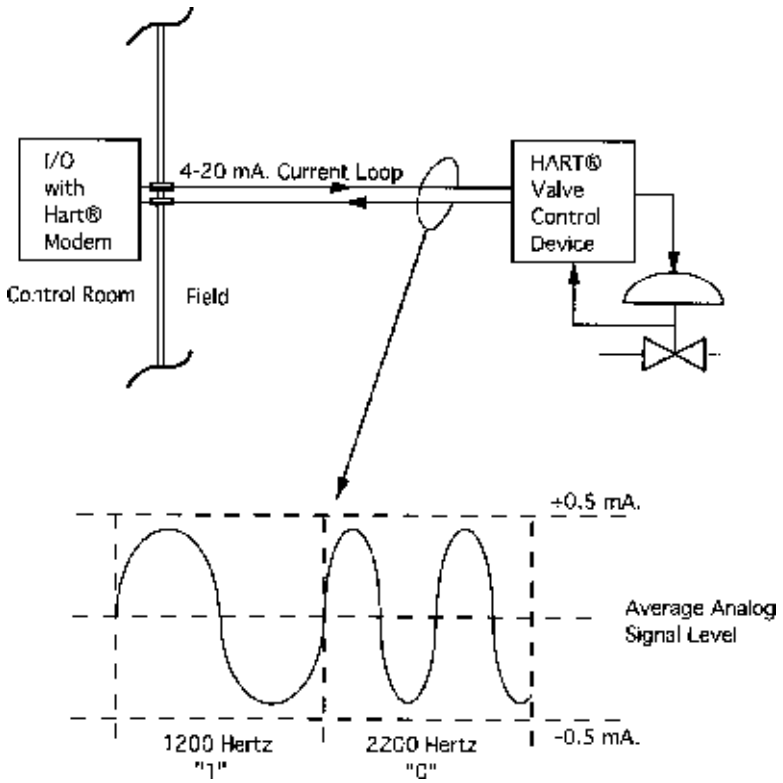

**FIG. 8-79** Hybrid point-to-point communications between the control room and the control valve device.

offline diagnostic tests. Figure 8-79 is an example of one offline diagnostic test performed on a small globe valve actuated by a spring and diaphragm actuator. During this test the command input, travel, actuator pressure, and servo drive level are recorded and plotted as they result from a command input that is slowly ramped by the diagnostic routine (Fig. 8-80*a*). This diagnostic is extremely useful in detecting problems with the valve/actuator system and can flag potential problems with the final control element before catastrophic failure occurs. For example, Fig. 8-80*b* indicates the overall tracking capability of the control valve, and Fig. 8-80*c* indicates the pressure operating range of the actuator and the amount of frictional force resulting from the combined effects of valve packing and valve plug contact. Figure 8-80*d* displays the level of servo drive required to stroke the valve from one end of travel to the other. The composite operative health of the control valve is determined through comparison of the empirical levels presented in Fig. 8-80 with the manufacturers' recommendations. Recommended maintenance actions result from this comparison.

Online diagnostics are diagnostics that monitor and evaluate conditions at the control valve during normal throttling periods (i.e., during valve-in-service periods). Online diagnostics monitor mean levels and disturbances generated in the normal operation of the valve and typically do not force or generate disturbances on the valve's operation. For example, an online diagnostic can calculate travel deviation relative to the input command and flag a condition where the valve travel has deviated beyond a preset band. Such an event, if it exists for more than a short time, indicates that the valve has lost its ability to track the input command within specified limits. Additional diagnostics could suggest that the feedback linkage has ceased functioning, or that the valve has stuck, or that some other specific malfunction is the cause of excess travel deviation. The manufacturer of the positioner diagnostic incorporates default limits into the host software application that are used to determine the relative importance of a specific deviation. To quickly indicate the severity of a problem detected by a diagnostic routine, a red, yellow, or green, or "advise, maintenance now, or failed," indication is presented on the user-interface screen for the valve problem diagnosed. Help notes and recommended remedial action are available by pointing and clicking on the diagnostic icon presented on the user's display.

Event-triggered recording is an online diagnostic technique supported in digital valve controllers (DVCs). Functionally a triggering event, such as a valve coming off a travel stop or a travel deviation alert, starts a time-series recording of selected variables. A collection of variables such as the input command, stem travel, actuator pressure, and drive command is stored for several minutes before and after the triggered event. These variables are then plotted as time series for immediate inspection or are stored in memory for later review. Event-triggering diagnostics are particularly useful in diagnosing valves that are closed or full-open for extended periods. In this case the event-triggered diagnostic focuses on diagnostic rich data at the time the valve is actually in operation and minimizes the recording of flat-line data with little diagnostic content. Other online diagnostics detected by DVC manufacturers include excess valve friction, supply pressure failure, relay operation failure, broken actuator spring, current to pressure module failure, actuator diaphragm leaking, and shifted travel calibration.

Safety shutdown valves, which are normally wide open and operate infrequently, are expected to respond to a safety trip command reliably and without fault. To achieve the level of reliability required in this application, the safety valve must be periodically tested to ensure positive operation under safety trip conditions. To test the operation of the shutdown system without disturbing the process, the traditional method is to physically lock the valve stem in the wide-open position and then to electrically operate the pneumatic shutdown solenoid valve. Observing that the pneumatic solenoid valve has properly vented the actuator pressure to zero, the actuator is seen as capable of applying sufficient spring force to close the valve, and a positive safety valve test is indicated. The pneumatic solenoid valve is then returned to its normal electrical state, the actuator pressure returns to full supply pressure, and the valve stem lock mechanism is removed. This procedure, though necessary to enhance process safety, is time-consuming and takes the valve out of service during the locked stem test. Digital valve controllers are able to validate the operation of a safety shutdown valve by using an online diagnostic referred to as a *partial stroke test*. The partial stroke test can be substituted for the traditional test method described above and does not require the valve to be locked in the wide-open position to perform the test. In a fashion similar to that shown in Fig. 8-80*a* (the partial stroke diagnostic), the system physically ramps the command input to the positioner from the wide-open position to a new position, pauses at the new position for a few seconds, and then ramps the command input back to the wide-open position. During this time, the valve travel measurement is monitored and compared to the input command. If the travel measurement deviates for the input by more than a fixed amount for the configured period of time, the valve is considered to have failed the test and a failed-test message is communicated to the host system. Also during this test, the actuator

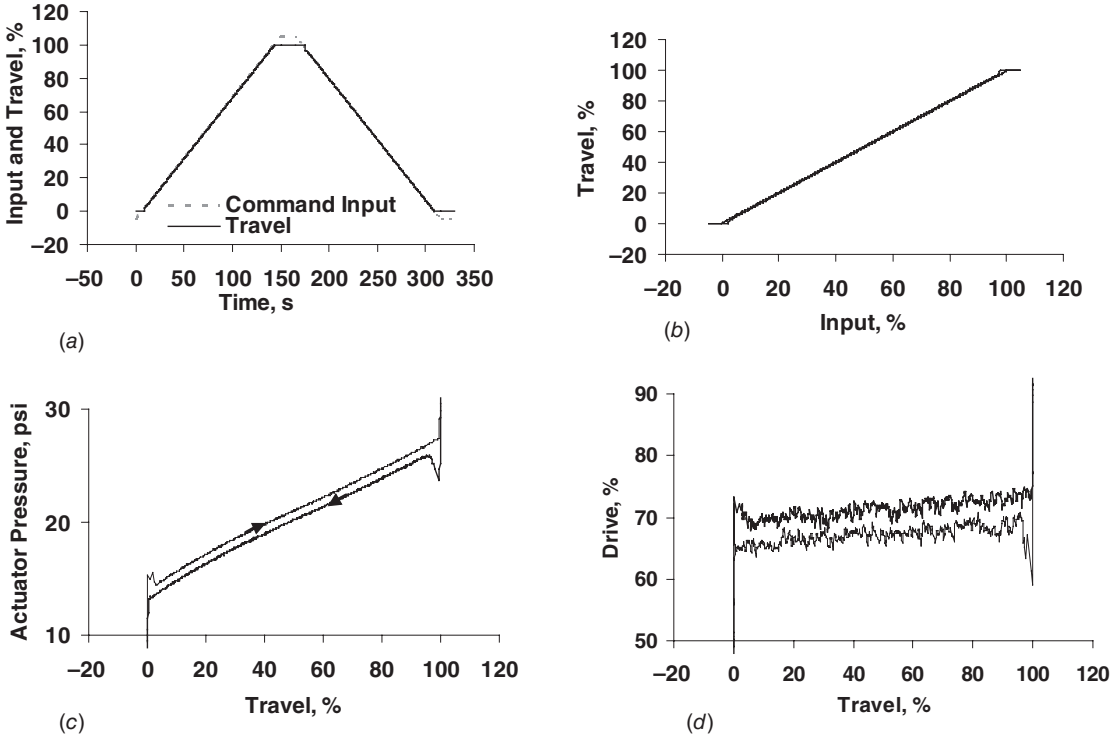

**FIG. 8-80** Offline valve diagnostic scan showing results of a diagnostic ramp. (*a*) The command input and resulting travel. (*b*) The dynamic scan. (*c*) The valve signature. (*d*) The servo drive versus travel plot. The hysteresis shown in the valve signature results from sliding friction due to valve packing and valve plug contact.

pressure required to move the valve is detected via a dedicated pressure sensor. If the thrust (pressure) required to move the valve during the partial stroke test exceeds the predefined thrust limit for this test, then the control valve is determined to have a serious sticking problem, the test is immediately aborted, and the valve is flagged as needing maintenance. The partial stroke test can be automated to perform on a periodic basis, for instance, once a week; or it can be initialized by operator request at any time. The amount of valve travel that occurs during the partial stroke test is typically limited to a minimum valve position of 70 percent open or greater. This limit is imposed to prevent the partial stroking of the safety valve from significantly affecting the process flow through the valve. Comparison of partial stroke curves from past tests can indicate the gradual degradation of valve components. Use of "overlay" graphics, identification of unhealthy shifts in servo drive, increases in valve friction, and changes in dynamic response provide information leading to a diagnosis of needed maintenance.

In addition to device-level diagnostics, networked final control elements, process controllers, and transmitters can provide "loop" level diagnostics that can detect loops that are operating below expectations. Process variability, time in a limit (saturated) condition, and time in the wrong control mode are metrics used to detect problems in process loop operation.

**Transducers** The current-to-pressure transducer (I/P transducer) is a conversion interface that accepts a standard 4- to 20-mA input current from the process controller and converts it to a pneumatic output in a standard pneumatic pressure range [normally 0.2 to 1.0 bar (3 to 15 psig) or, less frequently, 0.4 to 2.0 bar (6 to 30 psig)]. The output pressure generated by the transducer is connected directly to the pressure connection on a spring-opposed diaphragm actuator or to the input of a pneumatic valve positioner.

Figure 8-81*a* is the schematic of a basic I/P transducer. The transducer shown is characterized by (1) an input conversion that generates an angular displacement of the beam proportional to the input current, (2) a pneumatic amplifier stage that converts the resulting angular displacement to pneumatic pressure, and (3) a pressure area that serves as a means to return the beam to very near its original position when the new output pressure is achieved. The result is a device that generates a pressure output that tracks the input current signal. The transducer shown in Fig. 8-81*a* is used to provide pressure to small load volumes (normally 4.0 $in^3$ or less), such as a positioner or booster input. With only one stage of pneumatic amplification, the flow capacity of this transducer is limited and not sufficient to provide responsive load pressure directly to a pneumatic actuator.

The flow capacity of the transducer can be increased by adding a booster relay such as the one shown in Fig. 8-81*b*. The flow capacity of the booster relay is nominally 50 to 100 times that of the nozzle amplifier shown in Fig. 8-81*a* and makes the combined transducer/booster suitably responsive to operate pneumatic actuators. This type of transducer is stable for all sizes of load volume and produces measured accuracy (see ANSI/ISA-51.1, "Process Instrumentation Terminology," for the definition of measured accuracy) of 0.5 to 1.0 percent of span.

Better measured accuracy results from the transducer design shown in Fig. 8-81*c*. In this design, pressure feedback is taken at the output of the booster relay stage and fed back to the main summer. This allows the transducer to correct for errors generated in the pneumatic booster as well as errors in the I/P conversion stage. Also, particularly with the new analog electric and digital versions of this design, PID control is used in the transducer control network to give extremely good static accuracy, fast dynamic response, and reasonable stability into a wide range of load volumes (small instrument bellows to large actuators). Also environmental factors such as temperature change, vibration, and supply pressure fluctuation affect this type of transducer the least. Even a perfectly accurate I/P transducer cannot compensate for stem position errors generated by friction, backlash, and varying force loads coming from the actuator and valve. To do this compensation, a different control valve device—the valve positioner—is required.

**Booster Relays** The booster relay is a single-stage power amplifier having a fixed gain relationship between the input and output pressures. The device is packaged as a complete stand-alone unit with pipe thread connections for input, output, and supply pressure. The booster amplifier shown in Fig. 8-81*b* shows the basic construction of the booster relay. Enhanced versions are available that provide specific features such as (1) variable gain to split the output range of a pneumatic controller to operate more than one valve or to provide additional actuator force; (2) low hysteresis for relaying measurement and control signals; (3) high flow capacity for increased actuator stroking speed; and (4) arithmetic, logic, or other compensation functions for control system design.

A particular type of booster relay, called a *dead-band booster*, is designed to be used exclusively between the output of a valve positioner and the input to a pneumatic actuator. It provides extra flow capacity to stroke the actuator faster than with the positioner alone. The dead-band booster is designed intentionally with a large dead band (approximately 5 percent of the input span), elastomer seats for tight shutoff, and an adjustable bypass

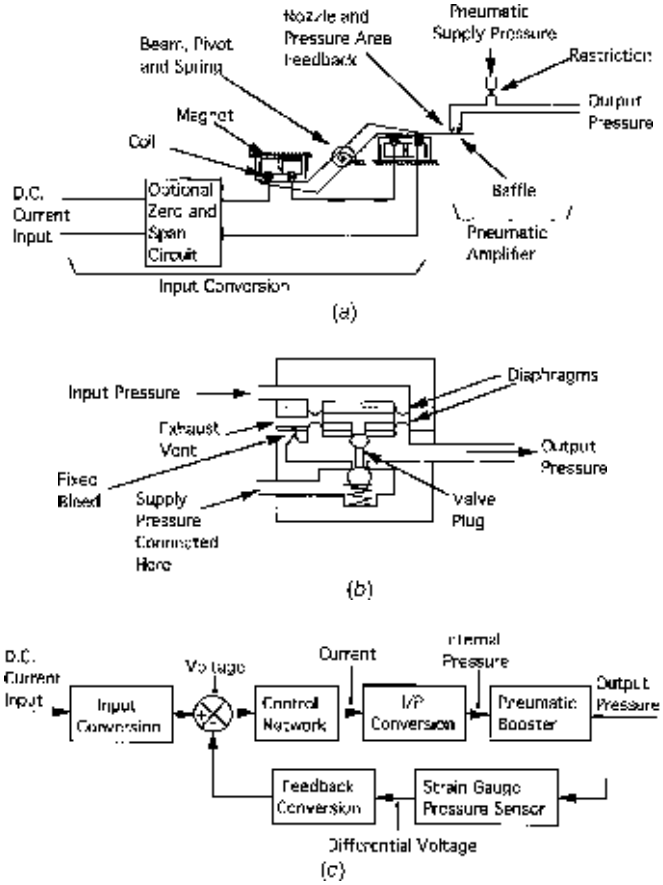

**FIG. 8-81** Current-to-pressure transducer component parts. (*a*) Direct-current–pressure conversion. (*b*) Pneumatic booster amplifier (relay). (*c*) Block diagram of a modern I/P transducer.

valve connected between the input and output of the booster. The bypass valve is tuned to provide the best compromise between increased actuator stroking speed and positioner/actuator stability.

With the exception of the dead-band booster, the application of booster relays has diminished somewhat by the increased use of current-to-pressure transducers, electropneumatic positioners, and electronic control systems. Transducers and valve positioners serve much the same functionality as the booster relay in addition to interfacing with the electronic process controller.

**Solenoid Valves** The electric solenoid valve has two output states. When sufficient electric current is supplied to the coil, an internal armature moves against a spring to an extreme position. This motion causes an attached pneumatic or hydraulic valve to operate. When current is removed, the spring returns the armature and the attached solenoid valve to the deenergized position. An intermediate pilot stage is sometimes used when additional force is required to operate the main solenoid valve. Generally, solenoid valves are used to pressurize or vent the actuator casing for on/off control valve application and safety shutdown applications.

**Trip Valves** The trip valve is part of a system used where a specific valve action (i.e., fail up, fail down, or lock in last position) is required when the pneumatic supply pressure to the control valve falls below a preset level. Trip systems are used primarily on springless piston actuators requiring fail-open or fail-closed action. An air storage or "volume" tank and a check valve are used with the trip valve to provide power to stroke the valve when supply pressure is lost. Trip valves are designed with hysteresis around the trip point to avoid instability when the trip pressure and the reset pressure settings are too close to the same value.

**Limit Switches and Stem Position Transmitters** Travel limit switches, position switches, and valve position transmitters are devices that detect the component's relative position, when mounted on the valve, actuator, damper, louver, or other throttling element. The switches are used to operate alarms, signal lights, relays, solenoid valves, or discrete inputs into the control system. The valve position transmitter generates a 4- to 20-mA output that is proportional to the position of the valve.

## FIRE AND EXPLOSION PROTECTION

Electrical equipment and wiring methods can be sources of ignition in environments with combustible concentrations of gas, liquid, dust, fibers, or flyings. Most of the time it is possible to locate the electronic equipment away from these hazardous areas. However, where electric or electronic valve-mounted instruments must be used in areas where there is a hazard of fire or explosion, the equipment and installation must meet requirements for safety. Articles 500 through 504 of the National Electrical Code cover the definitions and requirements for electrical and electronic equipment used in class I ( flammable gases or vapors), divisions 1 and 2; class II (combustible dust), divisions 1 and 2; and class III (ignitable fibers or flyings), divisions 1 and 2. Division 1 locations are locations with hazardous concentrations of gases, vapors, or combustible dust under normal operating conditions; hazardous concentration of gases, vapors, or combustible dust that occur frequently due to repair, maintenance, or leakage; or hazardous due to the presence of easily ignitable fibers or materials producing combustible flyings during handling, manufacturing, or use. Division 2 locations are locations that normally do not have ignitable concentrations of gases, vapors, or combustible dust. Division 2 locations might become hazardous through failure of ventilating equipment; adjacent proximity to a class I, division 1 location where ignitable concentrations of gases or vapors might occasionally exist; through dust accumulations on or in the vicinity of the electrical equipment sufficient to interfere with the safe dissipation of heat or by abnormal operation or failure of electrical equipment; or when easily ignitable fibers are stored or handled other than in the process of manufacture. An alternate method used for class I hazardous locations is the European "zone" method described in IEC 60079-10, "Electrical Apparatus for Explosive Gas Atmospheres." The zone designation for class I locations has been adapted by the NEC as an alternate method and is defined in Article 505 of the NEC.

Acceptable protection techniques for electrical and electronic valve accessories used in specific class and division locations include explosion-proof enclosures; intrinsically safe circuits; nonincendive circuits, equipment, and components; dust-ignition-proof enclosures; dust-tight enclosures; purged and pressurized enclosures; oil immersion for current-interrupting contacts; and hermetically sealed equipment. Details of these techniques can be found in the *National Electrical Code Handbook*, available from the National Fire Protection Association.

Certified testing and approval for control valve devices used in hazardous locations is normally procured by the manufacturer of the device. The manufacturer typically goes to a third-party laboratory for testing and certification. Applicable approval standards are available from CSA, CENELEC, FM, SAA, and UL.

**Environmental Enclosures** Enclosures for valve accessories are sometimes required to provide protection from specific environmental conditions. The National Electrical Manufacturers Association (NEMA) provides descriptions and test methods for equipment used in specific environmental conditions in NEMA 250. IEC 60529, "Degrees of Protection Provided by Enclosures (IP Code)," describes the European system for classifying the degrees of protection provided by the enclosures of electrical equipment. Rain, windblown dust, hose-directed water, and external ice formation are examples of environmental conditions covered by these enclosure standards.

Of growing importance is the electronic control valve device's level of immunity to, and emission of, electromagnetic interference in the chemical valve environment. *Electromagnetic compatibility* (EMC) for control valve devices is presently mandatory in the European Community and is specified in International Electrotechnical Commission (IEC) 61326, "Electrical Equipment for Measurement Control and Laboratory Use—EMC Requirements." Test methods for EMC testing are found in the series IEC 61000-4, "EMC Compatibility (EMC), Testing and Measurement Techniques." Somewhat more stringent EMC guidelines are found in the German document NAMUR NE21, "Electromagnetic Compatibility of Industrial Process and Laboratory Control Equipment."

## ADJUSTABLE-SPEED PUMPS

An alternative to throttling a process with a process control valve and a fixed-speed pump is by adjusting the speed of the process pump and not using a throttling control valve at all. Pump speed can be varied by using variable-speed prime movers such as turbines, motors with magnetic or hydraulic couplings, and electric motors. Each of these methods of modulating pump speed has its own strengths and weaknesses, but all offer energy savings and dynamic performance advantages over throttling with a control valve.

The centrifugal pump directly driven by a variable-speed electric motor is the most commonly used hardware combination for adjustable-speed pumping.

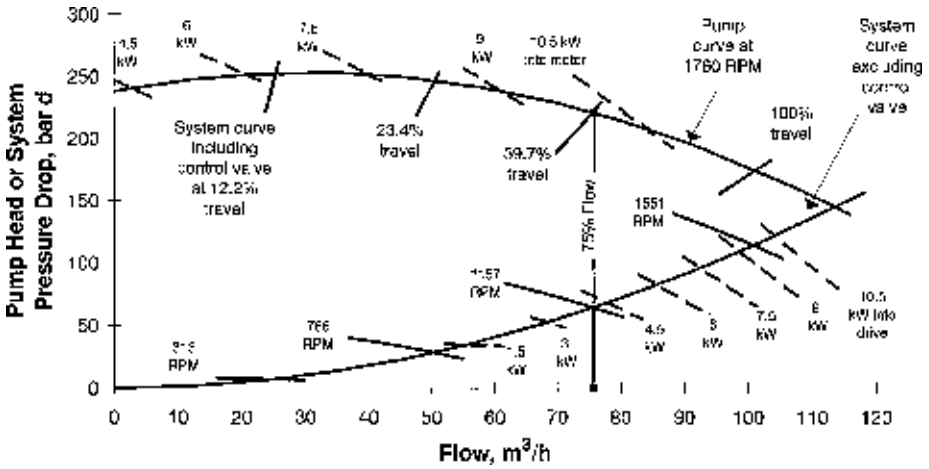

**FIG. 8-82** Pressure, flow, and power for throttling a process using a control valve and a constant-speed pump compared to throttling with an adjustable-speed pump.

The motor is operated by an electronic motor speed controller whose function is to generate the voltage or current waveform required by the motor to make the speed of the motor track the input command signal from the process controller.

The most popular form of motor speed control for adjustable-speed pumping is the voltage-controlled *pulse-width-modulated* (PWM) frequency synthesizer and ac squirrel-cage induction motor combination. The flexibility of application of the PWM motor drive and its 90+ percent electrical efficiency along with the proven ruggedness of the traditional ac induction motor make this combination popular.

From an energy consumption standpoint, the power required to maintain steady process flow with an adjustable-speed pump system (three-phase PWM drive and a squirrel-cage induction motor driving a centrifugal pump on water) is less than that required with a conventional control valve and a fixed-speed pump. Figure 8-82 shows this to be the case for a system where 100 percent of the pressure loss is due to flow velocity losses. At 75 percent flow, the figure shows that using the constant-speed pump/control valve results in a 10.1-kW rate, while throttling with the adjustable-speed pump and not using a control valve results in a 4.1-kW rate. This trend of reduced energy consumption is true for the entire range of flows, although amounts vary.

From a dynamic response standpoint, the electronic adjustable-speed pump has a dynamic characteristic that is more suitable in process control applications than those characteristics of control valves. The small amplitude response of an adjustable-speed pump does not contain the dead band or the dead time commonly found in the small amplitude response of the control valve. Nonlinearities associated with friction in the valve and discontinuities in the pneumatic portion of the control valve instrumentation are not present with electronic variable-speed drive technology. As a result, process control with the adjustable-speed pump does not exhibit limit cycles, problems related to low controller gain, and generally degraded process loop performance caused by control valve nonlinearities.

Unlike the control valve, the centrifugal pump has poor or nonexistent shutoff capability. A flow check valve or an automated on/off valve may be required to achieve shutoff requirements. This requirement may be met by automating an existing isolation valve in retrofit applications.

## REGULATORS

A regulator is a compact device that maintains the process variable at a specific value in spite of disturbances in load flow. It combines the functions of the measurement sensor, controller, and final control element in one self-contained device. Regulators are available to control pressure, differential pressure, temperature, flow, liquid level, and other basic process variables. They are used to control the differential across a filter press, heat exchanger, or orifice plate. Regulators are used for monitoring pressure variables for redundancy, flow check, and liquid surge relief.

Regulators may be used in gas blanketing systems to maintain a protective environment above any liquid stored in a tank or vessel as the liquid is pumped out. When the temperature of the vessel is suddenly cooled, the regulator maintains the tank pressure and protects the walls of the tank from possible collapse. Regulators are known for their fast dynamic response. The absence of time delay that often comes with more sophisticated control systems makes the regulator useful in applications requiring fast corrective action.

Regulators are designed to operate on the process pressures in the pipeline without any other sources of energy. Upstream and downstream pressures are used to supply and exhaust the regulator. Exhausting is connected back to the downstream piping so that no contamination or leakage to the external environment occurs. This makes regulators useful in remote locations where power is not available or where external venting is not allowed.

The regulator is limited to operating on processes with clean, nonslurry process fluids. The small orifice and valve assemblies contained in the regulator can plug and malfunction if the process fluid that operates the regulator is not sufficiently clean.

Regulators are normally not suited to systems that require constant set-point adjustment. Although regulators are available with capability to respond to remote set-point adjustment, this feature adds complexity to the regulator and may be better addressed by a control valve–based system. In the simplest of regulators, tuning of the regulator for best control is accomplished by changing a spring, an orifice, or a nozzle.

**Self-Operated Regulators** Self-operated regulators are the simplest form of regulator. This regulator (see Fig. 8-83) is composed of a main throttling valve, a diaphragm or piston to sense pressure, and a spring. The self-contained regulator is completely operated by the process fluid, and no outside control lines or pilot stage is used. In general, self-operated regulators are simple in construction, are easy to operate and maintain, and are usually stable devices. Except for some of the pitot-tube types, self-operated regulators have very good dynamic response characteristics. This is so because any change in the controlled variable registers directly and immediately upon the main diaphragm to produce a quick response to the disturbance.

The disadvantage of the self-operated regulator is that it is not generally capable of maintaining a set point as load flow is increased. Because of the proportional nature of the spring and diaphragm-throttling effect, offset from set point occurs in the controlled variable as flow increases. Reduced set-point offset with increasing load flow can be achieved by adding a pitot tube to the self-operated regulator. The tube is positioned somewhere near the vena contracta of the main regulator valve. As flow through the valve increases, the measured feedback pressure from the pitot tube drops below the control pressure. This causes the main valve to open or boost more than it would if the static value of control pressure were acting on the diaphragm. The resultant effect keeps the control pressure closer to the set point and thus prevents a large drop in process pressure during high-load-flow conditions.

**Pilot-Operated Regulators** Another category of regulators uses a pilot stage to provide the load pressure on the main diaphragm. This pilot is a regulator itself that has the ability to multiply a small change in downstream pressure into a large change in pressure applied to the regulator diaphragm. Due to this high-gain feature, pilot-operated regulators can achieve a dramatic improvement in steady-state accuracy over that achieved with a self-operated regulator.

The main limitation of the pilot-operated regulator is stability. When the gain in the pilot amplifier is raised too much, the loop can become unstable and oscillate or hunt.

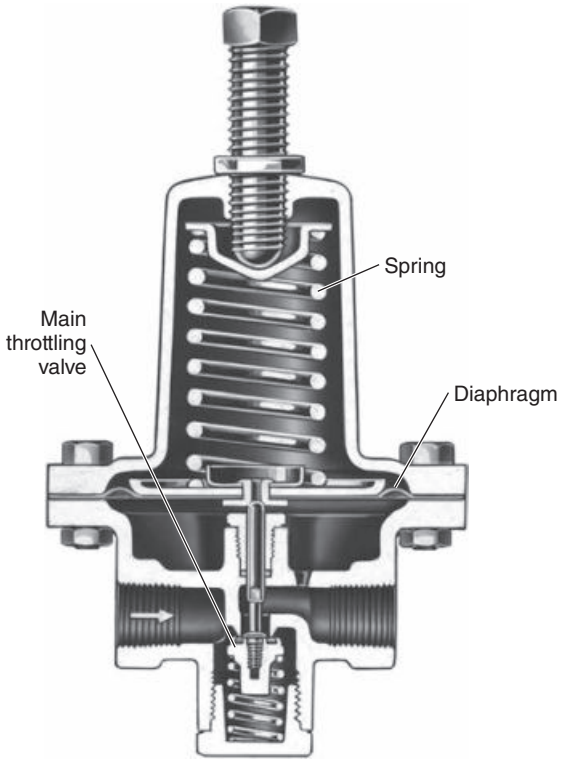

**FIG. 8-83** Self-operated regulators.

## PROCESS CONTROL AND PLANT SAFETY

**GENERAL REFERENCE:** *Guidelines for Safe Automation of Chemical Processes*, AIChE Center for Chemical Process Safety, New York, 1993.

Accidents in chemical plants make headline news, especially when there is loss of life or the general public is affected in even the slightest way. This increases the public's concern and may lead to government action. The terms *hazard* and *risk* are defined as follows:

- *Hazard.* A potential source of harm to people, property, or the environment.
- *Risk.* Possibility of injury, loss, or an environmental accident created by a hazard.

Safety is the freedom from hazards and thus the absence of any associated risks. Unfortunately, absolute safety cannot be realized, and so the objective is to reduce risks *as low as reasonably practicable* (ALARP).

The design and implementation of safety systems must be undertaken with a view to two issues:

- *Regulatory.* The safety system must be consistent with all applicable codes and standards as well as "generally accepted good engineering practices."
- *Technical.* Just meeting all applicable regulations and "following the crowd" do not relieve a company of its responsibilities. The safety system must work.

The regulatory environment will continue to change. As of this writing, the key regulatory instrument is OSHA 29 CFR 1910.119, "Process Safety Management of Highly Hazardous Chemicals," which pertains to process safety management within plants in which chemicals deemed to be highly hazardous are present.

In addition to government regulation, industry groups and professional societies are producing documents ranging from standards to guidelines. Two applicable standards are IEC 61508, "Functional Safety of Electrical/Electronic/Programmable Electronic Safety-related Systems," and IEC 61511, "Functional Safety—Safety Instrumented Systems for the Process Industry Sector" (the U.S. counterpart is ANSI/ISA S84.00.01-2004, "Application of Safety Instrumented Systems for the Process Industries"). *Guidelines for Safe Automation of Chemical Processes* (1993) from the American Institute of Chemical Engineers' Center for Chemical Process Safety provides comprehensive coverage of the various aspects of safety; and although short on specifics, it is very useful to operating companies developing their own specific safety practices (i.e., it does not tell you what to do, but it helps you decide what is proper for your plant).

The ultimate responsibility for safety rests with the operating company; OSHA 1910.119 is clear on this. Each company is expected to develop (and enforce) its own practices in the design, installation, testing, and maintenance of safety systems. Fortunately, some companies make these documents public. Monsanto's *Safety System Design Practices* was published in its entirety in the proceedings of the International Symposium and Workshop on Safe Chemical Process Automation, Houston, Texas, September 27–29, 1994 (available from the American Institute of Chemical Engineers' Center for Chemical Process Safety).

## ROLE OF AUTOMATION IN PLANT SAFETY

As microprocessor-based controls displaced hardwired electronic and pneumatic controls, the impact on plant safety has definitely been positive. When automated procedures replace manual procedures for routine operations, the probability of human errors leading to hazardous situations is lowered, especially in batch facilities. The enhanced capability for presenting information to the process operators in a timely manner and in the most meaningful form increases the operator's awareness of current conditions in the process. Process operators are expected to exercise due diligence in the supervision of the process, and timely recognition of an abnormal situation reduces the likelihood that the situation will progress to the hazardous state. Figure 8-84 depicts the layers of safety protection in a typical chemical plant. Although microprocessor-based process controls enhance plant safety, their primary objective is efficient process operation. Manual operations are automated to reduce variability, to minimize the time required, to increase productivity, and so on. Remaining competitive in the world market demands that the plant be operated in the best manner possible, and microprocessor-based process controls provide numerous functions that make this possible. Safety is never compromised in the effort to increase competitiveness; although not a primary objective, enhanced safety is a by-product of the process control function. By attempting to maintain process conditions at or near their design values, the process controls also attempt to prevent abnormal conditions from developing within the process.

Although process controls can be viewed as a protective layer, this is really a by-product and not the primary function. Where the objective of a function is specifically to reduce risk, the implementation is normally not within the process controls. Instead, logic is separately provided for the specific purpose of reducing risk.

## INTEGRITY OF PROCESS CONTROL SYSTEMS

Ensuring the integrity of process controls involves hardware issues, software issues, and human issues. Of these, the hardware issues are usually the easiest to assess and the software issues the most difficult.

The hardware issues are addressed by providing various degrees of redundancy, by providing multiple sources of power and/or an uninterruptible power supply, and the like. The manufacturers of process controls provide a variety of configuration options. Where the process is inherently safe and infrequent shutdowns can be tolerated, nonredundant configurations are acceptable. For more-demanding situations, an appropriate requirement might be that no single component failure be able to render the process

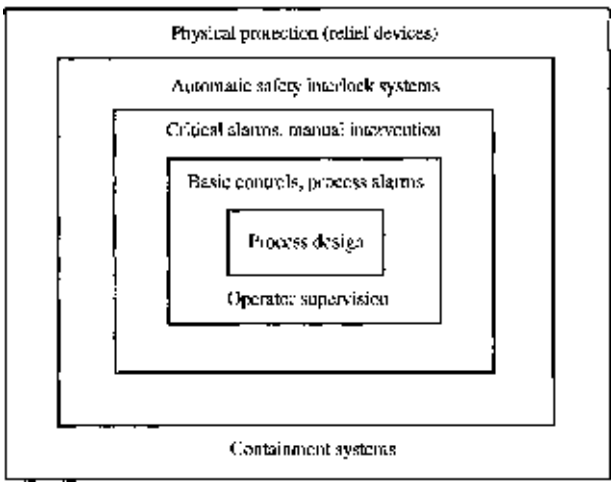

**FIG. 8-84** Layers of safety protection in chemical plants.

control system inoperable. For the very critical situations, triple-redundant controls with voting logic might be appropriate. The difficulty lies in assessing what is required for a given process.

Another difficulty lies in assessing the potential for human errors. If redundancy is accompanied with increased complexity, the resulting increased potential for human errors must be taken into consideration. Redundant systems require maintenance procedures that can correct problems in one part of the system while the remainder of the system is in full operation. When maintenance is conducted in such situations, the consequences of human errors can be rather unpleasant.

The use of programmable systems for process control presents some possibilities for failures that do not exist in hardwired electromechanical implementations. Probably of greatest concern are latent defects or "bugs" in the software, either the software provided by the supplier or the software developed by the user. The source of this problem is very simple. There is no methodology available that can be applied to obtain absolute assurance that a given set of software is completely free of defects. Increased confidence in a set of software is achieved via extensive testing, but no amount of testing results in absolute assurance that there are no defects. This is especially true of real-time systems, where the software can easily be exposed to a sequence of events that was not anticipated. Just because the software performs correctly for each event individually does not mean that it will perform correctly when two (or more) events occur at nearly the same time. This is further complicated by the fact that the defect may not be in the programming; it may be in how the software was designed to respond to the events.

The testing of any collection of software is made more difficult as the complexity of the software increases. Software for process control has become progressively complex, mainly because the requirements have become progressively demanding. To remain competitive in the world market, processes must be operated at higher production rates, within narrower operating ranges, closer to equipment limits, and so on. Demanding applications require sophisticated control strategies, which translate to more-complex software. Even with the best efforts of both supplier and user, complex software systems are unlikely to be completely free of defects.

## CONSIDERATIONS IN IMPLEMENTATION OF SAFETY INTERLOCK SYSTEMS

Where hazards can arise within a process that put plant workers and/or the general public at risk, some form of protective system is required. *Process hazards analysis* (PSA) addresses the various issues, ranging from assessment of the process hazards to ensuring the integrity of the protective equipment installed to cope with the hazards. Logic must be provided for the specific purpose of taking the process to a state where the hazardous condition cannot exist.

The *safety instrumented system* (SIS) provides the automatic actions that are deemed appropriate from the process hazards analysis. Prior to 1970, the logic was implemented in hardwired electrical circuits that were separate from and very different from the process control logic. The introduction of *programmable logic controllers* (PLCs) in the 1970s created the option to implement the logic in a *programmable electronic system* (PES). At approximately the same time, the increased attention to plant safety expanded the logic required within the safety instrumented system. More and more companies began to implement the logic pertaining to safety in PLCs, but with one caveat: the safety logic must be implemented in a manner that was entirely separate from the process controls (see Fig. 8-84). Separation also extends to the measurement devices and final control elements.

To some extent, this reflected the organizational structure. The "safety group" responsible for the safety logic relied on electrical personnel skilled in implementing discrete logic in the form of *relay ladder logic* (RLL), and thus were comfortable with PLCs. The "process control group" implemented the automatic controls as reflected in the piping and instrumentation (P&I) diagram using proportional-integral-derivative (PID) controllers and preferred *distributed control systems* (DCSs). The complete separation of the safety instrumented system in the form of a PLC from the process control system in the form of a DCS allows each group to proceed in whatever manner it deems most appropriate; that is, each uses its preferred "box."

Modifications to the process controls are more frequent than modifications to the safety instrumented system. Proponents of physically separating the safety instrumented system from the process controls cite the following benefits:

1. The possibility of a change to the process controls leading to an unintentional change to the safety instrumented system is eliminated.
2. The possibility of a human error in the maintenance of the process controls having consequences for the safety instrumented system is eliminated.
3. Management of change is simplified.
4. Administrative procedures for software version control are more manageable.

When PLCs are used in lieu of hardwired circuits for the safety instrumented system, the safety group must develop and strictly enforce administrative procedures to address the following issues:

1. Version controls for the PLC program must be implemented and rigidly enforced. Revisions to the program must be reviewed in detail and thoroughly tested before implementation in the PLC. The various versions must be clearly identified so that there can be no doubt as to what logic is provided by each version of the program.
2. The version of the program that is currently being executed by the PLC must be known with absolute certainty. It must be impossible for a revised version of the program undergoing testing to be downloaded to the PLC.

Constant vigilance is required to prevent lapses in such administrative procedures.

The complete separation of safety from process control usually works well in continuous processes, of which the refining industry is most influential. Continuous processes produce the same product (or possibly different grades of the product), generally meaning that the safety functions do not change. Batch processes present greater challenges to separating the safety logic from the process control logic. Conditions change throughout the batch, often presenting different requirements for the safety functions. Especially in flexible-batch facilities, the nature of the product for one batch could be very different from that for another batch, which often impacts the safety functions. In simple cases, the safety system can make the necessary adjustments based on the states of certain final control elements, but an interface between the process control system and the safety instrumented system is becoming increasingly necessary.

Physical separation is widely practiced within the process industries, but is not mandated by the standards. This opens the possibility for "integrated safety" in which the safety and control functions are implemented within the same "box." Although it is commonly described as "integrated," the current focus is to logically separate the safety functions from the control functions in much the same manner as when physically separated. This raises a number of issues: technical issues (non–safety-related activities must not compromise the safety functions), managerial issues (which group owns the common "box"), supplier issues (mainly commercial), etc. Strong feelings have been expressed on both sides of the physical versus logical separation issue. However, parameters such as *probability of failure on demand* (defined shortly) can be computed to quantify the risk reduction provided by both options. These promise to introduce quantitative data into the discussion, but computing such parameters requires many numbers, some of which are of debatable precision.

## SAFETY INSTRUMENTED FUNCTION

In the latest standards, *safety instrumented function* (SIF) is the term for what is commonly called a *safety interlock*, which can be defined as a protective response initiated on the detection of a process hazard. The *safety instrumented system* (SIS) consists of the measurement devices, logic solvers, and final control elements that recognize the hazard and initiate an appropriate response. Most interlocks consist of one or more logic conditions that detect out-of-limit process conditions and respond by driving the final control elements to the safe states.

The potential that the logic within the interlock could contain a defect or bug is a strong incentive to keep it simple. Within process plants, most interlocks are implemented with discrete logic, which usually means either hardwired electromechanical devices or PLCs.

The discrete logic within process plants can be broadly classified as follows:

1. *Safety interlocks.* These are designed to protect the public, plant personnel, and possibly plant equipment from process hazards. These are implemented within the safety instrumented system.
2. *Process interlocks* (those who associate *interlock* with safety prefer terms such as *process actions*). These are designed to prevent process conditions that would unduly stress equipment (perhaps leading to minor damage), lead to off-specification product, and so on. Basically, the process interlocks address situations whose consequences do not meet the requirements to be process hazards, but instead lead to a monetary loss, possibly even a short plant shutdown. Situations resulting in minor equipment damage that can be quickly repaired do not generally require a safety interlock; however, a process interlock might be appropriate.

Implementation of process interlocks within process control systems is perfectly acceptable. Furthermore, it is also permissible (and probably advisable) for responsible operations personnel to be authorized to bypass or ignore a process interlock. Bypassing or ignoring safety interlocks by operations personnel is simply not permitted. When this is necessary for actions such as verifying that the interlock continues to be functional, such situations must be infrequent and incorporated into the design of the interlock.

The process hazards analysis is conducted by an experienced, multidisciplinary team that examines the process design, plant equipment, operating procedures, and so on, using techniques such as *hazard and operability* (HAZOP), *failure mode and effect analysis* (FMEA), and others. The process hazards analysis recommends appropriate measures to reduce the risk, including (but not limited to) the safety interlocks to be implemented in the safety instrumented system.

The process hazards analysis must identify the safety interlocks required for a process and to provide the following for each:

1. The hazard that is to be addressed by the safety interlock
2. The category for the safety interlock (the category reflects the severity of the consequences of the hazard)
3. The logic for the safety interlock, including inputs from measurement devices and outputs to final control elements

The specific categories for safety interlocks used within a company are completely at the discretion of the company, but most use categories that distinguish among the following:

1. Hazards that pose a risk to the public (consequences extend to off-site)
2. Hazards that could lead to injury of company personnel (consequences are confined to the plant site)
3. Hazards that could result in major equipment damage and consequently lengthy plant downtime

Such categories reflect the severity of the consequences should the interlock fail to perform as intended. The requirement for redundancy (complete redundancy, redundant sensors only, etc.) could be associated with each category, but the standards contemplate a different approach.

The standards define the *probability of failure on demand* (PFD) as the probability that a hardware or software failure causes the safety instrumented system to not respond as required. The standards define four safety integrity levels:

Level 1: Probability of failure on demand between 0.1 and 0.01 (availability of 90 to 99 percent)

Level 2: Probability of failure on demand between 0.01 and 0.001 (availability of 99 to 99.9 percent)

Level 3: Probability of failure on demand between 0.001 and 0.0001 (availability of 99.9 to 99.99 percent)

Level 4: Probability of failure on demand less than 0.0001 (availability of 99.99 percent or better)

For each process hazard identified in the process hazards analysis, a safety instrumented function (or safety interlock) must be defined and assigned to a safety integrity level. The safety integrity level determines issues such as the need for redundancy in the safety instrumented system (complete redundancy, redundant measurements only, etc.).

Instead of associating the requirements for redundancy with each category, a safety integrity level is associated with each category. The safety interlocks assigned to a category must be implemented in a hardware and software configuration whose safety integrity level meets or exceeds the safety integrity level for that category.

Diversity is recognized as a useful approach to reduce the number of defects. The team that conducts the process hazards analysis does not implement the safety interlocks but provides the specifications for the safety interlocks to another organization for implementation. This organization reviews the specifications for each safety interlock, seeking clarifications as necessary from the process hazards analysis team and bringing any perceived deficiencies to the attention of the process hazards analysis team.

Diversity can be used to further advantage in redundant configurations. Where redundant measurement devices are required, different technology can be used for each. Where redundant logic is required, one can be programmed and one hardwired. Reliability of the interlock systems has two aspects:

1. It must react, should the hazard arise.
2. It must not react when there is no hazard.

Emergency shutdowns often pose risks in themselves, and therefore they should be undertaken only when truly appropriate. The need to avoid extraneous shutdowns is not motivated by a desire simply to avoid disruption in production operations.

## TESTING

As part of the detailed design of each safety interlock, written test procedures must be developed for the following purposes:

1. Ensure that the initial implementation complies with the requirements defined by the process hazards analysis team.
2. Ensure that the interlock (hardware, software, and I/O) continues to function as designed. The design must also determine the time interval over which this must be done. Often these tests must be done with the plant in full operation.

The former is the responsibility of the implementation team and is required for the initial implementation and following any modification to the interlock. The latter is the responsibility of plant maintenance, with plant management responsible for seeing that it is done at the specified interval of time.

Execution of each test must be documented, showing when it was done, by whom, and the results. Failures must be analyzed for possible changes in the design or implementation of the interlock. These tests must encompass the complete interlock system, from the measurement devices through the final control elements. Merely simulating inputs and checking the outputs is not sufficient. The tests must duplicate the process conditions and operating environments as closely as possible. The measurement devices and final control elements are exposed to process and ambient conditions and thus are usually the most likely to fail. Valves that remain in the same position for extended periods may stick in that position and not operate when needed. The easiest component to test is the logic; however, this is the least likely to fail.

## ALARMS

The purpose of an alarm is to alert the process operator to a process condition that requires immediate attention. An alarm is said to occur whenever the abnormal condition is detected and the alert is issued. An alarm is said to return to normal when the abnormal condition no longer exists. Analog alarms can be defined on measured variables, calculated variables, controller outputs, and the like. For analog alarms, the following possibilities exist:

1. *High/low alarms.* A high alarm is generated when the value is greater than or equal to the value specified for the high-alarm limit. A low alarm is generated when the value is less than or equal to the value specified for the low-alarm limit.
2. *Deviation alarms.* An alarm limit and a target are specified. A high-deviation alarm is generated when the value is greater than or equal to the target plus the deviation alarm limit. A low-deviation alarm is generated when the value is less than or equal to the target minus the deviation alarm limit.
3. *Trend or rate-of-change alarms.* A limit is specified for the maximum rate of change, usually specified as a change in the measured value per minute. A high-trend alarm is generated when the rate of change of the variable is greater than or equal to the value specified for the trend alarm limit. A low-trend alarm is generated when the rate of change of the variable is less than or equal to the negative of the value specified for the trend alarm limit.

Most systems permit multiple alarms of a given type to be configured for a given value. For example, configuring three high alarms provides a high alarm, a high-high alarm, and a high-high-high alarm.

One operational problem with analog alarms is that noise in the variable can cause multiple alarms whenever its value approaches a limit. This can be avoided by defining a dead band on the alarm. For example, a high alarm would be processed as follows:

1. *Occurrence.* The high alarm is generated when the value is greater than or equal to the value specified for the high-alarm limit.
2. *Return to normal.* The high-alarm return to normal is generated when the value is less than or equal to the high-alarm limit less the dead band.

As the degree of noise varies from one input to the next, the dead band must be individually configurable for each alarm.

Discrete alarms can be defined on discrete inputs, limit switch inputs from on/off actuators, and so on. For discrete alarms, the following possibilities exist:

1. *Status alarms.* An expected or normal state is specified for the discrete value. A status alarm is generated when the discrete value is other than its expected or normal state.
2. *Change-of-state alarm.* A change-of-state alarm is generated on any change of the discrete value.

The expected sequence of events on an alarm is basically as follows:

1. The alarm occurs. This usually activates an audible annunciator.
2. The alarm occurrence is acknowledged by the process operator. When all alarms have been acknowledged, the audible annunciator is silenced.
3. Corrective action is initiated by the process operator.
4. The alarm condition returns to normal.

However, additional requirements are imposed at some plants. Sometimes the process operator must acknowledge the alarm's return to normal. Some plants require that the alarm occurrence be reissued if the alarm remains in the occurred state longer than a specified time. Consequently, some "personalization" of the alarming facilities is done.

When alarms were largely hardware-based (i.e., the panel alarm systems), the purchase and installation of the alarm hardware imposed a certain discipline on the configuration of alarms. With digital systems, the suppliers have made it extremely easy to configure alarms. In fact, it is sometimes easier to configure alarms on a measured value than not to configure the alarms. Furthermore, the engineer assigned the responsibility for defining alarms is often paranoid that an abnormal process condition will go

undetected because an alarm has not been configured. When alarms are defined on every measured and calculated variable, the result is an excessive number of alarms, most of which are duplicative and unnecessary.

The accident at the Three Mile Island nuclear plant clearly demonstrated that an alarm system can be counterproductive. An excessive number of alarms can distract the operator's attention from the real problem that needs to be addressed. Alarms that merely tell the operator something that is already known do the same. In fact, a very good definition of a nuisance alarm is one that informs the operator of a situation of which the operator is already aware. The problem with applying this definition lies in determining what the operator already knows.

Unless some discipline is imposed, engineering personnel, especially where contractors are involved, will define far more alarms than plant operations require. This situation may be addressed by simply setting the alarm limits to values such that the alarms never occur. However, changes in alarms and alarm limits are changes from the perspective of management of change. It is prudent to impose the necessary discipline to avoid an excessive number of alarms. Potential guidelines are as follows:

1. For each alarm, a specific action is expected from the process operator. Operator actions such as call maintenance are inappropriate with modern systems. If maintenance needs to know, modern systems can inform maintenance directly.
2. Alarms should be restricted to abnormal situations for which the process operator is responsible. A high alarm on the temperature in one of the control system cabinets should not be issued to the process operator. Correcting this situation is the responsibility of maintenance, not the process operator.
3. Process operators are expected to be exercising normal surveillance of the process. Therefore, alarms are not appropriate for situations known to the operator either through previous alarms or through normal process surveillance. The "sleeping operator" problem can be addressed by far more effective means than the alarm system.
4. When the process is operating normally, no alarms should be triggered. Within the electric utility industry, this design objective is known as *darkboard*. Application of darkboard is especially important in batch plants, where much of the process equipment is operated intermittently.

Another serious distraction to a process operator is the multiple-alarm event, where a single event within the process results in multiple alarms. When the operator must individually acknowledge each alarm, considerable time can be lost in silencing the obnoxious annunciator before the real problem is addressed. Air-handling systems are especially vulnerable to this, where any fluctuation in pressure (e.g., resulting from a blower trip) can cause a number of pressure alarms to occur.

Point alarms (high alarms, low alarms, status alarms, etc.) are especially vulnerable to the multiple-alarm event. This can be addressed in one of two ways:

1. *Ganging alarms.* Instead of individually issuing the point alarms, all alarms associated with a certain aspect of the process are configured to give a single trouble alarm. The responsibility rests entirely with the operator to determine the nature of the problem.
2. *Intelligent alarms.* Logic is incorporated into the alarm system to determine the nature of the problem and then issue a single alarm to the process operator.

While the intelligent alarm approach is clearly preferable, substantial process analysis is required to support intelligent alarming. Meeting the following two objectives is quite challenging:

1. The alarm logic must consistently detect abnormal conditions within the process.
2. The alarm logic must not issue an alert to an abnormal condition when in fact none exists.

Often the latter case is more challenging than the former. Logically, the intelligent alarm effort must be linked to the process hazards analysis. Developing an effective intelligent alarming system requires substantial commitments of effort, involving process engineers, control systems engineers, and production personnel. Methodologies such as expert systems can facilitate the implementation of an intelligent alarming system, but they must still be based on a sound analysis of the potential process hazards.

Complaints regarding an excessive number of alarm occurrences, alarm acknowledgment fatigue on the part of operators, etc., arose with early digital controls and continue to the current day. The practice may suggest otherwise, but the methodology of designing, implementing, and maintaining an effective alarm system is well known. These practices are commonly followed in facilities with a heavy influence by regulatory agencies, the result being a very effective alarm system. In other facilities, achieving an effective alarm system requires production management to make adequate resources available for reviewing and analyzing the proposed alarm configurations and modifications thereof. The alarm system competes with other endeavors for resources of time and money, and in the absence of pressures from a regulatory agency, resources will be allocated to what is perceived to be most financially rewarding.

## HUMAN FACTORS

**General Reference:** *Investigation Report: Refinery Explosion and Fire, Texas City, Texas*, U.S. Chemical Safety and Hazard Investigation Board. Report no. 2005-04-I-TX. March 2007. Available at: http://www.csb.gov/assets/1/19/csbfinalreportbp.pdf

Human factors play an extremely important role in process safety. For example, the explosion that occurred at the BP Texas City refinery in 2005 was due to miscommunication, failure to meet blowdown drum safety standards, miscalibrated and nonfunctioning sensors and alarms, a history of violating proper start-up operating procedures, and poor siting of temporary office trailers. In this disaster, an isomerization unit was being restarted after a process shutdown. The unit had a number of failing and miscalibrated sensors and alarms, and proper start-up protocols were not followed. Also, there was miscommunication between operators at shift change, and there was inadequate supervision available. A separation column became overfilled, because of lack of knowledge of actual liquid level in the tower. A heavy, hot liquid was then sent to a local flash drum—and the resulting heavy vapor was released to the atmosphere. This vapor ignited when a truck engine backfired, causing an explosion that destroyed several trailers next to the unit, killing 15 workers. An investigation revealed that there was a history of plant safety violations and that one of the problems was due to the reward structure for plant managers, who would typically be in the position for only 1 or 2 years before being promoted to other positions in the company. Also, there was a history of violating the unit start-up procedure during many previous start-ups over a 5-year period. Start-ups and shut-downs are the most dangerous times, with an incident rate 10 times that of normal steady-state operation. See the CSB report on the Texas City explosion for more details.

## GLOSSARY

### Nomenclature and Units

| Symbol | Definition | Units |
|---|---|---|
| $A_1$ | Annual conversion expense at production rate 1 | $ |
| $A_{TC}$ | Annual capital outlay | $ |
| $B$ | Constant | Dimensionless |
| $C$ | Cost of equipment | $ |
| $C_B$ | Base cost of carbon steel exchanger | $ |
| CE | Chemical engineering cost index | Dimensionless |
| $(C_{FC})_{BL}$ | Battery-limits fixed capital investment | $ |
| $(C_{EQ})_{DEL}$ | Delivered equipment cost | $ |
| $C_{HE}$ | Purchased equipment cost of heat exchanger | $ |
| $C_L$ | Cost of labor | $ |
| COEs | Cash operating expenses | $ |
| $C_P$ | Equipment cost in base year | $ |
| cP | Viscosity in centipoise | cP |
| $D$ | Depreciation | $ |
| DCFROR | Discounted cash flow rate of return | % |
| EBIT | Earnings before interest and taxes | $ |
| $e$ | Naperian logarithm base | 2.718 |
| $F$ | Future value, future worth, future amount | $ |
| $F$ | Heat exchanger efficiency factor | Dimensionless |
| $F_B$ | Heat exchanger design type | Dimensionless |
| FCI | Fixed capital investment | $ |
| FE | Fixed expenses | $ |
| FEL | Front-end loading | |
| FIFO | First in, first out (inventory) | |
| FOB | Free on board | |
| $F_M$ | Material of construction cost factor | Dimensionless |
| $F_P$ | Design pressure cost factor | Dimensionless |
| $f_1, f_2, f_3$ | Inflation factors for years 1, 2, and 3 | Dimensionless |
| $f$ | Declining-balance factor | Dimensionless |
| $I$ | Investment | $ |
| IRS | Internal Revenue Service | |
| $i$ | Nominal interest | % |
| $i_{eff}$ | Effective interest | % |

| Symbol | Definition | Units |
|---|---|---|
| $K$ | Factor for cost index | Dimensionless |
| LIFO | Last in, first out (inventory) | |
| $M$ | Annual raw material expense | $ |
| MACRS | Modified Accelerated Cost Recovery System | |
| $m$ | Number of interest periods per year | Varies |
| $m, n, p, q$ | Constants or exponent | Dimensionless |
| $N$ | Annual labor requirement | Operators per shift per year |
| $n$ | Number of years, depreciation | Years |
| $P$ | Principal, present value, present worth | $ |
| PC | Personal computer | |
| POP | Payout period (no interest) | Years |
| POP + $I$ | Payout period plus interest | Years |
| $Q$ | Energy transferred | Btu/h |
| $R_1, R_2$ | Annual production rates | lb/yr |
| $S$ | Salvage value or equipment capacity | Various |
| SL | Straight-line depreciation | |
| Sp gr | Specific gravity | Dimensionless |
| TE | Total expenses | $ |
| $T_c$ | Combined incremental tax rate | % |
| $T_f$ | Incremental federal income tax rate | % |
| $T_s$ | Incremental state income tax rate | % |
| $U$ | Annual utility expenses | $ |
| UAC | Uniform annual cost | $ |
| $U_D$ | Overall heat-transfer coefficient | Btu/(h · ft$^2$ · °F) |
| $V_e$ | Asset value at end of year | $ |
| $V_i$ | Asset value at beginning of year | $ |
| VE | Variable expenses | $ |
| VIP | Value-improving practice | |
| $X$ | Plant capacity | tons/day |
| $Y$ | Operating labor | operator-hour/ton per processing step |

## GENERAL COMMENTS

One of the most confusing aspects of process engineering economics is the nomenclature used by various authors and companies. In this part of Sec. 9, generic, descriptive terms have been used. Further, an attempt has been made to bring together most of the methods currently in use for project evaluation and to present them in such a way as to make them amenable to modern computational techniques. Most of the calculations can be performed on handheld calculators equipped with scientific function keys. For calculations requiring greater sophistication than that of handheld calculators, algorithms may be solved by using such programs as MATHCAD, TKSOLVER, etc. Spreadsheets are also used whenever the solution to a problem lends itself to this technique.

The nomenclature in process economics has been developed by accountants, engineers, and others such that there is no one correct set of nomenclature. Often it seems confusing, but one must question what is meant by a certain term since companies have adopted their own language. A Glossary of terms is included at the end of this section to assist the reader in understanding the nomenclature. Further, abbreviations of terms such as DCFRR (discounted cash flow rate of return) are used to reduce the wordiness. The number of letters and numbers used to define a variable has been limited to five. The parentheses are removed whenever the letter group is used to define a variable for a computer. Also, a general symbol is defined for a type variable and is modified by mnemonic subscript, e.g., an annual cash quantity, annual capital outlay $A_{TC}$, \$/year. Wherever a term like this is introduced, it is defined in the text.

It is impossible to allow for all possible variations of equation requirements, but it is hoped that the nomenclature presented will prove adequate for most purposes and will be capable of logical extension to other more specialized requirements.

## ACCOUNTING AND FINANCIAL CONSIDERATIONS

### PRINCIPLES OF ACCOUNTING

*Accounting* has been defined as the art of recording business transactions in a systematic manner. It is the language of business and is used to communicate financial information. Conventions that govern accounting are fairly simple, but their application is complex. In this section, the basic principles are illustrated by a simple example and applied to analyzing a company report. The fair allocation of costs requires considerable technical knowledge of operations, so a close liaison between process engineers and accountants in a company is desirable.

In simplest terms, assets that are the economic resources of a company are balanced against equities that are claims against the firm. In equation form,

$$\text{Assets} = \text{Equities}$$

or

$$\text{Assets} = \text{Liabilities} + \text{Owners' Equity}$$

This dual aspect has led to the double-entry bookkeeping system in use today. Any transaction that takes place causes changes in the accounting equation. An increase in assets must be accompanied by one of the following:

- An increase in liabilities
- An increase in stockholders' equity
- An increase in assets

A change in one part of the equation due to an economic transaction must be accompanied by an equal change in another place—therefore, the term *double-entry bookkeeping*. On a page of an account, the left-hand side is designated the debit side, and the right-hand side is the credit side. This convention holds regardless of the type of account. Therefore, for every economic transaction, there is an entry on the debit side balanced by the same entry on the credit side.

All transactions in their original form (receipts and invoices) are recorded chronologically in a journal. The date of the transaction together with an account title and a brief description of the transaction is entered. Table 9-1 is an example of a typical journal page for a company. Journal entries are transferred to a ledger in a process called *posting*. Separate ledger accounts, such as a revenue account, expense account, liability account, or asset account, may be set up for each major transaction. Table 9-2 shows an example of a typical ledger page. The number of ledger accounts depends on the information that management needs to make decisions. Periodically, perhaps on a monthly basis but certainly on a yearly basis, the ledger sheets are closed and balanced. The ledger sheets are then intermediate documents between journal records and balance sheets, income statements, and retained earnings statements, and they provide information for management and various government reports. For example, a consolidated income statement can be prepared for the ledger, revenue, and expense accounts. In like manner, the asset and liability accounts provide information for balance sheets.

### FINANCIAL STATEMENTS

A basic knowledge of accounting and financial statements is necessary for a chemical professional to be able to analyze a firm's operation and to communicate with accountants, financial personnel, and managers. Financial reports of a company are important sources of information used by management, owners, creditors, investment bankers, and financial analysts. All publicly held companies are required to submit annual reports to the Securities and Exchange Commission. As with any field a certain basic nomenclature is used to be able to understand the financial operation of a company.

**TABLE 9-1 Typical Journal Page**

| Date | Explanation | LP | Debit | Credit |
|---|---|---|---|---|
| 200X | | | | |
| Mar 1 | Cash | 1 | $95,000 | |
| | J. Jones, Capital | 2 | | $95,000 |
| Mar 4 | Property | 4 | 5,000 | |
| | Cash | 1 | | 3,000 |

It should be emphasized that companies may also have their own internal nomenclature, but some terms are universally accepted. In this section, the common terminology is used.

A financial report contains two important documents—the balance sheet and the income statement. Two other documents that appear in the financial report are the accumulated retained earnings and the changes in working capital. All these documents are discussed in the following sections, using a fictitious company.

**Balance Sheet** The balance sheet represents an accounting view of the financial status of a company on a particular date. Table 9-3 is an example of a balance sheet for a company. The date frequently used by corporations is December 31 (calendar year), although some companies are now using June 30 or September 30 as the closing date, depending on when the company closes it books. It is as if the company's operation were frozen in time on that date. The term *consolidated* means that all the balance sheet and income statement data include information from the parent as well as subsidiary operations. The balance sheet consists of two parts: assets are the items that the company owns, and liabilities and stockholders' equity are what the company owes to creditors and stockholders. Although the balance sheet has two sides, it is not part of the double-entry accounting system. The balance sheet is not an account but a statement of claims against company assets on the date of the reporting period. The claims are the creditors and the stockholders. Therefore, the total assets must equal the total liabilities plus the stockholders' equity.

*Assets* are classified as current, fixed, or intangibles. *Current assets* include cash, cash equivalents, marketable securities, accounts receivable, inventories, and prepaid expenses. Cash and cash equivalents are those items that can be easily converted to cash. Marketable securities are securities that a company holds that also may be converted to cash. Accounts receivable are the amounts due to a company from customers from material that has been delivered but has not been collected as yet. Customers are given 30, 60, or 90 days in which to pay; however, some customers fail to pay bills on time or may not be able to pay at all. An allowance is made for doubtful accounts. The amount is deducted from the accounts receivables. Inventories include the cost of raw materials, goods in process, and product on hand. Prepaid expenses include insurance premiums paid, charges for leased equipment, and charges for advertising that are paid prior to the receipt of the benefit from these items. The sum of all the above items is the total current assets. The term *current* refers to the fact that these assets are easily converted within a year, or more likely in a shorter time, say, 90 days.

*Fixed assets* are items that have a relatively long life such as land, buildings, and manufacturing equipment. The sum of these items is the total property, plant, and equipment. From this total, accumulated depreciation is subtracted and the result is net property and equipment. Last, an item referred to as intangibles includes a variety of items such as patents, licenses, intellectual capital, and goodwill. Intangibles are difficult to evaluate since they have no physical existence; e.g., goodwill is the value of the company's name and reputation. The sum of the total current assets, net property, and intangibles is the total assets.

*Liabilities* are the obligations that the company owes to creditors and stockholders. Current liabilities are obligations that come due within a year and include accounts payable (money owed to creditors for goods and services), notes payable (money owed to banks, corporations, or other lenders), accrued expenses (salaries and wages to employees, interest on borrowed funds, fees due to professionals, etc.), income taxes payable, current part of long-term debt, and other current liabilities due within the year.

*Long-term liabilities* are the amounts due after 1 year from date of the financial report. They include deferred income taxes that a company is permitted to postpone due to accelerated depreciation to encourage investment (but they must be paid at some time in the future) and bonds and notes that do not have to be paid within the year but at some later date. The sum of the current and long-term liabilities is the total liabilities.

*Stockholders' equity* is the interest that all stockholders have in a company and is a liability with respect to the company. This category includes preferred and common stock as well as additional paid-in capital (the amount that stockholders paid above the par value of the stock) and retained earnings. These are earnings from accumulated profit that a company earns and are used for reinvestment in the company. The sum of these items is the stockholders' equity.

On a balance sheet, the sum of the total liabilities and the stockholders' equity must equal the total assets, hence the term *balance sheet.* Comparing balance sheets for successive years, one can follow changes in various items that will indicate how well the company manages its assets and meets its obligations.

**Income Statement** An income statement shows the revenue and the corresponding expenses for the year and serves as a guide for how the company may do in the future. Often income statements may show how the company performed for the last two or three years. Table 9-4 is an example of a consolidated income statement.

Net sales are the primary source of revenue from goods and services. This figure includes the amount reported after returned goods, discounts, and allowances for price reductions are taken into account. Cost of sales represents all the expenses to convert raw materials to finished products. The major components of these expenses are direct material, direct labor, and overhead. If the cost of sales is subtracted from net sales, the result is the gross margin. One of the most important items on the income statement is depreciation and amortization. Depreciation is an allowance the

federal government permits for the wear and tear as well as the obsolescence of plant and equipment and is treated as an expense. Amortization is the decline in value of intangible assets such as patents, franchises, and goodwill. Selling, general, and administrative expenses include the marketing salaries, advertising expenses, travel, executive salaries, as well as office and payroll expenses. When depreciation, amortization, and the sales and administrative expenses are subtracted from the gross margin, the result is the operating income. Dividends and interest income received by the company are then added. Next interest expense earned by the stockholders and income taxes are subtracted, yielding the term income before extraordinary loss. It is the expenses a company may incur for unusual and infrequent occasions. When all the above items are added or subtracted from the operating income, net income (or loss) is obtained. This latter term is the *bottom line* often referred to in various reports.

**TABLE 9-4 Consolidated Income Statement (December 31)**

| | 2005 | 2004 |
|---|---|---|
| Net sales (revenue) | $932,000 | $850,000 |

**Accumulated Retained Earnings** This is an important part of the financial report because it shows how much money has been retained for growth and how much has been paid as dividends to stockholders. When the accumulated retained earnings increase, the company has greater value. The calculation of this value of the retained earnings begins with the previous year's balance. To that figure add the net profit after taxes for the year. Dividends paid to stockholders are then deducted, and the result is the accumulated retained earnings for the year. See Table 9-5.

**Concluding Remarks** One of the most important sections of an annual report is the *notes*. These contain any liabilities that a company may have due to impending litigation that could result in charges or expenses not included in the annual report.

## OTHER FINANCIAL TERMS

*Profit margin* is the ratio of net income to total sales, expressed as a percentage or sometimes quoted as the ratio of profit before interest and taxes to sales, expressed as a percentage. *Operating margin* is obtained by subtracting operating expenses from gross profit expressed as a percentage of sales. *Net worth* is the difference between total assets and total liabilities plus stockholders' equity. *Working capital* is the difference between total current assets and current liabilities.

## FINANCIAL RATIOS

There are many financial ratios of interest to financial analysts. A brief discussion of some of these ratios follows; however, a more complete discussion may be found in Couper (2003).

*Liquidity ratios* are a measure of a company's ability to pay its short-term debts. *Current ratio* is obtained by dividing the current assets by the current liabilities. Depending on the economic climate, this ratio is 1.5 to 2.0 for the chemical process industries, but some companies operate closer to 1.0. The *quick ratio* is another measure of liquidity and is cash plus marketable securities divided by the current liabilities and is slightly greater than 1.0.

*Leverage ratios* are an indication of the company's overall debt burden. The *debt/total assets ratio* is determined by dividing the total debt by total assets expressed as a percentage. The industry average is 35 percent. *Debt/equity ratio* is another such ratio. The higher these ratios, the greater the financial risk since if an economic downturn did occur, it might be difficult for a company to meet the creditors' demands. The *times interest earned* is a measure of the extent to which profit could decline before a company is unable to pay interest charges. The ratio is calculated by dividing the *earnings before interest and taxes* (EBIT) by interest charges. The *fixed-charge coverage* is obtained by dividing the income available for meeting fixed charges by the fixed charges.

*Activity ratios* are a measure of how effectively a firm manages its assets. There are two inventory/turnover ratios in common use today. The *inventory/sales ratio* is found by dividing the inventory by the sales. Another method is to divide the cost of sales by inventory. The average collection period measures the number of days that customers' invoices remain unpaid. Fixed assets and total assets turnover indicate how well the fixed and total assets of the firm are being used.

*Profitability ratios* are used to determine how well income is being managed. The *gross profit margin* is found by dividing the gross profits by the net sales, expressed as a percentage. The *net operating margin* is equal to the earnings before interest and taxes divided by net sales. Another measure, the *profit margin on sales*, is calculated by dividing the net profit after taxes by net sales. The *return on total assets* ratio is the net profit after taxes divided by the total assets expressed as a percentage. The *return on equity ratio* is the net income after taxes and interest divided by stockholders' equity.

Table 9-6 shows the financial ratios for Tables 9-3 and 9-4. Table 9-7 is a summary of selected financial ratios and industry averages.

**TABLE 9-6 Financial Ratios for Tables 9-3 and 9-4**

| |
|---|
| Liquidity |
| Current ratio = \$391,200/\$201,500 = 1.94 |
| Cash ratio = \$391,200 − 149,000/\$201,500 = 1.20 |
| Leverage |
| Debt/assets ratio = [(\$448,100 − 201,500)/\$705,700] × 100 = 35% |
| Times interest earned = \$74,500 − 22,000/\$22,000 = 4.39 |
| Fixed-charge coverage = \$86,500/\$22,000 = 3.93 |
| Activity |
| Inventory turnover = \$932,000/\$149,000 = 6.25 |
| Average collection period = \$135,000/(\$932,000/365) = 52.8 days |
| Fixed-assets turnover = \$932,000/\$438,000 = 2.13 |
| Total-assets turnover = \$932,000/\$705,700 = 1.32 |
| Profitability |
| Gross profit margin = [(\$932,000 − 692,000)/\$932,000] × 100 = 25.8% |
| Net operating margin = \$74,500/\$932,000 × 100 = 7.99% |
| Profit margin on sales = \$50,000/\$932,000 × 100 = 5.36% |
| Return on net worth (return on equity) = [\$50,000/(\$705,700 − 448,100)] × 100 = 19.4% |
| Return on total assets = (\$50,000/\$705,700) × 100 = 7.09% |

## RELATIONSHIP BETWEEN BALANCE SHEETS AND INCOME STATEMENTS

There is a relationship between these two documents because information obtained from each is used to calculate the returns on assets and equity. Figure 9-1 is an operating profitability tree for a fictitious company and contains the fixed and variable expenses as reported on internal company reports, such as the manufacturing expense sheet. Figure 9-2 is a financial family tree for the same company depicting the relationship between values in the income statement and in the balance sheet.

## FINANCING ASSETS BY DEBT AND/OR EQUITY

The various options for obtaining funds to finance new projects are not a simple matter. Significant factors such as the state of the economy, inflation, a company's present indebtedness, and the cost of capital will affect the decision. Should a company incur more long-term debt, or should it seek new venture capital from equity sources? A simple yes or no answer will not suffice because the financial decision is complex. One consideration is the company's position with respect to leverage. If a company has a large proportion of its debt in bonds and preferred stock, the common stock is highly leveraged. Should the earnings decline, say, by 10 percent, the dividends available to common stockholders might be wiped out. The company also might not be able to cover the interest on its bonds without dipping into the accumulated earnings. A high debt/equity ratio illustrates the fundamental weakness of companies with a large amount of debt. When low-interest financing is available, such as for large government projects, the return-on-equity evaluations are used. Such leveraging is tantamount to transferring money from one pocket to another; or, to put it another way, a company may find itself borrowing from itself. In the chemical process industries, debt/equity ratios of 0.3 to 0.5 are common for industries that are capital-intensive (Couper and Beasley, 2001). Much has been written on the strategies of financing a corporate venture. The correct strategy has to be evaluated from the standpoint of what is best for the company. It must maintain a debt/equity ratio similar to those of successful companies in the same line of business.

## COST OF CAPITAL

The cost of capital is what it costs a company to borrow money from all sources, such as loans, bonds, and preferred and common stock. It is an important consideration in determining a company's minimum acceptable rate of return on an investment. A company must make more than the cost of capital to pay its debts and make a profit. From profits, a company pays dividends to the stockholders. If a company ignores the cost of capital to increase dividends to the stockholders, then management is not meeting its obligations to pay off outstanding debts.

A sample calculation of the after-tax weighted cost of capital is found in Table 9-8. Each debt item is divided by the total debt, and that result is multiplied by the after-tax yield to maturity that equals the after-tax weighted average cost of that debt item contributing to the cost of capital. The information to estimate the cost of capital may be obtained from the annual report, the 10K, or the 10Q reports.

## WORKING CAPITAL

The accounting definition of *working capital* is total current assets minus total current liabilities. This information can be found from the balance sheet. Current assets consist chiefly of cash, marketable securities, accounts receivable, and inventories; current liabilities include accounts payable, short-term debts, and the part of the long-term debt currently due. The accounting definition is in terms of the entire company.

For economic evaluation purposes, another definition of working capital is used. It is the funds, in addition to the fixed capital, that a company must contribute to a project. It must be adequate to get the plant in operation and to meet subsequent obligations when they come due. Working capital is not a one-time investment that is known at the project inception, but varies with the sales level and other factors. The relationship of working capital to other project elements may be viewed in the cash flow model (see Fig. 9-9). Estimation of an adequate amount of working capital is found in the section Capital Investment.

## INVENTORY EVALUATION AND COST CONTROL

Under ordinary circumstances, inventories are priced (valued) at some form of cost. The problem in valuating inventory lies in "determining what costs are to be identified with inventories in a given situation" (Nickerson, 1979).

Valuation of materials can be made by using the

- Cost of a specific lot
- Average cost
- Standard cost

Under cost of a specific lot, those lots to be valuated must be identified by referring to related invoices. Many companies use the average cost for valuating inventories. The average used should be weighted by the quantities purchased rather than by an average purchase price. The average cost method tends to spread the effects of short-run price changes and has a tendency to level out profits in those industries that use raw materials whose prices are volatile. For many manufacturing companies, inventory valuation is an important consideration varying in degree of importance. Inventories that are large are subject to significant fluctuations from time to time in size and mix and in prices, costs, and values.

**TABLE 9-7 Selected Financial Ratios**

| Item | Equation for calculation | Industry average |
|---|---|---|
| Liquidity | | |
| Current ratio | Current assets/current liabilities | 1.5–2.0 |
| Cash ratio | Current assets − inventory/current liabilities | 1.0–1.5 |
| Leverage | | |
| Debt to total assets | Total debt/total assets | 30–40% |
| Times interest earned | Profit before taxes plus interest charges/interest charges | 7.0–8.0 |
| Fixed-charge coverage | Income available for meeting fixed charges/fixed charges | 6.0 |
| Activity | | |
| Inventory turnover | Sales or revenue/inventory | 7.0 |
| Average collection period | Receivables/sales per day | 40–60 days |
| Fixed assets turnover | Sales/fixed assets | 2–4 |
| Total assets turnover | Sales/total assets | 1–2 |
| Profitability | | |
| Gross profit margin | Net sales − cost of goods sold/sales | 25–40% |
| Net operating margin | Net operating profit before taxes/sales | 10–15% |
| Profit margin on sales | Net profit after taxes/sales | 5–8% |
| Return on net worth (return on equity) | Net profit after taxes/net worth | 15% |
| Return on total assets | Net profit after taxes/total assets | 7–10% |

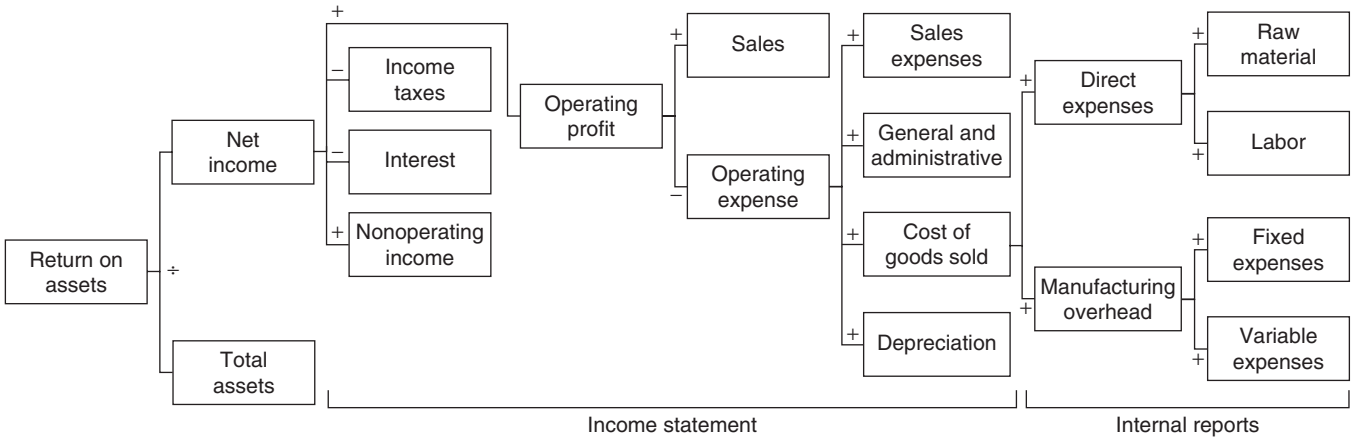

**FIG. 9-1** Operating profitability tree. (*Source: Adapted from Couper, 2003.*)

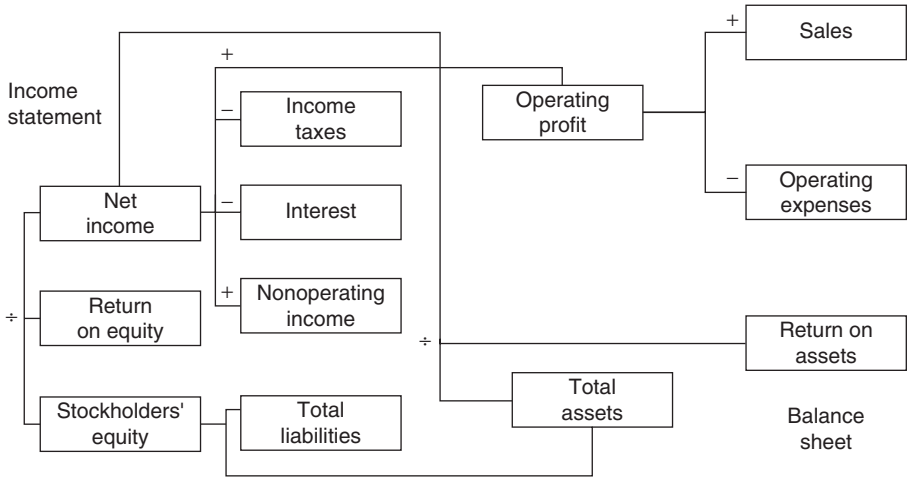

**FIG. 9-2** Financial family tree. (*Source: Adapted from Couper, 2003.*)

Materials are valuated in accordance with their acquisition. Some companies use the *first-in, first-out* (FIFO) basis. Materials are used in order of their acquisition to minimize losses from deterioration. Another method is *last-in, first-out* (LIFO) in which materials coming in are the first to leave storage for use. The method used depends on a number of factors. Accounting texts discuss the pros and cons of each method, often giving numerical examples. Some items to consider are income tax considerations and cash flow that motivate management to adopt conservative valuation policies. Tax savings may accrue using one method compared to the other, but they may not be permanent. Whatever method is selected, consistency is important so that comparability of reported figures may be maintained from one time period to another. It is management's responsibility to make the decision regarding the method used. In some countries, government regulations control the method to be used. There are several computer software programs that permit the user to organize, store, search, and manage inventory from a desktop computer.

**TABLE 9-8 Cost of Capital Illustration**

| Balance sheet 12/31/XX | Debt, $M | After-tax yield to maturity, % | After-tax weighted average cost, % |
|---|---|---|---|
| Long-term debt | | | |
| Revolving account | 5.0 | 4.5 | 0.02 |
| $4\frac{3}{8}$% debentures | 12.0 | 4.0 | 0.05 |
| $6\frac{1}{2}$% debentures | 3.4 | 4.7 | 0.02 |
| $6\frac{3}{4}$% debentures | 9.4 | 4.2 | 0.04 |
| $7\frac{1}{2}$% debentures | 74.5 | 4.2 | 0.30 |
| $9\frac{3}{8}$% loan | 125.0 | 4.4 | 0.53 |
| Other | 23.2 | 4.4 | 0.10 |
| Total long-term debt | 252.5 | | 1.06 |
| Deferred taxes | 67.7 | 0.0 | 0 |
| Reserves | 16.1 | 0.0 | 0 |
| Preferred stock | 50.0 | 8.6 | 0.42 |
| Shareholders' equity | 653.9 | 15.6 | 9.80 |
| Total debt | 1,040.2 | | 11.28 |

Each debt item in $M divided by the total debt times the after-tax yield to maturity equals the after-tax weighted average cost contributing to the cost of capital.

## BUDGETS AND COST CONTROL

A budget is an objective expressed in monetary terms for planning and controlling the resources of a company. Budgeted numbers are objectives, not achievements. A comparison of actual expenses with budgeted (cost standards) figures is used for control at the company, plant, departmental, or project level. A continuing record of performance should be maintained to provide the data for preparing future budgets (Nickerson, 1979). Often when a company compares actual results with cost standards or budgeted figures, a need for improving operations will surface. For example, if repairs to equipment continuously exceed the budgeted amount, perhaps it is time to consider replacement of that older equipment with a newer, more efficient model. Budgets are usually developed for a 1-year period; however, budgets for various time frames are frequently prepared. For example, in planning future operations, an intermediate time period of, say, 5 years may be appropriate, or for long-range planning the time period selected may be 10 years.

A cost control system is used

- To provide early warning of uneconomical or excessive costs in operations
- To provide relevant feedback to the personnel responsible for developing budgets
- To develop cost standards
- To promote a sense of cost consciousness
- To summarize progress

Budgetary models based upon mathematical equations are available to determine the effect of changes in variables. There are numerous sources extant in the literature for these models.

# CAPITAL COST ESTIMATION

## TOTAL CAPITAL INVESTMENT

The *total capital investment* includes funds required to purchase land, design and purchase equipment, structures, and buildings as well as to bring the facility into operation (Couper, 2003). The following is a list of items constituting the total capital investment:

Land
Fixed capital investment
Offsite capital
Allocated capital
Working capital
Start-up expenses
Other capital items (interest on borrowed funds prior to start-up; catalysts and chemicals; patents, licenses, and royalties; etc.)

**Land** Land is often acquired by a company some time prior to the building of a manufacturing facility. When a project is committed to be built on this land, the value of the land becomes part of that facility's capital investment.

**Fixed Capital Investment** When a firm considers the manufacture of a product, a capital cost estimate is prepared. These estimates are required for a variety of reasons such as feasibility studies, the selection of alternative processes or equipment, etc., to provide information for planning capital appropriations, or to enable a contractor to bid on a project. Included in the fixed capital investment is the cost of purchasing, delivery, and installation of manufacturing equipment, piping, automatic controls, buildings, structures, insulation, painting, site preparation, environmental control equipment, and engineering and construction costs. The fixed capital investment is significant in developing the economics of a process since this figure is used in estimating operating expenses and calculating depreciation, cash flow, and project profitability. The estimating method used should be the best, most accurate means consistent with the time and money available to prepare the estimate.

***Classification of Estimates*** There are two broad classes of estimates: grass roots and battery limits. Grass-roots estimates include the entire facility, starting with site preparation, buildings and structures, processing equipment, utilities, services, storage facilities, railroad yards, docks, and plant roads. A battery-limits estimate is one in which an imaginary boundary is drawn around the proposed facility to be estimated. It is assumed that all materials, utilities, and services are available in the quality and quantity required to manufacture a product. Only costs within the boundary are estimated.

***Quality of Estimates*** Capital cost estimation is more art than science. An estimator must use considerable judgment in preparing the estimate, and as the estimator gains experience, the accuracy of the estimate improves. There are several types of fixed capital cost estimates:

- *Order-of-magnitude (ratio estimate).* Rule-of-thumb methods based on cost data from similar-type plants are used. The probable accuracy is −30 percent to +50 percent.
- *Study estimate (factored estimate).* This type requires knowledge of preliminary material and energy balances as well as major equipment items. It has a probable accuracy of −25 to +30 percent.
- *Preliminary estimate (budget authorization estimate).* More details about the process and equipment, e.g., design of major plant items, are required. The accuracy is probably −20 to +25 percent.
- *Definitive estimate (project control estimate).* The data needed for this type of estimate are more detailed than those for a preliminary estimate and include the preparation of specifications and drawings. The probable accuracy is −10 to +15 percent.
- *Detailed estimate (firm estimate).* Complete specifications, drawings, and site surveys for the plant construction are required, and the estimate has an accuracy of −5 to +10 percent.

Detailed information requirements for each type of estimate may be found in Fig. 9-3.

In periods of high inflation, the results of various estimates and accuracy may overlap. At such times, four categories may be more suitable, namely, study, preliminary, definitive, and detailed categories. At present, some companies employing the *front-end loading* (FEL) process for project definition and execution use three categories:

| Project stage | Accuracy |
|---|---|
| Conceptual | ±40% |
| Feasibility | ±25% |
| Definition | ±10% |

For more information on the FEL process, see Capital Project Execution and Analysis near the end of Sec. 9.

***Scope*** The *scope* is a document that defines a project. It contains words, drawings, and costs. A scope should answer the following questions clearly:

What product is being manufactured?
How much is being produced?
What is the quality of the product?
Where is the product to be produced?
What is the quality of the estimate?
What is the basis for the estimate?
What are the knowns and unknowns with respect to the project?

Before an estimate can be prepared, it is essential to prepare a scope. It may be as simple as a single page, such as for an order-of-magnitude estimate, or several large manuals, for a detailed estimate. As the project moves forward from inception to a detailed estimate, the scope must be revised and updated to provide the latest information. Changes during the progress of a project are inevitable, but a well-defined scope prepared in advance can help minimize costly changes. If a scope is properly defined, the following results:

An understanding between those who prepared the scope (engineering) and those who accept it (management)
A document that indicates clearly what is provided in terms of technology, quality, schedule, and cost
A basis in enough detail to be used in controlling the project and its costs to permit proper evaluation of any proposed changes
A device to permit subsequent evaluation of the performance compared to the intended performance
A document to control the detailed estimate for the final design and construction

***Equipment Cost Data*** The foundation of a fixed capital investment estimate is the equipment cost data. From this information, through the application of factors or percentages based upon the estimator's experience, the fixed capital investment is developed.

Cost data are reported as purchased, delivered, or installed cost. Purchased cost is the price of the equipment FOB at the manufacturer's plant, whereas delivered cost is the purchased price plus the delivery charge to the purchaser's plant FOB. Installed cost means the equipment has been purchased, delivered, uncrated, and placed on a foundation in the purchaser's operating department but does not include costs for piping, electrical, instrumentation, insulation, etc. Perhaps a better name might be *set-in-place cost.*

It is essential to have up-to-date, reliable cost data since the engineer producing the estimate starts with this information and develops the fixed capital cost estimate. The estimator must know the source of the data, the basis for the data, the date, potential errors, and the range over which the data apply. There are many sources of graphical equipment cost data in the literature, but some are old and the latest published data were in the early 1990s. There have been no significant cost data published recently. To obtain current cost data, one should solicit bids from vendors; however, it is essential to impress on the vendor that the information is to be used for preliminary estimates. A disadvantage of using vendor sources is that there is a chance of compromising proprietary information.

Cost-capacity plots of equipment indicate a straight-line relationship on a log-log plot. Figure 9-4 is an example of such a plot. A convenient method of presenting these data is in equation format:

$$C_2 = C_1\left(\frac{S_2}{S_1}\right)^n \tag{9-1}$$

where $C_1$ = cost of equipment of capacity $S_1$
$C_2$ = cost of equipment of capacity $S_2$
$n$ = exponent that may vary between 0.4 and 1.2 depending on type of equipment

Equation (9-1) is known as the *six-tenths rule* since the average value of $n$ for all equipment is about 0.6. D. S. Remer and L. H. Chai (*Chemical Engineering Progress*, August 1990, pp. 77–82) published an extensive list of six-tenths data. Figure 9-5 shows how the exponent may vary from 0.4 to 0.9 for a given equipment item. Data accuracy is the highest in the narrow, middle range of capacity, but at either end of the plot, the error is great. These errors occur when one correlates cost data with one independent variable when more than one variable is necessary to represent the data; or when pressure, temperature, materials of construction, or design features vary considerably.

ESTIMATING INFORMATION GUIDE

Information Either Required or Available

| Estimate types | Detailed (firm) | Definitive (project control) | Preliminary (budget authorization) | Study (factored) | Order of magnitude (ratio) |

**FIG. 9-3** Information guide for preparing estimates. (*Source*: Perry's Chemical Engineers' Handbook, *5th ed., McGraw-Hill, New York, 1973.*)

A convenient way to display cost-capacity data is by algorithms. They are readily adaptable for computerized cost estimation programs. Algorithm modifiers in equation format may be used to account for temperature, pressure, material of construction, equipment type, etc. Equation (9-2) is an example of obtaining the cost of a shell-and-tube heat exchanger by using such modifiers.

$$C_{HE} = KC_BF_DF_MF_P \tag{9-2}$$

where $C_{HE}$ = purchased equipment cost
$K$ = factor for cost index based upon a base year
$C_B$ = base cost of a carbon-steel floating-head exchanger, 150-psig design pressure
$F_D$ = design-type cost factor if different from that in $C_B$
$F_M$ = material-of-construction cost factor
$F_P$ = design pressure cost factor

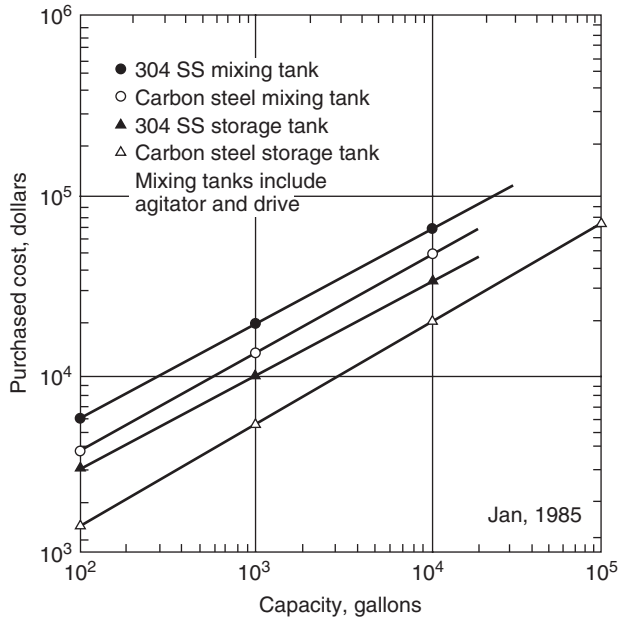

**FIG. 9-4** Cost-capacity plot.

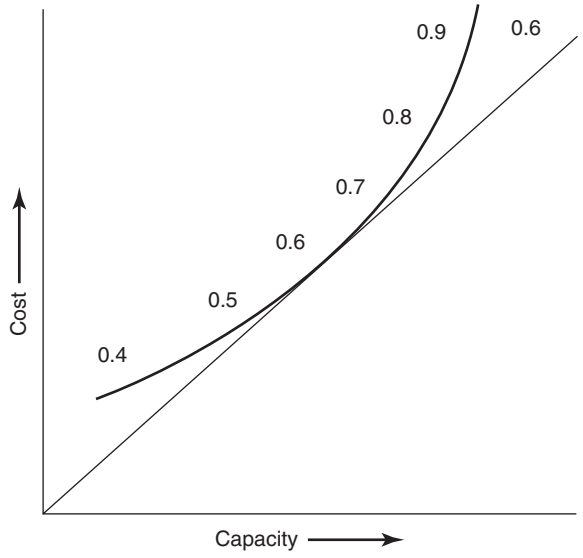

**FIG. 9-5** Variation of $n$ on cost-capacity plot.

Each cost factor is obtained from equations or tables from Couper (2003, App. C) and have been updated to third-quarter 2002.

***Cost Indices*** Cost data are given as of a specific date and can be converted to more recent costs through the use of cost indices. In general, the indices are based upon constant dollars in a base year and actual dollars in a specific year. In this way, with the proper application of the index, the effect of inflation (or deflation) and price increases by multiplying the historical cost by the ratio of the present cost index divided by the index applicable in the historical year. Labor, material, construction costs, energy prices, and product prices all change at different rates. Most cost indices represent national averages, and local averages may vary considerably. Table 9-9 is a list of selected values of three cost indices of significance in the chemical process industries. The chemical engineering (CECI) index, which is most commonly used by the CPI, is found in each issue of *Chemical Engineering* magazine. The *Oil and Gas Journal* reports the *Nelson-Farrar Refinery* indices in the first issue of each quarter. The base years selected for each index are generally periods of low inflation so that the index is stable. The derivation of base values is referred to in the respective publications.

**TABLE 9-9 Selected Chemical Engineering Indices**

| Year base | CE index (CECI) 1957–1959 = 100 | Year base | CE index (CECI) |
|---|---|---|---|
| 2000 | 394.1 | 2008 | 575.4 |
| 2001 | 394.3 | 2009 | 521.9 |
| 2002 | 395.6 | 2010 | 550.8 |
| 2003 | 402.0 | 2011 | 585.7 |
| 2004 | 444.2 | 2012 | 584.6 |
| 2005 | 468.2 | 2013 | 567.3 |
| 2006 | 496.7 | 2014 | 576.1 |
| 2007 | 525.4 | 2015 (est.) | 550 |

SOURCE: *Chemical Engineering*, Nov. 2015, p. 76.

A cost index is used to project a cost from a base year to another selected year. The following equation is used:

$$\text{Cost at } \Theta_2 = \text{Cost at } \Theta_1 \left( \frac{\text{index at } \Theta_2}{\text{index at } \Theta_1} \right) \tag{9-3}$$

***Example 9-1 Use of Cost Index*** A centrifuge cost $95,000 in 1999. What is the cost of the same centrifuge in the third quarter of 2004? Use the CE index.

*Solution:*

CE index in 1999 = 390.6

CE index in 3d quarter 2004 = 457.4

Cost in 2004 = cost in 1999 × (CE index in 3d quarter 2004/CE index in 1999)

$$= \$95{,}000 \left( \frac{457.4}{390.6} \right) = \$111{,}200$$

***Inflation*** When costs are to be projected into the future due to inflation, it is a highly speculative exercise, but it is necessary for estimating investment costs, operating expenses, etc. Inflation is the increase in price of goods without a corresponding increase in productivity. A method for estimating an inflated cost is

$$C_i = (1 + f_1)(1 + f_2)(1 + f_3)\, C_P \tag{9-4}$$

where $C_i$ = inflated cost
$f_1$ = inflation rate the first year
$f_2$ = inflation rate the second year
$f_3$ = inflation rate the third year
$C_P$ = cost in a base year

The assumed inflation factors $f$ are obtained from federal economic reports, financial sources such as banks and investment houses, and news media. These factors must be reviewed periodically to update estimates.

***Example 9-2 Inflation*** A dryer today costs $475,000. The projected inflation rates for the next 3 years are 3, 4.2, and 4.7 percent. Calculate the projected cost in 3 years.

*Solution:*

$$C_i = (1 + f_1)(1 + f_2)(1 + f_3) C_P$$

$$= (1.030)(1.042)(1.047)(\$475{,}000) = \$533{,}800$$

***Equipment Sizing*** Before equipment costs can be obtained, it is necessary to determine equipment size from material and energy balances. For preliminary estimates, rules of thumb may be used; but for definitive and detailed estimates, detailed equipment calculations must be made.

***Example 9-3 Equipment Sizing and Costing*** Oil at 490,000 lb/h is to be heated from 100 to 170°F with 145,000 lb/h of kerosene initially at 390°F from another section of a plant. The oil enters at 20 psig and the kerosene at 25 psig. The physical properties are

Oil: 0.85 sp gr, 3.5 cP at 135°F, 0.49 sp ht

Kerosene: 0.82 sp gr, 0.45 cP, 0.61 sp ht

Estimate the cost of an all-carbon-steel exchanger in late 2004. Assume an exchanger consisting of a TEMA E-shell with an even number of tube passes.

*Solution:*
Energy required to heat oil stream (490,000)(0.49)(170 − 100) = 16,807,000 Btu/h

$$\text{Exit kerosene temperature } T = 390 - \left(\frac{490{,}000}{145{,}000}\right)\left(\frac{0.49}{0.61}\right)(170-100)$$
$$= 200°\text{F}$$
$$\text{LMTD} = \frac{220-100}{\ln(220/100)} = 152°\text{F}$$

Calculate the exchanger efficiency factor $F_T$.

$$S = \frac{170-100}{390-100} = 0.241$$
$$R = \frac{390-200}{170-100} = 2.71$$

Using these values of $R$ and $S$ in Sec. 11, Fig. 11.4(a), $F_T = 0.88$. Since the factor must be greater than 0.75, the exchanger is satisfactory. Therefore, $\Delta T = (F)$ (LMTD) = (0.88)(152) = 134°F.

Assume $U_D = 50$ Btu/(h · ft² · °F).

$$Q = U_D A\,\Delta T = 16{,}800{,}000 = (50)(A)(134)$$
$$A = 2510 \text{ ft}^2$$

Use the cost algorithm cited above.

$C_B = \exp\,[8.821 - 0.30863 \ln A + 0.0681(\ln A)^2]$
$= \exp\,[8.821 - 0.30863(7.83) + 0.0681(61.3)] = \$39{,}300$ base cost
$F_D = 1.0$
$F_M = 1.0$ for materials of this type
$F_P = 1.00$ since this exchange is operating below 4 bar

$$K = 1.218\,(\text{CE index 4th qtr 2004}/\text{CE index 1st qtr 2003}) = 1.218\left(\frac{463}{406}\right) = 1.389$$

Therefore, $C_{HE} = KC_BF_DF_MF_P = (1.389)(39{,}300)(1.0)(1.0)(1.0) = \$54{,}600$.

**Quality of an Estimate** Capital cost is more art than science. An estimator must use a great deal of judgment in the preparation of an estimate. Estimates may be classified base *k* on the quality and the amount of information available. The American Association of Cost Engineers proposed the following:

| Estimate type | Accuracy range |
|---|---|
| Order of magnitude | −30 to +50% |
| Budget | −15 to +30% |
| Definitive | −5 to +15% |

Many companies have a fourth type between budget and definitive called an "authorization" estimate with a range of −10 to +20 percent. Other companies have a fifth category or detailed estimate.

| Estimate type | Accuracy range |
|---|---|
| Order of magnitude | −30 to +50% |
| Study | −25 to +30% |
| Preliminary | −20 to +25% |
| Definitive | −10 to +15% |
| Detailed | −5 to +10% |

**Estimation of Fixed Capital Investment**

***Order-of-Magnitude Methods*** The *ratio method* will give the fixed capital investment per gross annual sales; however, most of these data are from the 1960s, and no recent data have been published. The ratio above is called the *capital ratio*, often used by financial analysts. The reciprocal of the capital ratio is the *turnover ratio* that for various businesses ranges from 4 to 0.3. The chemical industry has an average of about 0.4 to 0.5. The ratio method of obtaining fixed capital investment is rapid but suitable only for order-of-magnitude estimates.

The *exponential method* may be used to obtain a rapid capital cost for a plant based upon existing company data or from published sources such as those of D. S. Remer and L. H. Chai, *Chemical Engineering*, April 1990, pp. 138–175. In the method known as the seven-tenths rule, the cost-capacity data for process plants may be correlated by a logarithmic plot similar to the six-tenths plot for equipment. Remer and Chai compiled exponents for a variety of processes and found that the exponents ranged from 0.6 to 0.8. When the data are used to obtain a capital cost for a different-size plant, the estimated capital must be for the same process.

The equation is

$$\text{Cost of plant B} = \text{Cost of plant A}\left(\frac{\text{capacity of plant B}}{\text{capacity of plant A}}\right)^{0.7} \tag{9-5}$$

Cost indices may be used to correct costs for time changes.

***Example 9-4 Seven-Tenths Rule*** A company is considering the manufacture of 150,000 tons annually of ethylene oxide by the direct oxidation of ethylene. According to Remer and Chai (1990), the cost-capacity exponent for such a plant is 0.67. A subsidiary of the company built a 100,000-ton annual capacity plant for $70 million fixed capital investment in 1996. Using the seven-tenths rule, estimate the cost of the proposed new facility in the third quarter 2004.

*Solution:*

$$\text{Cost}_{150} = \text{Cost}_{100}\left(\frac{\text{Cap}_{150}}{\text{Cap}_{100}}\right)^{0.67}\left(\frac{\text{CE index 3Q 2004}}{\text{CE index 1996}}\right)$$
$$= (\$70{,}000{,}000)\left(\frac{150{,}000}{100{,}000}\right)^{0.67}\left(\frac{457.4}{381.7}\right) = \$110{,}000{,}000$$

***Study Method*** The single-factor method begins with collecting the delivered cost of various items of equipment and applying one factor to obtain the battery-limits (BL) fixed capital (FC) investment or total capital investment as follows:

$$(C_{FC})_{BL} = f\Sigma(C_{EQ})_{DEL} \tag{9-6}$$

where $(C_{FC})_{BL}$ = battery-limits fixed capital investment or total capital investment
$(C_{EQ})_{DEL}$ = purchased equipment costs

The single factors include piping, automatic controls, insulation, painting, electrical work, engineering costs, etc. (Couper, 2003). Table 9-10 shows the Lang factors for various types of processing plants. The boundaries between the classifications are not clear-cut, and considerable judgment is required in the selection of the appropriate factors.

***Preliminary Estimate Methods*** A refinement of the Lang factor method is the Hand method. The Hand factors are found in Table 9-11. Equipment is grouped in categories, such as heat exchangers and pumps, and then a factor is applied to each group to obtain the installed cost; finally the groups are summed to give the battery-limits installed cost. Wroth compiled a more detailed list of installation factors; a selection of these can be found in Table 9-12. The Lang and Hand methods start with purchased equipment costs whereas the Wroth method begins with delivered equipment costs, so delivery charges must be included in the Lang and Hand methods. At best the Lang and Hand methods will yield study quality estimates, and the Wroth method might yield a preliminary quality estimate.

**TABLE 9-10 Lang Factors**

| | Lang factors | |
|---|---|---|
| Type of plant | Fixed capital investment | Total capital investment |
| Solid processing plant | 4.0 | 4.7 |
| Solid-fluid processing | 4.3 | 5.0 |
| Fluid processing | 5.0 | 6.0 |

| Process | 4.1 |
| Storage | 3.5 |
| Fabricated and field-erected 50,000+ gal | 2.0 |
| Towers (columns) | 4.0 |

Abstracted from W. F. Wroth, *Chemical Engineering*, October 17, 1960, p. 204.

***Example 9-5 Fixed Capital Investment Using the Lang and Hand Methods*** The following is a list of the purchased equipment costs for a proposed processing unit:

| | |
|---|---|
| Heat exchangers | $620,000 |
| Distillation towers and internals | 975,000 |
| Receivers | 320,000 |
| Accumulator drum | 125,000 |
| Pumps and motors | 220,000 |
| Automatic controls | 275,000 |
| Miscellaneous equipment | 150,000 |

Assume delivery charges are 5 percent of the purchased price. Estimate the fixed capital investment 2 years into the future, using the Lang, Hand, and Wroth methods. The inflation rates are 3.5 percent for the first year and 4.0 percent for the second.

*Solution:*

| Equipment | Purchased equipment cost | Delivered equipment cost |
|---|---|---|
| Heat exchangers | $620,000 | $651,000 |
| Distillation towers, internals | 975,000 | 1,024,000 |
| Receivers | 320,000 | 336,000 |
| Accumulator drum | 125,000 | 131,000 |
| Pumps and motors | 220,000 | 231,000 |
| Automatic controls | 275,000 | 289,000 |
| Miscellaneous equipment | 150,000 | 158,000 |
| Total | $2,685,000 | $2,820,000 |

*Lang method:* The Lang factor for a fluid processing unit starting with purchased equipment costs is 5.0. Therefore, fixed capital investment is $\$2{,}820{,}000 \times 5.0 \times 1.035 \times 1.040 = \$15{,}177{,}000$.

*Hand method*: The Hand method begins with purchased equipment costs, and factors are applied from Table 9-11.

Hand method:

| Equipment | Purchased equipment cost | Hand factor | Purchased equipment installed cost |
|---|---|---|---|
| Heat exchangers | $620,000 | 3.5 | $2,170,000 |
| Distillation towers, internals | 975,000 | 4.0 | 3,900,000 |
| Receivers | 320,000 | 2.5* | 800,000 |
| Accumulator drum | 125,000 | 2.5* | 313,000 |
| Pumps and motors | 220,000 | 4.0 | 880,000 |
| Automatic controls | 275,000 | 4.0 | 1,100,000 |
| Miscellaneous | 150,000 | 2.5 | 375,000 |
| Total | $2,685,000 | | $9,538,000 |

The asterisk on the receivers and accumulators indicates that if these vessels are pressure vessels, a factor of 4.0 should be used instead of 2.5. The total purchased equipment installed is $9,538,000 for non–pressure vessels and the delivered cost is $10,015,000. Therefore, the fixed capital investment installed would be $\$10{,}015{,}000 \times 1.035 \times 1.040 = \$10{,}780{,}000$. Using pressure vessels increases the total purchased equipment cost $667,000; therefore, the fixed capital investment for this case including inflation would be $\$10{,}780{,}000 \times 1.05 \times 1.035 \times 1.04 = \$11{,}534{,}000$.

Therefore, the summary of the fixed capital investment by the various methods is

| | |
|---|---|
| Lang | $15,177,000 |
| Hand | 11,534,000 |

Experience has shown that the fixed capital investment by the Lang method is generally higher than that of the other methods. Whatever figure is reported to management, it is advisable to state the potential accuracy of these methods.

Garrett (1989) developed a similar method based upon a variety of equipment modules, starting with purchase equipment costs obtained from plots and applying factors for materials of construction and plant location. The method provides all supporting and connecting equipment to make the equipment installation operational.

T. R. Brown developed guidelines for the preparation of order-of-magnitude and study capital cost estimates based upon the Lang and Hand methods. Brown modified the Lang and Hand methods for cost of services, environmental equipment, materials of construction, instrumentation, and location factors. He found that the modified Hand and Garrett module factor methods gave results within 3.5 percent.

It is necessary to refer to pages 50–54 of Brown's book (op. cit.) in order to implement Brown's method. The Brown method is adequate for FEL/VIP studies, which are explained later in this section.

Other multiple-factor methods that have been published in the past are those by C. E. Chilton, *Cost Estimation in the Process Industries*, McGraw-Hill, New York, 1960; M. S. Peters, K. D. Timmerhaus, and R. E. West, *Plant Design and Economics for Chemical Engineers*, 5th ed., McGraw-Hill, New York, 2003; C. A. Miller, *Chem. Eng.*, Sept. 13, 1965, pp. 226–236; and F. A. Holland, F. A. Watson, and V. K. Wilkinson, *Chem. Eng.*, Apr. 1, 1974, pp. 71–76. These methods produced preliminary quality estimates. Most companies have developed their own in-house multiple-factor methods for preliminary cost estimation.

Step-counting methods are based upon a number of processing steps or "functional units." The concept was first introduced by H. E. Wessel, *Chem. Eng.*, 1952, p. 209. Subsequently, R. D. Hill, *Petrol. Refin.*, **35**(8): 106–110, August 1956; F. C. Zevnik and R. L. Buchanan, *Chem. Eng. Progress*, **59**(2): 70–77, February 1963; and J. H. Taylor, *Eng. Process Econ.*, **2:** 259–267, 1977, further developed the step-counting method.

A step or functional unit is a significant process step including all process equipment and ancillary equipment necessary for operating the unit. A functional unit may be a unit operation, unit process, or separation in which mass and energy are transferred. The sum of all functional units is the total fixed capital investment. Pumping and heat exchangers are considered as part of a functional unit. In-process storage is generally ignored except for raw materials, intermediates, or products. Difficulties are encountered in applying the method due to defining a step. This takes practice and experience. If equipment has been omitted from a step, the resulting estimate is seriously affected. These methods are reported to yield estimates of study quality or at best preliminary quality.

**Definitive Estimate Methods** Modular methods are an extension of the multiple-factor methods and have been proposed by several authors. One of the most comprehensive methods and one of the earliest was that of K. M. Guthrie, *Chem. Eng.*, **76:** 114–142, Mar. 24, 1969. It began with equipment FOB equipment costs, and through the use of factors listed in Table 9-13, the module material cost was obtained. Labor for erection and setting equipment was added to the material cost as well as indirect costs for freight, insurance, engineering, and field expenses to give a total module cost. Such items as contingencies, contractors' fees, auxiliaries, site development land, and industrial buildings were added if applicable. Since any plant consists of equipment modules, these are summed to give the total fixed capital investment. Unfortunately, the factors and data are old, but the concept is useful. See Table 9-14. T. R. Brown, *Hydrocarbon Processing*, October 2000, pp. 93–100, made modifications to the Garrett method.

Another method, called the *discipline method*, mentioned by L. R. Dysert, *Cost Eng.* **45**(6), June 6, 2003, is similar to the models of Guthrie and Garrett. It uses equipment factors to generate separate costs for each of the "disciplines" associated with the installation of equipment, such as installation labor, concrete, structural steel, and piping, to obtain direct field costs for each type of equipment, e.g., heat exchangers, towers, and reactors.

*Modular methods*, depending on the amount of detail provided, will yield preliminary quality estimates.

***Detailed Estimate Method*** For estimates in the detailed category, a code of account needs to be used to prevent oversight of certain significant items in the capital cost. See Table 9-15. Each item in the code is estimated and provides the capital cost estimate; then this estimate serves for cost control during the construction phase of a project.

**TABLE 9-13 Guthrie Method Factors**

| Details | Exchangers | | | Vessels | | Pump and driver | Compressor and driver | Tanks |
|---|---|---|---|---|---|---|---|---|
| | Furnaces | Shell and tube | Air-cooled | Vertical | Horizontal | | | |
| FOB equipment | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 |
| Piping | 0.18 | 0.46 | 0.18 | 0.61 | 0.42 | 0.30 | 0.21 | |
| Concrete | 0.10 | 0.05 | 0.02 | 0.10 | 0.06 | 0.04 | 0.12 | |
| Steel | | 0.03 | | 0.08 | | | | |
| Instruments | 0.04 | 0.10 | 0.05 | 0.12 | 0.06 | 0.03 | 0.08 | |
| Electrical | 0.02 | 0.02 | 0.12 | 0.05 | 0.05 | 0.31 | 0.16 | |
| Insulation | | 0.05 | | 0.08 | 0.05 | 0.03 | 0.03 | |
| Paint | | | 0.01 | 0.01 | 0.01 | 0.01 | 0.01 | |
| Total materials = $M$ | 1.34 | 1.71 | 1.38 | 2.05 | 1.65 | 1.72 | 1.61 | 1.20 |
| Erection and setting ($L$) | 0.30 | 0.63 | 0.38 | 0.95 | 0.59 | 0.70 | 0.58 | 0.13 |
| $\chi$, excluding site preparation and auxiliaries ($M + L$) | 1.64 | 2.34 | 1.76 | 3.00 | 2.24 | 2.42 | 2.19 | 1.33 |
| Freight, insurance, taxes, engineering, home office, construction | | 0.08 | | 0.08 | 0.08 | 0.08 | 0.08 | 0.08 |
| Overhead or field expense | 0.60 | 0.95 | 0.70 | 1.12 | 0.92 | 0.97 | 0.97 | |
| Total module factor | 2.24 | 3.37 | 2.46 | 4.20 | 3.24 | 3.47 | 3.24 | 1.41 |

SOURCE: From K. M. Guthrie, *Chem. Eng.*, **76,** 114–142 (Mar. 24, 1969). Based on FOB equipment cost = 100 (carbon steel).

**Comments on Significant Cost Items**

***Piping*** This cost includes the cost of the pipe, installation labor, valves, fittings, supports, and miscellaneous items necessary to complete installation of all pipes in the process. The accuracy of the estimates can be seriously in error by the improper application of estimating techniques to this component. Many pipe estimating methods are extant in the literature.

Two general methods have been used to estimate piping costs when detailed flow sheets are not available. One method is to use a percentage of the FOB equipment costs or a percentage of the fixed capital investment. Typical figures are 80 to 100 percent of the FOB equipment costs or 20 to 30 percent of the fixed capital investment. This method is used for preliminary estimates. Another group of methods such as the Dickson $N$ method

**TABLE 9-14 Selected Garrett Module Factors**

| Equipment type (carbon steel unless otherwise noted) | Module factor |
|---|---|
| Agitators: dual-bladed turbines/single-blade propellers | 2.0 |
| Agitated tanks | 2.5 |
| Air conditioning | 1.46 |
| Blender, ribbon | 2.0 |
| Blowers, centrifugal | 2.5 |
| Centrifuges: solid-bowl, screen-bowl, pusher, stainless steel | 2.0 |
| Columns: distillation, absorption, etc. | |
| Horizontal | 3.05 |
| Vertical | 4.16 |
| Compressors: low-, medium-, high-pressure | 2.6 avg. |
| Coolers, quenchers | 2.7 |
| Crystallizers | 2.6 avg. |
| Drives/motors | |
| Electric, for fans, compressors, pumps | 1.5 |
| Electric for other units | 2.0 |
| Gasoline | 2.0 |
| Turbine: gas and steam | 3.5 |
| Dryers | |
| Fluid bed, spray | 2.7 |
| Rotary | 2.3 |
| Dust collectors | |
| Bag filters | 2.2 |
| Cyclones, multiclones | 3.0 |
| Evaporators, single-effect stainless steel | |
| Falling film | 2.3 |
| Forced circulation | 2.9 |
| Fans | 2.2 |
| Filters | |
| Belt, rotary drum and leaf, tilting pan | 2.4 |
| Others | 2.8 |

SOURCE: Private communication.

(R. A. Dickson, *Chem. Eng.,* **57:** 123–135, Nov. 1947), estimating by weight, estimating by cost per joint, etc., requires a detailed piping takeoff from either PID or piping drawings with piping specifications, material costs, labor expenses, etc. These methods are used for definitive or detailed estimates where accuracy of 10 to 15 percent is required. The takeoff methods must be employed with great care and accuracy by an experienced engineer. A detailed breakdown by plant type for process piping costs is presented in Peters et al. (2003) and in *Perry's Chemical Engineers' Handbook*, 6th ed., McGraw-Hill, New York, 1984.

***Electrical*** This item consists of transformers, wiring, switching gear, as well as instrumentation and control wiring. The installed costs of the electrical items may be estimated as 20 to 40 percent of the delivered equipment costs or 5 to 10 percent of the fixed capital investment for preliminary estimates. As with piping estimation, the process design must be well along toward completion before detailed electrical takeoffs can be made.

***Buildings and Structures*** The cost of the erection of buildings and structures in a chemical process plant as well as the plumbing, heating and ventilation, and miscellaneous building service items may be estimated as 20 to 50 percent of delivered equipment costs or as 10 to 20 percent of the fixed capital investment for a preliminary estimate.

***Yards, Railroad Sidings, Roads, etc.*** This investment includes roads, railroad spurs, docks, and fences. A reasonable figure for preliminary estimates is 15 to 20 percent of the FOB equipment cost or 3 to 7 percent of the fixed capital investment for a preliminary estimate.

***Service Facilities*** For a process plant, utility services such as steam, water, electric power, fuel, compressed air, shop facilities, and a cafeteria require capital expenditures. The cost of these facilities lumped together may be 10 to 20 percent of the fixed capital investment for a preliminary estimate. (*Note:* Buildings, yards, and service facilities must be well defined to obtain a definitive or detailed estimate.)

***Environmental Control and Waste Disposal*** These items are treated as a separate expenditure and are difficult to estimate due to the variety and complexity of the process requirements. Pollution control equipment is generally included as part of the process design. Couper (2003) and Peters and Timmerhaus (2003) mention that at present there are no general guidelines for estimating these expenditures.

**Computerized Cost Estimation** With the advent of powerful personal computers (PCs) and software packages, capital cost estimates advanced from large mainframe computers to the PCs. The reasons for using computer cost estimation and economic evaluation packages are time saved on repetitive calculations and reduction in mathematical errors. Numerous computer simulation software packages have been developed over the past two decades. Examples of such software are those produced by ASPEN, ICARUS, CHEMCAD, SUPERPRO, PRO II, HYSYS, etc.; but most do not contain cost estimation software packages. ICARUS developed a PC cost estimation and economic evaluation package called Questimate. This system built a cost estimate from design and equipment cost modules, bulk items, site construction, piping and ductwork, buildings, electrical equipment, instruments, etc., developing worker-hours for engineering and fieldwork costs. This process is similar to quantity takeoff methods to which unit costs are applied. A code of accounts is also provided.

ASPEN acquired ICARUS in 2000 and developed Process Evaluator based on Questimate that is used for conceptual design, known as *front-end loading* (FEL). More information on FEL and *value-improving process* (VIP) is found later in Sec. 9. Basic and detailed estimates are coupled with a business decision framework in ASPENTECH ICARUS 2000.

Many companies have developed their own factored estimates using computer spreadsheets based upon their in-house experience and cost database information that they have developed from company project history. For detailed estimates, the job is outsourced to design-construction companies that have the staff to perform those estimates.

Whatever package is used, it is recommended that computer-generated costs be spot-checked for reasonable results using a handheld calculator, since errors do occur. Some commercial software companies will develop cost estimation databases in cooperation with a company for site-specific costs.

**Contingency** This is a provision for unforeseen events that experience has demonstrated are likely to occur. Contingencies are of two types: process and project contingency. In the former, there are uncertainties in

Equipment and performance
Integration of old and new process steps
Scaling up to a large-scale plant size

Accurate definition of certain process parameters, such as severity of process conditions, number of recycles, process blocks and equipment, multiphase streams, and unusual separations

No matter how much time and effort are spent preparing estimates, there is a chance of errors occurring due to

Engineering errors and omissions
Cost and labor rate changes
Construction problems
Estimating inaccuracies
Miscellaneous "unforeseens"
Weather-related problems
Strikes by fabricators, transportation, and construction personnel

For preliminary estimates, a 15 to 20 percent project contingency should be applied if the process information is firm. As the quality of the estimate moves to definitive and detailed, the contingency value may be lowered to 10 to 15 percent and 5 to 10 percent, respectively. Experience has shown that the smaller the dollar value of the project, the higher the contingency should be.

**Offsite Capital** These facilities include all structures, equipment, and services that do not enter into the manufacture of a product but are important to the functioning of the plant. Such capital items might be steam-generating and electrical-generating and distribution facilities, well-water cooling tower, and pumping stations for water distribution. Service capital might be auxiliary buildings, such as warehouses, service roads, railroad spurs, material storage, fire protection equipment, and security systems. For estimating purposes, the following percentages of the fixed capital investment might be used:

Small modification of offsites, 1 to 5 percent
Restructuring of offsites, 5 to 15 percent
Major expansion of offsites, 15 to 45 percent
Grass-roots plants, 45 to 150 percent

**Allocated Capital** This is capital that is shared due to its proportionate share use in a new facility. Such items include intermediate chemicals, utilities, services and sales, administration, research, and engineering overhead.

**Working Capital** Working capital is the funds necessary to conduct day-to-day company business. These are funds required to purchase raw materials, supplies, etc. It is continuously liquidated and rejuvenated from the sale of products or services. If an adequate amount of working capital is available, management has the necessary flexibility to cover expenses in case of strikes, delays, fires, etc. Several methods are available for estimating an adequate amount of working capital. They may be broadly classified into percentage and inventory methods. The percentage methods are satisfactory for study and preliminary capital estimates. The percentage methods are of two types: percentage based on capital investment and percentage based upon sales. In the former method, 15 to 25 percent of the total capital investment may be sufficient for preliminary estimates. In the case of certain specialty chemicals where the raw materials are expensive, it is perhaps better to use the percentage of sales method. Such chemicals as flavors, fragrances, perfumes, etc., are in this category. Experience has shown that 15 to 45 percent of sales has been used with 30 to 35 percent being a reasonable average value.

**Start-Up Expenses** *Start-up expenses* are defined as the total costs directly related to bringing a new manufacturing facility onstream. Start-up time is the time span between the end of construction and the beginning of normal operation. Normal operation is operation at a certain percentage of design capacity or a specified number of days of continuous operation or the ability to make product of a specified purity. Start-up costs are part of the total capital investment and include labor, materials, and overhead for design modifications or changes due to errors on the part of engineering, contractors, costs of tests, final alterations, and adjustments. These items cannot be included as contingency because it is known that such work will be necessary before the project is completed. Experience has shown that start-up costs are a percentage of the battery-limits fixed capital investment of the order on average of 3 percent.

Depending on the tax laws in effect, not all start-up costs can be expensed and a portion must be capitalized. Start-up costs can reduce the after-tax earnings during the early years of a project because of a delay in the start-up of production causing a loss of earnings. Construction changes are items of capital cost, and production start-up costs are expensed as an operating expense.

**Other Capital Items** Paid-up royalties and licenses are considered part of the capital investment since these are replacements for capital to perform process research and development. The initial catalyst and chemical charge, especially for noble metal catalysts and/or in electrolytic processes, is a large amount. These materials are considered to have a life of 1 year. If funds must be borrowed for a new facility, then the interest on borrowed funds during the construction period is capitalized; otherwise, the interest is part of the operating expense.

# MANUFACTURING/OPERATING EXPENSES

The estimation of manufacturing expenses has received less attention in the open literature than the estimation of capital requirements. Operating expenses are estimated from proprietary company files. In this section, methods for estimating the elements that constitute operating expenses are presented. Operating expenses consist of the expense of manufacturing a product, packaging and shipping, as well as general overhead expense. These are described later in this section. Figure 9-6 shows an example of a typical manufacturing expense sheet.

## RAW MATERIAL EXPENSE

Estimates of the amount of raw material consumed can be obtained from the process material balance. Normally, the raw material expense is the largest expense item in the manufacture of a product. Since yields in a chemical reaction determine the quantity of raw materials consumed, assumed yields may be used to obtain approximate exploratory estimates if possible ranges are given. The prices of the raw materials are published in various trade journals that list material according to form, grade, method of delivery, unit of measure, and cost per unit. The *Chemical Marketing Reporter* is a typical source of these prices. The prices are generally higher than quotations from suppliers, and these latter should be used whenever possible. It may be possible for a company to negotiate the price of a raw material based upon large-quantity use on a long-term basis. With the amount of material used from the material balance and the price of the raw material, the following information can be obtained: annual material consumption, annual material expense, as well as the consumption and expense per unit of product.

Occasionally, by-products may be produced, and if there is a market for these materials, a credit can be given. By-products are treated in the same manner as raw materials and are entered into the manufacturing expense sheet as a credit. If by-products are intermediates for which no market exists, they may be credited to downstream or subsequent operations at a value equivalent to their value as a replacement, or no credit may be obtained.

## DIRECT EXPENSES

These are the expenses that are directly associated with the manufacture of a product, e.g., utilities, labor, and maintenance.

**Utilities** The utility requirements are obtained from the material and energy balances. Utilities include steam, electricity, cooling water, fuel, compressed air, and refrigeration. The current utility prices can be obtained from company plant accounting or from the plant utility supervisor. This person might be able to provide information concerning rate prices for the near future. As requirements increase, the unit cost declines. If large incremental amounts are required, e.g., electricity, it may be necessary to tie the company's utility line to a local utility as a floating source.

With the current energy demands increasing, the unit costs of all utilities are increasing. Any prices quoted need to be reviewed periodically to determine their effect on plant operations. A company utility supervisor is a good source of future price trends. Unfortunately, there are no shortcuts for estimating and projecting utility prices. Utilities are the third largest expense item in the manufacture of a product, behind raw materials and labor.

**Operating Labor** The most reliable method for estimating labor requirements is to prepare a table of shift, weekend, and vacation coverage. For round-the-clock operation of a continuous process, one operator per shift requires 4.2 operators, if it is assumed that 21 shifts cover the operation and each operator works five 8-h shifts per week. For batch or semicontinuous operation, it is advisable to prepare a labor table, listing the number of tasks and the number of operators required per task, paying particular attention to primary processing steps such as filtration and distillation that may have several items of equipment per step.

Labor rates may be obtained from the union contract or from a company labor relations supervisor. This person will know the current labor rates and any potential labor rate increases in the near future. One should not forget shift differential and overtime charges. Once the number of operators per shift has been established, the annual labor expense and unit expense may be estimated. Wessel (*Chem. Eng.*, **59:** 209–210, July 1952) developed a method for estimating labor requirements for various types of chemical processes in the United States. The equation is applicable for a production rate of 2 to 2000 tons/day (2000 lb/ton).

$$\log Y = -0.783 \log X + 1.252 + B \qquad (9\text{-}7)$$

where $Y$ = operating labor, operator h/ton per processing step
$X$ = plant capacity, tons/day
$B$ = constant depending upon type of process
+ 0.132 ( for batch operations that have minimum labor requirements)
+ 0 ( for operations with average labor requirements)
– 0.167 ( for a well-instrumented continuous process)

A processing step is one in which a unit operation occurs; e.g., a filtration step might consist of a feed (precoat) tank, pump, filter, and receiver so a processing step may have several items of equipment. By using a flow sheet, the number of processing steps may be counted. The Wessel equation does not take into account changes in labor productivity, but this information can be obtained from each issue of *Chemical Engineering*. Labor productivity varies widely in various sections of this country but even more widely in foreign countries.

Ulrich and Vasudevan (2004) developed a table for estimating labor requirements from flow sheets and drawings of the process. Consideration is given to the type and arrangement of equipment, multiplicity of units, and amount of process control equipment. This method is easier to use than the Wessel method and has been updated in a new edition of the original text.

**Supervision** The approximate expense for supervision of operations depends on process complexity, but 15 to 30 percent of the operating labor expense is reasonable.

**Payroll Charges** This item includes workers' compensation, social security premiums, unemployment taxes, paid vacations, holidays, and some part of health and dental insurance premiums. The figure has steadily declined from 1980 and now is 30 to 40 percent of operating labor plus supervision expenses.

**Maintenance** The maintenance expense consists of two components, namely, materials and labor, approximately 60 and 40 percent, respectively. Company records are the best information sources; however, a value of 6 to 10 percent of the fixed capital investment is a reasonable figure. Processes with a large amount of rotating equipment or that operate at extremes of temperature and/or pressure have higher maintenance requirements.

**Miscellaneous Direct Expenses** These items include operating supplies, clothing and laundry, laboratory expenses, royalties, environmental control expenses, etc.

| Item | Basis | Percent |
|---|---|---|
| Operating supplies | Operating labor | 5–7 |
| Clothing and laundry | Operating labor | 10–15 |
| Laboratory expenses | Operating labor | 10–20 |
| Royalties and patents | Sales | 1–5 |

**Environmental Control Expense** Wastes from manufacturing operations must be disposed of in an environmentally acceptable manner. This direct expense is borne by each manufacturing department. Some companies have their own disposal facilities, or they may contract with a firm that handles the disposal operation. Regardless of how the wastes are handled, there is an expense. Published data are found in the open literature, some of which have been published by Couper (2003).

## INDIRECT EXPENSES

These indirect expenses consist of two major items; depreciation and plant indirect expenses.

**Depreciation** The Internal Revenue Service allows a deduction for the "exhaustion, wear and tear and normal obsolescence of equipment used in the trade or business." (This topic is treated more fully later in this section.) Briefly, for manufacturing expense estimates, straight-line depreciation is used, and accelerated methods are employed for cash flow analysis and profitability calculations.

**Plant Indirect Expenses** These expenses cover a wide range of items such as property taxes, personal and property liability insurance premiums, fire protection, plant safety and security, maintenance of plant roads, yards and docks, plant personnel staff, and cafeteria expenses (if one is available). A quick estimate of these expenses based upon company records is of the order of 2 to 4 percent of the fixed capital investment. Hackney presented a method for estimating these expenses based upon a capital investment factor, and a labor factor, but the result is high.

## TOTAL MANUFACTURING EXPENSE

The total manufacturing expense for a product is the sum of the raw materials and direct and indirect expenses.

TOTAL OPERATING EXPENSES

**FIG. 9-6** (*Continued*)

## PACKAGING AND SHIPPING EXPENSES

The packaging expense depends on how the product is sold. The package may vary from small containers to fiber packs to lever packs, or the product may be shipped via tank truck, tank car, or pipeline. Each product must be considered and the expense of the container included on a case-by-case basis. The shipping expense includes the in-plant movement to warehousing facilities. Product delivery expenses are difficult to estimate because products are shipped in various amounts to numerous destinations. Often these expenses come under the heading of freight allowed in the sale of a product.

## TOTAL PRODUCT EXPENSE

The sum of the total manufacturing expense and the packaging and in-plant shipping expense is the total product expense.

## GENERAL OVERHEAD EXPENSE

This expense is often separated from the manufacturing expenses. It includes the expense of maintaining sales offices throughout the country, staff engineering departments, and research and development facilities and administrative offices. All manufacturing departments are expected to share in these expenses so an appropriate charge is made for each product varying between 6 and 15 percent of the product's annual revenue. The wide range in percentage will vary depending on the amount of customer service required due to the nature of the product.

## TOTAL OPERATING EXPENSE

The sum of the total product expense and the general overhead expense is the total operating expense. This item ultimately becomes part of the operating expense on the income statement.

## RAPID MANUFACTURING EXPENSE ESTIMATION

Holland et al. (1983) developed an expression for estimating annual manufacturing expenses for production rates other than the base case based upon fixed capital investment, labor requirements, and utility expense.

$$A_1 = mC_{\text{fci}} + nC_L N_1 + pU_1 \tag{9-8}$$

where $C_{\text{fci}}$ = cost of fixed capital investment, \$
$C_L$ = cost of labor, \$ per operator per shift
$N_1$ = annual labor requirements, operators/shift/year at rate 1
$U_1$ = annual utility expenses at production rate 1
$A_1$ = annual conversion expense at rate 1
$m, n, p$ = constants obtained from company records in consistent units

Equation (9-8) can be modified to include raw materials by adding a term $qM_1$, where $q$ = a constant and $M_1$ = annual raw material expense at rate 1. See also Table 9-16.

## SCALE-UP OF MANUFACTURING EXPENSES

If it is desired to estimate the annual manufacturing expense at some rate other than a base case, the following modification may be made:

$$A_2 = mC_{\text{fci}}\left(\frac{R_2}{R_1}\right)^{0.7} + nC_L N_1\left(\frac{R_2}{R_1}\right)^{0.25} + pU_1\left(\frac{R_2}{R_1}\right) + qM_1\left(\frac{R_2}{R_1}\right) \tag{9-9}$$

where $A_2$ = annual manufacturing expense at production rate 2
$R_1$ = production rate 1
$R_2$ = production rate 2

Equation (9-9) may also be used to calculate data for a plot of manufacturing expense as a function of annual production rate, as shown in Fig. 9-7. Plots of these data show that the manufacturing expense per unit of production decreases with increasing plant size. The first term in Eq. (9-9) reflects the increase in the capital investment by using the 0.7 power for variations in production rates. Labor varies as the 0.25 power for continuous operations based upon experience. Utilities and raw materials are essentially in direct proportion to the amount of product manufactured, so the exponent of these terms is 1.

**TABLE 9-16 Typical Labor Requirements for Various Equipment**

| Equipment | Laborers per unit per shift |
|---|---|
| Blowers and compressor | 0.1–0.2 |
| Centrifuge | 0.25–0.50 |
| Crystallizer, mechanical | 0.16 |
| Dryers | |
| Rotary | 0.5 |
| Spray | 1.0 |
| Tray | 0.5 |
| Evaporator | 0.25 |
| Filters | |
| Vacuum | 0.125–0.25 |
| Plate and frame | 1.0 |
| Rotary and belt | 0.1 |
| Heat exchangers | 0.1 |
| Process vessels, towers (including auxiliary pumps and exchangers) | 0.2–0.5 |
| Reactors | |
| Batch | 1.0 |
| Continuous | 0.5 |

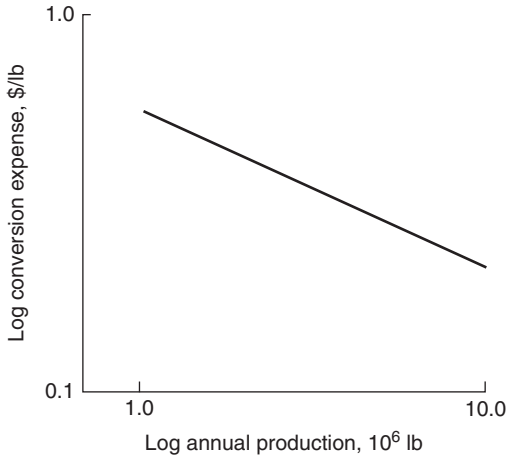

**FIG. 9-7** Annual conversion expense as a function of production rate.

# FACTORS THAT AFFECT PROFITABILITY

## DEPRECIATION

According to the Internal Revenue Service (IRS), *depreciation* is defined as an allowance for the decrease in value of a property over a period of time due to wear and tear, deterioration, and normal obsolescence. The intent is to recover the cost of an asset over a period of time. It begins when a property is placed in a business or trade for the production of income and ends when the asset is retired from service or when the cost of the asset is fully recovered, whichever comes first. Depreciation and taxes are irrevocably tied together. It is essential to be aware of the latest tax law changes because the rules governing depreciation will probably change. Over the past 70 to 80 years, there have been many changes in the tax laws of which depreciation is a major component. Couper (2003) discussed the history and development of depreciation accounting. Accelerated depreciation was introduced in the early 1950s to stimulate investment and the economy. It allowed greater depreciation rates in the early years of a project when markets were not well established, manufacturing facilities were coming onstream, and expenses were high due to bringing the facility up to design capacity.

The current methods for determining annual depreciation charges are the straight-line depreciation and the Modified Accelerated Cost Recovery System (MACRS). In the straight-line method, the cost of an asset is distributed over its expected useful life such that the annual charge is

$$D = \frac{I + S}{n} \text{ \$ per year} \tag{9-10}$$

where $D$ = annual depreciation charge
$I$ = investment
$n$ = number of years
$S$ = salvage value

The MACRS went into effect in January 1987 (Couper, 2003) with six asset recovery periods: 3, 5, 7, 10, 15, and 20 years. It is based upon the declining-balance method. The equation for the declining-balance method is

$$V_e = V_i(1 - f) \tag{9-11}$$

where $V_i$ = value of asset at beginning of year
$V_e$ = value of asset at end of year
$f$ = declining-balance factor

For 150 percent declining balance $f = 1.5$, and for 200 percent $f = 2.0$. These factors are applied to the previous year's remaining balance. It is evident that the declining-balance method will not recover the asset that the IRS permits. Therefore, a combination of the declining-balance and straight-line methods forms the basis for the MACRS method.

Class lives for selected industries are found in Couper (2003), but most chemical processing equipment falls in the 5-year category and petroleum processing equipment in the 7-year category. For those assets with class lives less than 10 years, a 200 percent declining-balance method with a switch to straight-line method in the later years is used. The IRS adopted a half-year convention for both depreciation methods. Under this convention, a property placed in service is considered to be only one-half year irrespective of when during the year the property was placed in service. Table 9-17 is a listing of the class lives, and Table 9-18 contains factors with the half-year convention for both the MACRS and straight-line methods.

Depreciation is entered as an indirect expense on the manufacturing expense sheet based upon the straight-line method. However, when one is determining the after-tax cash flow, straight-line depreciation is removed from the manufacturing expense and the MACRS depreciation is entered. This is illustrated under the section on cash flow.

There are certain terms that apply to depreciation:

- *Depreciation reserve* is the accumulated depreciation at a specific time.
- *Book value* is the original investment minus the accumulated depreciation.
- *Service life* is the time period during which an asset is in service and is economically feasible.
- *Salvage value* is the net amount of money obtained from the sale of a used property over and above any charges involved in the removal and sale of the property.
- *Scrap value* implies that the asset has no further useful life and is sold for the amount of scrap material in it.
- *Economic life* is the most likely period of successful operation before a need arises for subsequent investment in additional equipment as the result of product or process obsolescence or equipment due to wear and tear.

## DEPLETION

Depletion is concerned with the diminution of natural resources. Generally depletion does not enter into process economic studies. Rules for determining the amount of depletion are found in the IRS Publication 535.

## AMORTIZATION

Amortization is the ratable deduction for the cost of an intangible property over its useful life, perhaps a 15-year life, via straight-line calculations. An example of an intangible property is a franchise, patent, trademark, etc. Two IRS publications, Form 4562 and Publication 535 (1999), established the regulations regarding amortization.

**TABLE 9-17 Depreciation Class Lives and MACRS Recovery Periods**

| Asset class | Description of asset | Class life, yr | MACRS recovery period, yr |
|---|---|---|---|
| 00.12 | Information systems | 6 | 5 |
| 00.4 | Industrial steam and electric generation and/or distribution systems | 22 | 15 |
| 13.3 | Petroleum refining | 16 | 10 |
| 20.3 | Manufacture of vegetable oils and vegetable oil products | 18 | 10 |
| 20.5 | Manufacture of food and beverages | 4 | 3 |
| 22.4 | Manufacture of textile yams | 8 | 5 |
| 22.5 | Manufacture of nonwoven fabrics | 10 | 7 |
| 26.1 | Manufacture of pulp and paper | 13 | 7 |
| 28.0 | Manufacture of chemicals and allied products | 9.5 | 5 |
| 30.1 | Manufacture of rubber products | 14 | 7 |
| 30.2 | Manufacture of finished plastic products | 11 | 7 |
| 32.1 | Manufacture of glass products | 14 | 7 |
| 32.2 | Manufacture of cement | 20 | 15 |
| 32.3 | Manufacture of other stone and clay products | 15 | 7 |
| 33.2 | Manufacture of primary nonferrous metals | 14 | 7 |
| 32.4 | Manufacture of primary steel mill products | 15 | 7 |
| 49.223 | Substitute natural gas-coal gasification | 18 | 10 |
| 49.25 | Liquefied natural gas plant | 22 | 15 |

SOURCE: "How to Depreciate Property," Publication 946, Internal Revenue Service, U.S. Department of Treasury, Washington, 1999.

## TAXES

Most major corporations pay the federal tax rate of 21 percent on their annual gross earnings. In addition, some states have a stepwise corporate income tax rate. State income tax is deductible as an expense item before the calculation of the federal tax. If $T_s$ is the incremental tax rate and $T_f$ is the incremental federal tax, both expressed as decimals, then the combined incremental rate $T_c$ is

$$T_c = T_s + (1 - T_s)T_f \tag{9-12}$$

If the federal rate is 21 percent and the state rate is 7 percent, then the combined rate is

$$T_c = 0.07 + (1 - 0.07)(0.21) = 0.265$$

Therefore, the combined tax rate is 26.5 percent.

## TIME VALUE OF MONEY

In business, money is either borrowed or loaned. If money is loaned, there is the risk that it may not be repaid. From the lender's standpoint, the funds could have been invested somewhere else and made a profit; therefore, the interest charged for the loan is compensation for the forgone profit. The borrower may look upon this interest as the cost of renting money. The amount of interest charged depends on the scarcity of money, the size of the loan, the length of the loan period, the risk that the lender feels that the loan may not be repaid, and the prevailing economic conditions. Engineers involved in the presentation and/or the evaluation of an investment of funds in a venture, therefore, need to understand the time value of money and how it is applied in the evaluation of projects.

The amount of the loan is called the *principal P*. The longer the time for which the money is loaned, the greater the total amount of interest paid. The future amount of the money $F$ is greater than the principal or *present worth P*. The relationship between $F$ and $P$ depends upon the type of interest used. Table 9-19 is a summary of the nomenclature used in time value of money calculations.

**Simple Interest** The relationship between $F$ and $P$ is $F = P(1 + \text{interest})$. The interest is charged on the original loan and not on the unpaid balance (Couper and Rader, 1986). The interest is paid at the end of each time interval. Although the simple-interest concept still exists, it is seldom used in business.

**Discrete Compound Interest** In financial transactions, loans or deposits are made using compound interest. The interest is not withdrawn but is added to the principal for that time period. In the next time period, the interest is calculated upon the principal plus the interest from

**TABLE 9-19 Interest Nomenclature**

| Symbol | Definition |
|---|---|
| $F$ | Future sum<br>Future value<br>Future worth<br>Future amount |
| $P$ | Principal<br>Present worth<br>Present value<br>Present amount |
| $A$ | End of period payment in a uniform series |

| 21 | | | | | | 2.5 | 21 | | | | | | 2.231 |

*General depreciation system. Declining-balance switching to straight-line. Recovery periods 3, 5, 7, 10, 15, and 20 years.
SOURCE: "How to Depreciate Property," Publication 946, Internal Revenue Service, U.S. Department of Treasury, Washington, 1999.

the preceding time period. This process illustrates compound interest. In equation format,

$$\text{Year 1: } P + Pi = P(1+i) = F_1 \tag{9-13a}$$

$$\text{Year 2: } P + Pi(1+i) = P(1+i)^2 = F_2 \tag{9-13b}$$

$$\text{Year } n\text{: } P(1+i)^n = F \tag{9-13c}$$

An interest rate quoted on an annual basis is called *nominal interest*. However, interest may be payable on a semiannual, quarterly, monthly, or daily basis. To determine the amount compounded, the following equation applies:

$$F = P\left(1+\frac{i}{m}\right)^{mn} \tag{9-14}$$

where $m$ = number of interest periods per year
$n$ = number of years
$i$ = nominal interest

Interest calculated for a given time period is known as *discrete compound interest*, with *discrete* referring to a discrete time period. Table 9-20 contains 5 and 6 percent discrete interest factors.

Examples of the use of discrete factors for various applications are found in Table 9-21, assuming that the present time is when the first funds are expended.

**Continuous Compound Interest** In some companies, namely, petroleum, petrochemical, and chemical companies, money transactions occur hourly or daily, or essentially continuously. The receipts from sales and services are invested immediately upon receipt. The interest on this cash flow is continuously compounded. To use continuous compounding when evaluating projects or investments, one assumes that cash flows continuously.

In continuous compounding, the year is divided into an infinite number of periods. Mathematically, the limit of the interest term is

$$\lim_{n\to\infty}\left(1+\frac{r}{m}\right)^{mn} = e^{rn} \tag{9-15}$$

where $n$ = number of years
$m$ = number of interest periods per year
$r$ = nominal interest rate
$e$ = base for naperian logarithms

The numerical difference between discrete compound interest and continuous compound interest is small, but when large sums of money are involved, the difference may be significant. Table 9-22 is an abbreviated continuous interest table, assuming that time zero is when start-up occurs. A summary of the equations for discrete compound and continuous compound interest is found in Table 9-23.

**Compounding and Discounting** When money is moved forward in time from the present to a future time, the process is called *compounding*. The effect of compounding is that the total amount of money increases with time due to interest. *Discounting* is the reverse process, i.e., a sum of money moved backward in time. Figure 9-8 is a sketch of this process. The time periods are years, and the interest is normally on an annual basis using end-of-year money flows. The longer the time before money is received, the less it is worth at present.

**Effective Interest Rates** When an interest rate is quoted, it is nominal interest that is stated. These quotes are on an annual basis, however, when compounding occurs that is not the actual or effective interest. According to government regulations, an effective rate APY must be stated also. The effective interest is calculated by

$$i_{\text{eff}} = \left(1+\frac{i}{m}\right)^{(m)(1)} - 1 \tag{9-16}$$

The time period for calculating the effective interest rate is 1 year.

***Example 9-6 Effective Interest Rate*** A person is quoted an 8.33 percent nominal interest rate on a 4-year loan compounded monthly. Determine the effective interest rate.

*Solution:*

$$i_{\text{eff}} = \left(\frac{1+i}{m}\right)^{(m)(1)} = \left(\frac{1+0.833}{12}\right)^{(12)(1)} - 1 = (1.00694)^{12} - 1$$
$$= 1.0865 - 1 = 0.865$$

The effective interest rate is 8.65 percent.

## CASH FLOW

Cash flow is the amount of funds available to a company to meet current operating expenses. Cash flow may be expressed on a before- or after-tax basis. *After-tax cash flow* is defined as the net profit (income) after taxes plus depreciation. It is an integral part of the *net present worth* (NPW) and discounted cash flow profitability calculations.

The cash flow diagram, also referred to as a cash flow model (Fig. 9-9), shows the relationship between revenue, cash operating expenses, depreciation, and profit. This diagram is similar in many respects to a process flow diagram, but it is in dollars. Revenue is generated from the sale of a product manufactured in "operations." Working capital is replenished from sales and may be considered to be in dynamic equilibrium with operations. Leaving the operations box is a stream, "cash operating expenses." It includes all the cash expenses incurred in the operation but does not include the noncash item depreciation. Since depreciation is an allowance, it is reported on the operating expense sheet, in accordance with the tax laws, as an operating expense item. (See the section Operating Expense Estimation.) Depreciation is an internal expense, and this allowance is retained within the company. If the cash operating expenses are subtracted from the revenue, the result is the operating income. If depreciation is subtracted from the operating income, the net profit before taxes results. Federal income taxes are then deducted from the net profit before taxes, giving the net profit after taxes. When depreciation and net profit after taxes are summed, the result is the after-tax cash flow. The terminology in Fig. 9-9 is consistent with that found in most company income statements in company annual reports.

An equation can be developed for cash flow as follows:

$$\text{CF} = D + (R - C^* - D)(1-t) \tag{9-17}$$

where CF = after-tax cash flow
$D$ = depreciation
$R$ = revenue
$C^*$ = cash operating expenses
$t$ = tax rate

Example 9-7 is a sample calculation of the after-tax cash flow and the tabulated results.

***Example 9-7 After-Tax Cash Flow*** The revenue from the manufacture of a product in the first year of operation is $9.0 million, and the cash operating expenses are $4.5 million. Depreciation on the invested capital is $1.7 million. If the federal income tax rate is 35 percent, calculate the after-tax cash flow.

*Solution:* The resulting after-tax cash flow is $3.52 million. See Fig. 9-10.

**Cumulative Cash Position Table** To organize cash flow calculations, it is suggested that a cumulative cash position table be prepared by using an electronic spreadsheet. For this discussion, time zero is assumed to be at project start-up. Expenditures for land and equipment occurred prior to time zero and represent negative cash flows. At time zero, working capital is charged to the project as a negative cash flow. Start-up expenses are charged in the first year, and positive cash flow from the sale of product as net income after taxes plus depreciation begins, reducing the negative cash position. This process continues until the project is terminated. At that time, adjustments are made to recover land and working capital. An example of a cumulative cash position table is Table 9-24.

When equipment is added for plant expansions to an existing facility, it may be more convenient to use time zero when the first expenditures occur. The selection of either time base is satisfactory for economic analysis as long as consistency is maintained.

**TABLE 9-20 Discrete Compound Interest Factors***

| | Single payment | | Uniform annual series | | | | Single payment | | Uniform annual series | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | Compound-amount factor | Present-worth factor | Sinking-fund factor | Capital-recovery factor | Compound-amount factor | Present-worth factor | Compound-amount factor | Present-worth factor | Sinking-fund factor | Capital-recovery factor | Compound-amount factor | Present-worth factor | |

*Factors presented for two interest rates only. By using the appropriate formulas, values for other interest rates may be calculated.

**TABLE 9-21 Examples of the Use of Compound Interest Table**

*Given:* \$2500 is invested now at 5 percent.
*Required:* Accumulated value in 10 years (i.e., the amount of a given principal).

*Solution:*

$$F = P(1+i)^n = \$2500 \times 1.05^{10}$$
$$\text{Compound-amount factor} = (1+i)^n = 1.05^{10} = 1.629$$
$$F = \$2500 \times 1.629 = \$4062.50$$

*Given:* \$19,500 will be required in 5 years to replace equipment now in use.
*Required:* With interest available at 3 percent, what sum must be deposited in the bank at present to provide the required capital (i.e., the principal which will amount to a given sum)?

*Solution:*

$$P = F\frac{1}{(1+i)^n} = \$19{,}500\frac{1}{1.03^5}$$
$$\text{Present-worth factor} = 1/(1+i)^n = 1/1.03^5 = 0.8626$$
$$P = \$19{,}500 \times 0.8626 = \$16{,}821$$

*Given:* \$50,000 will be required in 10 years to purchase equipment.
*Required:* With interest available at 4 percent, what sum must be deposited each year to provide the required capital (i.e., the annuity which will amount to a given fund)?

*Solution:*

$$A = F\frac{i}{(1+i)^n - 1} = \$50{,}000\frac{0.04}{1.04^{10} - 1}$$
$$\text{Sinking-fund factor} = \frac{i}{(1+i)^n - 1} = \frac{0.04}{1.04^{10} - 1} = 0.08329$$
$$A = \$50{,}000 \times 0.08329 = \$4{,}164$$

*Given:* \$20,000 is invested at 10 percent interest.
*Required:* Annual sum that can be withdrawn over a 20-year period (i.e., the annuity provided by a given capital).

*Solution:*

$$A = P\frac{i(1+i)^n}{(1+i)^n - 1} = \$20{,}000\frac{0.10 \times 1.10^{20}}{1.10^{20} - 1}$$
$$\text{Capital-recovery factor} = \frac{i(1+i)^n}{(1+i)^n - 1} = \frac{0.10 \times 1.10^{20}}{1.10^{20} - 1} = 0.11746$$
$$A = \$20{,}000 \times 0.11746 = \$2349.20$$

*Given:* \$500 is invested each year at 8 percent interest.
*Required:* Accumulated value in 15 years (i.e., amount of an annuity).

*Solution:*

$$F = A\frac{(1+i)^n - 1}{i} = \$500\frac{1.08^{15} - 1}{0.08}$$
$$\text{Compound-amount factor} = \frac{(1-i)^n - 1}{i} = \frac{1.08^{15} - 1}{0.08} = 27.152$$
$$F = \$500 \times 27.152 = \$13{,}576$$

*Given:* \$8000 is required annually for 25 years.
*Required:* Sum that must be deposited now at 6 percent interest.

*Solution:*

$$P = A\frac{(1+i)^n - 1}{i(1+i)^n} = \$8000\frac{1.06^{25} - 1}{0.06 \times 1.06^{25}}$$
$$\text{Present-worth factor} = \frac{(1+i)^n - 1}{i(1+i)^n} = \frac{1.06^{25} - 1}{0.06 \times 1.06^{25}} = 12.783$$
$$P = \$8000 \times 12.783 = \$102{,}264$$

***Example 9-8 Cumulative Cash Position Table (Time Zero at Start-Up)*** A specialty chemical company is considering the manufacture of an additive for use in the plastics industry. The following is a list of production, sales, and cash operating expenses.

| Year | Production, Mlb | Sales, \$1000 | Cash operating expenses, \$1000 |
|---|---|---|---|
| 1 | 40 | 20,000 | 10,320 |
| 2 | 42 | 21,000 | 10,800 |
| 3 | 45 | 23,400 | 11,520 |
| 4 | 48 | 24,960 | 12,240 |
| 5 | 50 | 27,500 | 13,470 |
| 6 | 50 | 28,000 | 13,970 |
| 7 | 47 | 23,500 | 13,175 |
| 8 | 45 | 21,600 | 12,645 |
| 9 | 40 | 18,800 | 11,320 |
| 10 | 35 | 15,750 | 9,995 |

Land for the project is available at \$300,000. The fixed capital investment was estimated to be \$12,000,000. A working capital of \$1,800,000 is needed initially for the venture. Start-up expenses based upon past experience are estimated to be \$750,000. The project qualifies under IRS guidelines as a 5-year class life investment. The company uses MACRS depreciation with the half-year convention. At the conclusion of the project, the land and working capital are returned to management. Develop a cash flow analysis for this project, using a cumulative cash position table (Table 9-24).

**Cumulative Cash Position Plot** A pictorial representation of the cumulative cash flows as a function of time is the cumulative cash position plot. All expenditures for capital as well as revenue from sales are plotted as a function of time. Figure 9-11 is such an idealized plot showing time zero at start-up in part a and time zero when the first funds are expended in part b. It should be understood that the plots have been idealized for illustration purposes. Expenditures are usually stepwise, and accumulated cash flow from sales is seldom a straight line but more likely a curve with respect to time.

**TABLE 9-22 Condensed Continuous Interest Table***

Factors for determining zero-time values for cash flows which occur at other than zero time.

| **Compounding of Cash Flows Which Occur:** | 1% | 5% | 10% | 15% | 20% | 25% | 30% | 35% | 40% | 50% | 60% | 70% | 80% | 90% | 100% |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| A. In an Instant | | | | | | | | | | | | | | | |
| ½ year before | 1.005 | 1.025 | 1.051 | 1.078 | 1.105 | 1.133 | 1.162 | 1.191 | 1.221 | 1.284 | 1.350 | 1.419 | 1.492 | 1.568 | 1.649 |

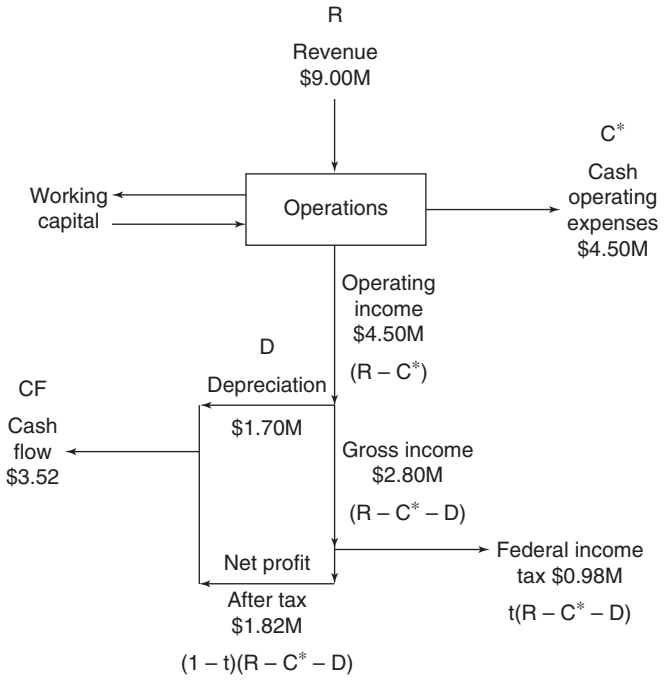

**FIG. 9-10** Cash flow model for Example 9-7. M = million.

**Time Zero at Start-Up** Prior to time zero, expenditures are made for land, fixed capital investment, and working capital. It is assumed that land had been purchased by the company at some time in the past, and a parcel is allocated for the project under consideration. Land is allocated instantaneously to the project sometime prior to the purchase of equipment and construction of the plant. The fixed capital investment is purchased and installed over a period of time prior to start-up. For the purpose of this presentation, it is assumed that it occurs uniformly over a period of time. Both land and fixed capital investment are compounded to time zero by using the appropriate compound interest factors. At time zero, working capital is charged to the project. Start-up expenses are entered in the first year of operation after start-up. After time zero, start-up occurs and then manufacturing begins and income is generated, so cash flow begins to accumulate if the process is sound. At the end of the project life, land and working capital are recovered instantaneously.

**TABLE 9-24 Cash Flow Analysis for Example 9-8**

| Year | −2 | −2 to 0 | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | End 10 |

## PROFITABILITY

In the free enterprise system, companies are in business to make a profit. Management has the responsibility of investing in ventures that are financially attractive by increasing earnings, providing attractive rates of return, and increasing the value added of the company. Every viable business has limitations on the capital available for investment; therefore, it will invest in the most economically attractive ventures. The objectives and goals of a company are developed by management. Corporate objectives may include one or several of the following: maximize return on investment, maximize return on stockholders' equity, maximize aggregate earnings, maximize common stock prices, increase market share, increase economic value, increase earnings per share of stock, and increase market value added. These objectives are the ones most frequently listed by executives.

To determine the worthiness of a venture, quantitative and qualitative measures of profitability are considered.

### QUANTITATIVE MEASURES OF PROFITABILITY

When a company invests in a venture, the investment must earn more than the cost of capital for it to be worthwhile. A profitability estimate is an attempt to quantify the desirability of taking a risk in a venture.

The *minimum acceptable rate of return* (MARR) for a venture depends on a number of factors such as interest rate, cost of capital, availability of capital, degree of risk, economic project life, and other competing projects. Management will adjust the MARR depending on any of the above factors to screen out the more attractive ventures. When a company invests in a venture, the

investment must earn more than the cost of capital and should be able to pay dividends.

Although there have been many quantitative measures suggested through the years, some did not take into account the time value of money. In today's economy, the following measures are the ones most companies use:

Payout period (POP) plus interest
Net present worth (NPW)
Discounted cash flow rate of return (DCFROR)

**Payout Period Plus Interest** Payout period (POP) is the time that will be required to recover the depreciable fixed capital investment from the accrued after-tax cash flow of a project with no interest considerations. In equation format

$$\text{Payout period} = \frac{\text{depreciable fixed capital investment}}{\text{after-tax cash flow}} \tag{9-18}$$

This model does not take into account the time value of money, and no consideration is given to cash flows that occur in a project's later years after the depreciable investment has been recovered. A variation on this method includes interest, called payout period plus interest (POP + $I$); and the net effect is to increase the payout period. This variation accounts for the time value of money.

$$\text{Payout period plus interest (POP} + I) = \left(\frac{\text{depreciable fixed capital investment}}{\text{after-tax cash flow}}\right)_i \tag{9-19}$$

Neither of these methods makes provision for including land and working capital, and no consideration is given to cash flows that occur in a project's later years after the depreciable fixed investment has been recovered for projects that earn most of their profit in the early years.

**Net Present Worth** In the net present worth method, an arbitrary time frame is selected as the basis of calculation. This method is the measure many companies use, as it reflects properly the time value of money and its effect on profitability. In equation form

$$\text{Net present worth (NPW)} = \text{present worth of all cash inflows} - \text{present worth of all investment items} \tag{9-20}$$

When the NPW is calculated according to Eq. (9-20), if the result is positive, the venture will earn more than the interest (discount) rate used; conversely, if the NPW is negative, the venture earns less than that rate.

**Discounted Cash Flow** In the discounted cash flow method, all the yearly after-tax cash flows are discounted or compounded to time zero depending upon the choice of time zero. The following equation is used to solve for the interest rate $i$, which is the discounted cash flow rate of return (DCFROR).

$$\text{DCFROR} = \sum_{o}^{n} (\text{after-tax cash flows}) = 0 \tag{9-21}$$

Equation (9-21) may be solved graphically or analytically by an iterative trial-and-error procedure for the value of $i$, which is the discounted cash flow rate of return. It has also been known as the *profitability index*. For a project to be profitable, the interest rate must exceed the cost of capital.

The effect of interest on the cash position of a project is shown in Fig. 9-12. As interest increases, the time to recover the capital expenditures is increased.

In the chemical business, operating net profit and cash flow are received on a nearly continuous basis. Therefore, there is justification for using the condensed continuous interest tables, such as Table 9-22, in discounted cash flow calculations.

***Example 9-9 Profitability Calculations*** Example 9-8 data are used to demonstrate these calculations. Calculate the following:

*a.* Payout period (POP)
*b.* Payout period with interest (POP + $I$)
*c.* NPW at a 30 percent interest rate
*d.* DCF rate of return

*Solution:*

*a.* From Table 9-25, the second column is the cash flow by years with no interest. The payout period occurs where the cumulative cash flow is equal to the fixed capital investment, $12,000,000 or 1.7 years.

*b.* In Table 9-25, the payout period at 30 percent interest occurs at 2.4 years.

*c.* The results of the present worth calculations for 20, 30, and 40 percent interest rates are tabulated. At 30 percent interest, the net present worth is $4,782,000, and since it is a positive figure, this means the project will earn more than 30 percent interest.

*d.* Discounted cash flow rate of return is determined by interpolating in Table 9-25. At 30 percent interest the net present worth is positive, and at 40 percent interest it is negative. By definition, the DCFROR occurs when the summation of the net present worth equals zero. This occurs at an interest of 33.9 percent.

## QUALITATIVE MEASURES

In addition to quantitative measures, there are certain qualitative measures or intangible factors that may affect the ultimate investment decision. Those most frequently mentioned by management are employee morale, employee safety, environmental constraints, legal constraints, product liability, corporate image, and management goals. Attempts have been made to quantify these intangibles by using an ordinal or a ranking system, but most have had little or no success. Couper (2003) discussed in greater detail the effect of qualitative measures on the decision-making process.

## SENSITIVITY ANALYSIS

Whenever an economic study is prepared, the marketing, capital investment, and operating expense data used are estimates, and therefore a degree of uncertainty exists. Questions arise such as, What if the capital investment is 15 percent greater than the value reported? A sensitivity analysis is used to determine the effect of percentage changes in pertinent variables on the profitability of the project. Such an analysis indicates which variables are most susceptible to change and need further study.

**Break-Even Analysis** Break-even analysis is a simple form of sensitivity analysis and is a useful concept that can be of value to managers. *Break-even* refers to the point in an operation where income just equals expenses. Figure 9-13 is a pictorial example of the results of a

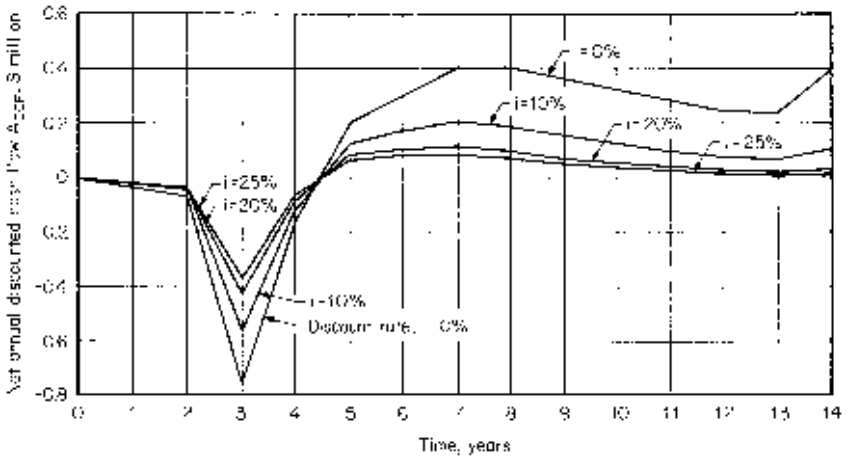

**FIG. 9-12** Effect of interest rate on cash flow (time zero occurs when first funds are expanded).

**TABLE 9-25 Profitability Analysis for Example 9-9**

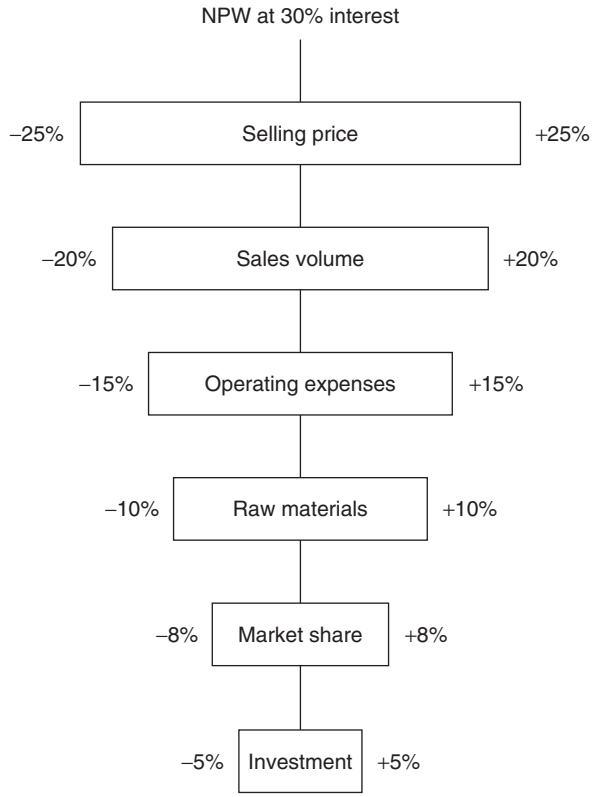

**FIG. 9-15** Typical tornado plot. (*Source: Adapted from Couper, 2003.*)

break-even analysis, showing that the break-even point is at 26 percent of production capacity. Management wants to do better than just break even; therefore, such plots can be used as a profit planning tool, for product pricing, production operating level, incremental equipment costs, etc. Another significant point is the shutdown point where revenue just equals the fixed expenses. Therefore, if a proposed operation can't make fixed expenses, it should be shut down.

**Strauss Plot** R. Strauss (*Chem. Eng.,* pp. 112–116, Mar. 25, 1968) developed a sensitivity plot, in Fig. 9-14, in which the ordinate is a measure of profitability and the abscissa is the change in a variable greater than (or less than) the value used in the base case. Where the abscissa crosses the ordinate is the result of the base case of NPW, return, annual worth, etc. The slope of a line on this "spider" plot is the degree of change in profitability resulting from a change in a variable, selling price, sales volume, investment, etc. The length of the line represents the sensitivity of the variable and its degree of uncertainty. Positive-slope lines are income-related, and negative-slope lines are expense-related. A spreadsheet is useful in developing data for this "what if" plot since numerous scenarios must be prepared to develop the plot.

**Tornado Plot** Another graphical sensitivity analysis is the "tornado" plot. Its name is derived from the shape of the resulting envelope. As in other methods, a base case is solved first, usually expressing the profitability as the net present worth. In Fig. 9-15, the NPW is a vertical line, and variations in each selected variable above and below the base case are solved and plotted. In this figure, the variables of selling price, sales volume, operating expenses, raw material expenses, share of the market, and investment are plotted. It is apparent that the selling price and sales volume are the critical factors affecting the profitability. A commercial computer program known as @RISK® developed by the Palisade Corporation, Newfield, N.Y., may be used to prepare a tornado plot.

**Relative Sensitivity Plot** Another type of analysis developed by J. C. Agarwal and I. V. Klumpar (*Chem. Eng.*, pp. 66–72, Sept. 29, 1975) is the relative sensitivity plot. The variables studied are related to those in the base case, and the resulting plot is the relative profitability.

Although sensitivity analyses are easy to prepare and they yield useful information for management, there is a serious disadvantage. Only one variable at a time can be studied. Frequently, there are synergistic effects among variables; e.g., in marketing, variables such as sales volume, selling price, and market share may have a synergistic effect, and that effect cannot be taken into account. Other interrelated variables such as fixed capital investment, maintenance, and other investment-based items also cannot be represented properly. These disadvantages lead to another management tool—uncertainty analysis.

## UNCERTAINTY ANALYSIS

This analysis allows the user to account for variable interaction that is another level of sophistication. Two terms need clarification—uncertainty and risk. *Uncertainty* is exactly what the word means—not certain. *Risk*, however, implies that the probability of achieving a specific outcome is known within certain confidence limits.

Since sensitivity analysis has the shortcoming of being able to inspect only one variable at a time, the next step is to use probability risk analysis, generally referred to as the Monte Carlo technique. R. C. Ross (*Chem. Eng.*, pp. 149–155, Sept. 20, 1971), P. Macalusa (BYTE, pp. 179–192, March 1984), and D. B. Hertz (*Harvard Bus. Rev.,* pp. 96–108, Jan.-Feb. 1968) have written classic articles on the use of the Monte Carlo technique in uncertainty analysis. These articles incorporate subjective probabilities and assumptions of the distribution of errors into the analysis. Each variable is represented by a probability distribution model. Figure 9-16 is a pictorial representation of the steps in the Monte Carlo simulation. The first step is to gather enough data to develop a reasonable probability model. Not all variables follow the normal distribution curve, but perhaps sales volume and sales-related variables do. Studies have shown that capital investment estimates are best represented by a beta distribution. Next the task is to select random values from the various models by using a random number generator and from these data calculate a profitability measure such as NPW or rate of return. The procedure is repeated a number of times to generate a plot of the probability of achieving a given profitability versus profitability. Figure 9-17 is a typical plot. Once the analysis has been performed, the next task is to interpret the results. Management must understand what the results mean and the reliability of the results. Experience can be gained only by performing uncertainty analyses, not just one or two attempts, to develop confidence in the process. The stakes may be high enough to spend time and learn the method. Software companies such as @RISK or SAS permit the user to develop probability models and perform the Monte Carlo analysis. The results may be plotted as the probability of achieving at least a given return or of achieving less than the desired profitability.

## FEASIBILITY ANALYSIS

A feasibility analysis is prepared for the purpose of determining that a proposed investment meets the minimum requirements established by management.

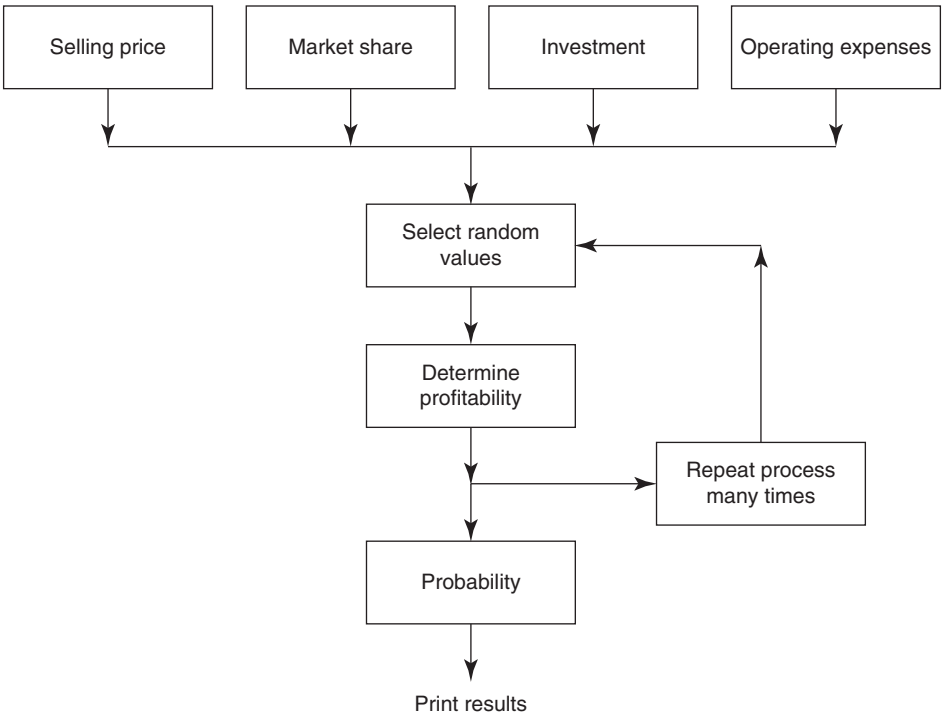

**FIG. 9-16** Schematic diagram of Monte Carlo simulation.

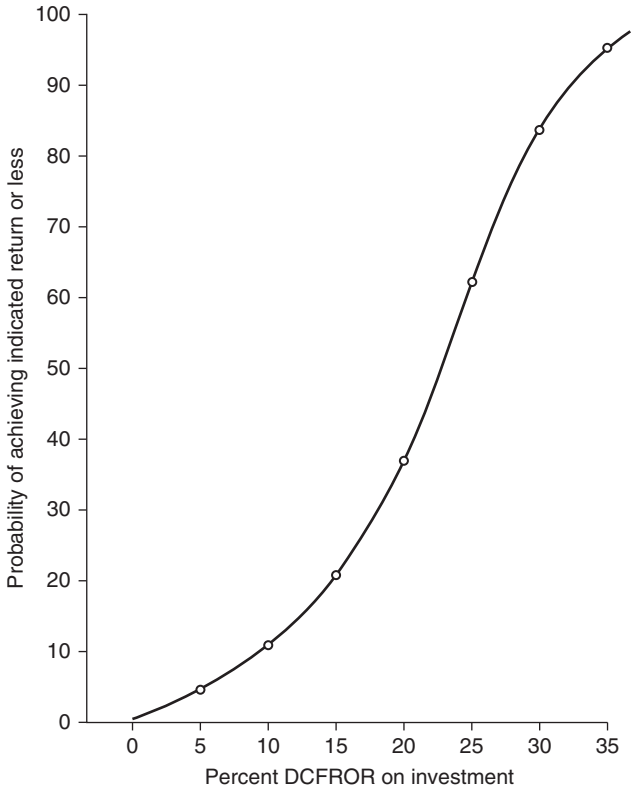

**FIG. 9-17** Probability curve for Monte Carlo simulation.

**TABLE 9-26 Checklist of Required Information for a Feasibility Analysis**

| |
|---|
| Fixed capital investment |
| Working capital requirements |
| Total capital investment |
| Total manufacturing expense |
| Packaging and in-plant expense |
| Total product expense |
| General overhead expense |
| Total operating expense |
| Marketing data |
| Cash flow analysis |
| Project profitability |
| Sensitivity analysis |
| Uncertainty analysis |

It should be in sufficient detail to provide management with the facts required to make an investment decision. All the basic information has been discussed in considerable detail in the earlier parts of Sec. 9.

The minimum information required should include, but not be limited to, that in Table 9-26. Forms and spreadsheets are the most succinct method to present the information. The forms should state clearly the fund amounts and the date that each estimate was performed. The forms may be developed so that data for other scenarios may be reported by extending the tables to the right of the page. It is suggested that blank lines be included for any additional information. Finally the engineer preparing the feasibility analysis should make recommendations based upon management's guidelines.

The development of the information required for Table 9-26 was discussed previously in Sec. 9 with the exception of marketing information. An important document for a feasibility analysis is the marketing data so that the latest income projections can be included for management's consideration. As a minimum, the tabulation of sales volume, sales prices, and market share both domestically and globally should be included. Table 9-27 shows a sample of such marketing information.

Other templates may be prepared for total capital investment, working capital, total product expense, general overhead expense, and cash flow. Table 9-28 may be used to organize cash flow data by showing investment, operating expenses, cash flow, and cumulative cash flow.

# OTHER ECONOMIC TOPICS

## COMPARISON OF ALTERNATIVE INVESTMENTS

Engineers are often confronted with making choices between alternative equipment, designs, procedures, plans, or methods. The courses of action require different amounts of capital and different operating expenses. Some basic concepts must be considered before attempting to use mathematical methods for a solution. It is necessary to clearly define the alternatives and their merits. Flow of money takes the form of expenditures or income. Savings from operations are considered as income or as a reduction in operating expenses. Income taxes and inflation as well as a reasonable return on the investment must be included. Money spent is negative and money earned or saved is positive.

Expenditures are of two kinds; instantaneous like land, working capital and capital recovery or uniformly continuous for plant investment, operating expenses, etc. A methodology involving after-tax cash flow is developed to reduce all the above to a manageable format.

In an earlier part of this section, after-tax cash flow was defined as

$$\mathrm{CF} = D + (R - C^* - D)(1 - t) \tag{9-17}$$

where CF = after-tax cash flow
$D$ = depreciation
$R$ = revenue
$C^*$ = cash operating expenses
$t$ = tax rate

Several methods are available for determining the choice among alternatives:

Net present worth
Rate of return
Capitalized cost
Cash flow
Uniform annual cost

Humphreys in Jelen and Black, *Cost and Optimization Engineering* (1991), has shown that each of these methods would result in the same decision, but the numerical results will differ.

**Net Present Worth Method** The NPW method allows the conversion of all money flows to be discounted to the present time. Appropriate interest factors are applied depending on how and when the cash flow enters a venture. They may be instantaneous, as in the purchase of capital equipment, or uniform, as in operating expenses. The alternative with the more positive NPW is the one to be preferred. In some instances, the alternatives may have different lives so the cost analysis must be for the least common multiple number of years. For example, if alternative A has a 2-year life and alternative B has a 3-year life, then 6 years is the least common multiple. The rate of return, capitalized cost, cash flow, and uniform annual cost methods avoid this complication.

Rate of return and capitalized cost methods are discussed at length in Humphreys (1991).

**Cash Flow Method** Cash flows for each case are determined, and the case that generates the greater cash flow is the preferred one.

**Uniform Annual Cost (UAC) Method** In the uniform annual cost method, the cost is determined over the entire estimated project life. The least common multiple does not have to be calculated, as in the NPW method. This is the advantage of the UAC method; however, the result obtained by this method is more meaningful than the results obtained by other methods.

The UAC method begins with a calculation for each alternative. If discrete interest is used, the annual cost $C$ is found by multiplying the present worth $P$ by the appropriate discrete interest factor, found in Table 9-20, for the number of years $n$ and the interest rate $i$. If continuous interest is preferred, the UAC equation is

$$\text{UAC} = \frac{\text{NPW}}{(\text{years of life})\,(\text{continuous interest factor})} \tag{9-22}$$

The continuous interest factor may be found from continuous interest equations or from the continuous interest table, Table 9-29. In this table time zero is the present, and all cash flows are discounted back to the present. Note that there are three sections to this table, depending on the cash flow: uniform, instantaneous, or declining uniformly to zero. One enters the table with the argument $R \times T$, where $R$ is the interest rate expressed as a whole number and $T$ is the time in years to obtain a factor. This factor is then used to calculate the present worth of the cash flow item. All cash flows are summed algebraically, giving the net present worth, which is substituted in Eq. (9-22). This procedure is followed for both alternatives, and the alternative that yields the more positive UAC (or the least negative) value is the preferred alternative. In Eq. (9-22) the "factor" is always the uniform factor that annualizes all the various cash flows.

This method of comparing alternatives is demonstrated in Example 9-10.

***Example 9-10 Choice among Alternatives*** Two filters are considered for installation in a process to remove solids from a liquid discharge stream to meet environmental requirements. The equipment is to be depreciated over a 7-year period by the straight-line method. The income tax rate is 35 percent, and 15 percent continuous interest is to be used. Assume that the service life is 7 years and there is no capital recovery. Data for the two systems are as follows:

| System | B | C |
|---|---|---|
| Fixed investment | $18,000 | $30,000 |
| Annual operating expenses | 14,200 | 4,800 |

Which alternative is preferred?

*Solution:*

System B:

| Year | Item | Cash flow, $ | Factor | PW, $ |
|---|---|---|---|---|
| 0 | Investment | −18,000 | 1.0 | −18,000 |
| 0–7 | Contribution to cash flow from depreciation | (0.35)(18,000) | 0.6191 | +3,900 |
| 0–7 | Contribution to cash flow from operating expense | (1 − 0.35)(7)(14,200) | 0.6191 | −40,000 |
| | | | NPW B | −54,100 |

$$\text{UAC}_B = \frac{\text{NPW}}{(\text{years of life})(\text{uniform factor})} = \frac{-\$54{,}100}{(7)(0.6191)} = -\$12{,}484$$

System C:

| Year | Item | Cash flow, $ | Factor | PW, $ |
|---|---|---|---|---|
| 0 | Investment | −30,000 | 1.0 | −30,000 |
| 0–7 | Contribution to cash flow from depreciation | (0.35)(30,000) | 0.6191 | +6,500 |
| 0–10 | Contribution to cash flow from operating expense | (1 − 0.35)(10)(4,800) | 0.6191 | −19,316 |
| | | | NPW C | −42,816 |

$$\text{UAC}_C = \frac{\text{NPW}}{(\text{years of life})(\text{uniform factor})} = \frac{-\$42{,}816}{(10)(0.6191)} = -\$6{,}916$$

Alternative C is preferred because it has the more positive UAC.

## REPLACEMENT ANALYSIS

During the lifetime of a physical asset, continuation of its use may make it a candidate for replacement. In this type of analysis, a replacement is intended to supplant a similar item performing the same service without plant or equipment expansion. In a chemical plant, *replacement* usually refers to a small part of the processing equipment such as a heat exchanger, filter, or compressor. If the replacement is required due to "physical" deterioration, there is no question of whether to replace the item, but the entire plant may be shut down if it is not replaced. The problem then becomes whether the equipment should be replaced like for like or whether an alternative should be chosen that may be different in cost and/or efficiency. If the replacement is due to technical obsolescence, the timing of the replacement may be important, especially if a plant expansion may be imminent in the near future. Whatever the situation, the replaced item should not present a bottleneck to the processing. The engineer should understand replacement theory to determine if alternative equipment is adequate for the job but with different costs and timing.

Certain terminology has been developed to identify the equipment under consideration. The item in place is called the *defender*, and the candidate for replacement is called the *challenger*. This terminology and methodology was reported by E. L. Grant and W. G. Ireson in *Engineering Economy*, Wiley, New York, 1950. To apply this method, there are certain rules. The value of the defender asset is a sunk cost and is irrelevant except insofar as it affects cash flow from depreciation for the rest of its life and a tax credit for the book loss if it is replaced sooner than its depreciation life. A capital cost for the defender is the net capital recovery forgone and the tax credit from the book loss of the defender asset that was not realized. The UAC method will be used and will be computed for each case, using the time period most favorable to each. For the defender it is 1 year, and for the challenger it is the full economic life. The UAC for the challenger is handled in the same manner as in the comparison of alternatives. The method is demonstrated in Example 9-11.

***Example 9-11 Replacement Analysis*** A 3-year-old reciprocating compressor is being considered for replacement. Its original cost was $150,000, and it was being depreciated over a 7-year period by the straight-line method. If it is replaced now, the net proceeds from its sale are $50,000, and it is believed that 1 year from now they will be $35,000. A new centrifugal compressor can be installed for $160,000, which would save the company $2000 per year in operating expenses for the 10-year life. At the end of the 10th year, its net proceeds are estimated to be zero. The 7-year depreciation applies also to the centrifugal compressor. A 35 percent tax rate may be assumed. The company requires a 15 percent after-tax return on an investment of this type. Should the present compressor be replaced now?

*Solution:* The UAC method will be used as a basis for comparison. It is assumed that all money flows are continuous, and continuous interest will be used.

**Defender case:** The basis for this unit will be 1 year. If it is not replaced now, the rules listed above indicate that there is an equivalent of a capital cost for two benefits forgone (given up). They are

1. Net proceeds now at 3 years of $50,000
2. Tax credit for the loss not realized

Thus net loss forgone = book value at the end of 3 years minus net capital recovery, or

$$\text{NLF}_3 = \text{BV}_3 - \text{NCR}_3$$

where $\text{NLF}_3$ = net loss forgone at end of 3 years
$\text{BV}_3$ = book value at end of 3 years
$\text{NCR}_3$ = net capital recovery at end of 3 years

$$\text{NLF}_3 = \$150{,}000\left(1 - \frac{1}{7}\right) - \$50{,}000 = \$35{,}714$$

SOURCE: Adapted and abridged from Couper, 2003.

$$\text{Depreciation for 4th year} = \$150{,}000\left(\frac{1}{7}\right) = \$21{,}429$$

$$\text{NLF}_4 = \text{BV}_4 - \text{NCR}_4 = \$150{,}000\left(1 - \frac{4}{7}\right) - \$35{,}000 = \$29{,}286$$

| Year | Item | Cash flow, $ | Factor | PW, $ |
|---|---|---|---|---|
| At 0[a] | Tax credit for net loss forgone | (0.35)(−35,714) | 1.0 | −12,500 |
| At 0[a] | Net cash recovery forgone | −50,000 | 1.0 | −50,000 |
| 0–1 | Contribution to CF from depreciation | (0.35)(−21,429) | 0.9286[b] | 6,965 |
| 0–1 | Contribution to CF from operating expense | (1 − 0.35)(−15,000) | 0.9286[b] | −9,054 |
| End 1 | Tax credit for net loss | (0.35)(29,286) | 0.8607[c] | 8,822 |
| End 1 | Net cash | 35,000 | 0.8607[c] | 30,125 |
| | | | NPW | −25,642 |

[a]For the defender case, 0 year is the end of the third year.
[b]From Table 9-29, uniform section, for the argument $R \times T = 15 \times 1 = 15$.
[c]From Table 9-29, instantaneous section, for the argument $R \times T = 15 \times 1 = 15$.

$$\text{UAC} = \frac{\text{NPW}}{(\text{years of life})(\text{uniform factor})} = \frac{-\$25{,}642}{(1)(0.9286)} = -\$27{,}614$$

**Challenger case:**

| Year | Item | Cash flow, $ | Factor | PW, $ |
|---|---|---|---|---|
| 0 | First cost | −160,000 | 1.0 | −160,000 |
| 0–7 | Contribution to CF from depreciation | (0.35)(160,000) | 0.6191[d] | 56,000 |
| 0–10 | Contribution | (1 − 0.35)(10)(−13,000) | 0.5179[e] | −43,763 |
| | | | NPW | −147,763 |

[d]From Table 9-29, uniform section, $R \times T = 15 \times 7 = 105$.
[e]From Table 9-29, uniform section, $R \times T = 15 \times 10 = 150$.

$$\text{UAC} = \frac{\text{NPW}}{(\text{years of life})(\text{uniform factor})} = \frac{-\$147{,}763}{(10)(0.5179)} = -\$28{,}531$$

The UAC for the defender case is less negative (more positive) than that for the challenger case; therefore, the defender should not be replaced now. But there will be a time in the near future when the defender should be replaced, as maintenance and deterioration will increase.

## OPPORTUNITY COST

*Opportunity cost* refers to the cost or value that is forgone or given up because a proposed investment is undertaken, often used as a base case.

Perhaps the term should be lost opportunity. For example, the profit from production in obsolete facilities is an opportunity cost of replacing them with more efficient ones. In cost analysis on investments, an incremental approach is often used, and if it is applied properly, the correct cost analysis will result.

### INTERACTIVE SYSTEMS

If the TE does not pass through a minimum or maximum, but continues to decline or to increase with the number of equipment items or equipment size, the next step is to look at the flow sheet for equipment upstream or downstream from the selected item. It may be necessary to group two or more items and treat them as one in the analysis. Such a system is said to be *interactive*, since more than one item affects the optimum results. An example of such an interactive system is the removal of nitrogen from helium in a natural gas stream. Carbon adsorption is a method for removing nitrogen, but compressors are also required since this is a high-pressure process. If one attempts to find the optimum operating pressure, optimizing on compressor pressure will not result in an optimum condition; and conversely, optimizing on the size of the carbon bed will not yield an optimum. This is an example of an interactive system. Therefore, to find the optimum pressure, both the size of the carbon bed and the compressor pressure must be considered together.

## CAPITAL PROJECT EXECUTION AND ANALYSIS

*Front-end loading* (FEL) and *value-improving practices* (VIPs) are closely integrated project management practices that are performed primarily during the early stages of a project's life cycle. They have been proved statistically by Independent Project Analysis, Inc. (IPA) to be the most effective means for improving project profitability. FEL and VIPs have very different characteristics, which are presented in the following sections. Properly performed together, they both contribute to maximizing project performance by ensuring that matters which influence project profitability are considered in the most productive manner and at the optimal time.

### FRONT-END LOADING

**Introduction** *Front-end loading* (FEL) is a specialized and adaptable work process that translates business opportunities into a technical reality by developing a sufficiently defined project scope of work and execution plan that satisfies the intended business objectives. The product of the FEL process is also a design-basis package of customized information used to support the production of detailed engineering design documents. Completion of the FEL design-basis package is required for the project *final investment decision* (FID) or project authorization. Project authorization is that point in the project life cycle where the owner organization commits the majority of the project's capital investment and contracts. FID is also the point where overall project risks have been identified and sufficiently mitigated to support project funding approval.

The term *front-end loading* was first coined by the DuPont Company in 1987 and is commonly used throughout the chemical, refining, and oil and gas industries (Porter, James B., E.I. DuPont de Nemours and Company). FEL starts when a project idea is first conceived by a group with a company such as research and development, facilities planning, or project planning. After the initial concept is organized into a project strategy, organized and collaborative interaction and development are required among the various project stakeholders to create and assemble a project design-basis package suitable for subsequent authorization.

Typically at the end of each FEL phase, there are decision gates often called *stage gates*. These decision gates are formally established by the operating company authorizing or funding the project. These formal gates allow for continuity across the enterprise for authorization of additional funding for the next phase of engineering and project definition. FID often follows company corroboration that the project has achieved or exceeded the minimum company requirements for level of definition, risk exposure, capital cost, investment rate of return, and execution planning. Figure 9-18 illustrates the typical decision gates or stage gates for capital projects.

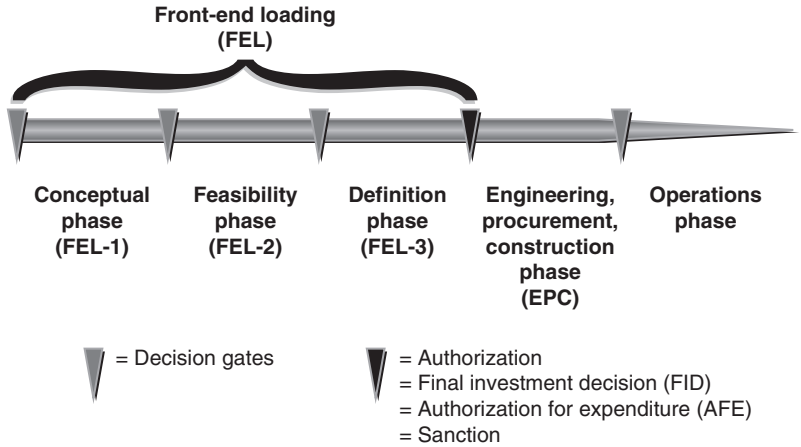

**FIG. 9-18** FEL phases and decision gates.

**Emphasis for Each FEL Phase** There is a different emphasis for each FEL phase that builds on the previous phase deliverables and findings to produce a product or package that is sufficiently detailed to support the project FID.

***Conceptual Phase (FEL-1)*** In FEL-1, the emphasis is to determine the basic economic viability of the conceptual project before committing to more-definitive engineering and study expense. The FEL-1 phase also emphasizes confirmation that the preferred conceptual process flow scheme and supporting economics fulfill the business case that caused its initiation. This phase also involves determining the suitable site or short list of candidate sites for the project that have the best combination of location attributes to best support the planned construction and operational environment that will fulfill the project business drivers. For each candidate site, a conceptual plot plan is generated that confirms the area requirements for processing units and systems, area to support construction operations, and operations and maintenance activities once the facility is operational. Once this work is defined adequately, generation of a representative cost estimate and milestone schedule for the entire project is possible.

***Feasibility Phase (FEL-2)*** In FEL-2, the emphasis is to determine the best technical and economic flow scheme, associated technology, and support systems required to provide the necessary annual production rate at the sales quality required. In this phase, the final site is selected and preliminary geotechnical surveys are completed. A preliminary plot plan is generated that confirms the site area and infrastructure are adequate. This plot plan must be sufficiently detailed to support the FEL-2 cost estimate.

***Definition Phase (FEL-3)*** In FEL-3, the emphasis is on achieving a "best practical" level of project definition that includes a good-quality project estimate, schedule, and a detailed EPC phase project execution plan that includes buy-in from key owner operations and maintenance staff. FEL-3 also involves process optimization to determine the best flow scheme and support systems combination. This optimum includes consideration of the plot plan and equipment arrangements for the entire facility. Process optimization cannot be done in isolation and depends on significant interaction with owner operations, maintenance, and construction experts to produce the best results. This level of project definition and planning for the post-FID project is normally required in order to present to management a candidate project that has the right combination of overall risk and projected economic performance, and thereby secure the project FID.

**FEL Terminology** Various FEL terms and definitions are used by operating and engineering companies today, which are often points of confusion. This situation results from differing terms for each FEL phase, differing levels of project definition ascribed to each phase, and differing project-level and discipline-level deliverables expected at the end of each FEL phase. Table 9-30 provides some insight to the differing FEL terminology in use today. Since these terms change periodically, due diligence is important to confirm definitions of FEL terms as they relate to the planned project work. Depending on what FEL phase is involved and how the owner organization has defined it, information expected prior to starting the work can be significantly more or less defined than originally expected. Therefore, clarity must be sought and confirmed as to the amount of work required versus originally planned to produce the intended deliverables and their level of thoroughness or detail.

**Project Changes** Project changes are a reality in every project phase. The influence of changes on capital projects is a function of when those changes are identified and incorporated into the project scope of work. The earlier the change is considered and incorporated into the project scope, the greater its potential influence on the project's profitability and the greater the ease of incorporating the change. Conversely, the later a change is identified, the more negative the impact on the project. Later changes such as those in the EPC phase are far more expensive to implement, are more disruptive, and are considered very undesirable. This disruption often delays completion of engineering deliverables which have strong statistical linkage to downstream procurement and construction work.

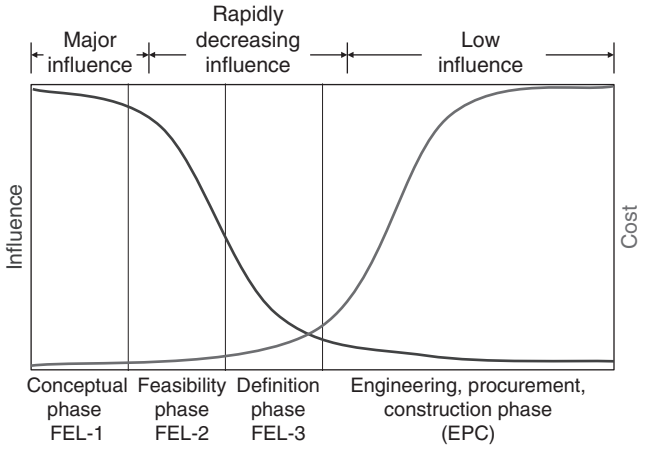

**FIG. 9-19** Project life cycle cost-influence curve.

Figure 9-19 shows how quickly this influence curve changes as the typical project progresses. This is why proactively seeking changes during FEL is far more advantageous to project profitability than allowing those needed changes to be "discovered" during later project phases. This also means that potentially beneficial changes (value improvements) must be sought during FEL. If not, their likelihood of being cost effective to implement during the EPC phase may be very low. This is also why seeking owner operations, maintenance, and construction experience during FEL offers significant profitability advantages over practices which bring such experience onto the project team following FEL.

The FEL project team should proactively seek value improvement alternatives that challenge the project premises, scope, and design until such time that implementing those alternatives loses their economic and technical advantage. By doing so, such value improvements will not develop into costly corrections, which surface later, during the EPC phase.

**Goals and Objectives of FEL** The FEL work process enables a nearly constant consideration of changes as the work progresses. FEL phases also consider the long-term or life cycle cost implications of every aspect of the design and project execution. Predictability of equipment and process system life cycle costs must always be balanced with operations and maintenance preferences. Additional important goals and objectives of FEL projects are listed below.

- Develop a well-defined and acceptably profitable project.
- Define the primary technical and financial drivers for capital project investment.

**TABLE 9-30 Project Life Cycle Terminology**

| FEL-1 | FEL-2 | FEL-3 | EPC | Operations |
|---|---|---|---|---|
| Conceptual | Feasibility | Definition | EPC | Operations |
| Early pre-FEED* | Late pre-FEED* | FEED* | Execute | Operation |
| Appraise | Select | Define | Project execution | Operate |
| Identify | Selection | Develop | Execution | Start-up and operation |
| Business planning | Facility planning | Project planning | Implementation | Operate/evaluate |
| Assess opportunities | Evaluate alternatives | Development | EPC/start-up | |
| Assessment | Development | Validation | | |
| Concept development | | Scope finalization | | |
| Feasibility | | AFD† | | |
| Appraisal/conceptual | | | | |
| Assess | | | | |

*Front-end engineering design
†Authority For Development
SOURCE: KBR compilation of clients' project terminology, 1995–2016.

- Challenge baseline premises and purposely seek out and evaluate alternatives and opportunities.
- Minimize changes during the EPC, turnover, and start-up phases.
- Reduce project schedule and capital cost.
- Reduce business and project execution risk.
- Balance project technical, financial, and operational profitability drivers.

**Comparison of FEL Projects and EPC Projects** FEL projects are very different from EPC projects. Engineers and project managers having significant experience with projects only in the EPC phase often are unfamiliar with the significant differences and challenges of the FEL phase. One of the most important, but most subtle, aspects of FEL is the demand for more highly experienced staff and more sophisticated analysis tools when compared to EPC projects. This is so because of the need in FEL to create, analyze, and implement improvements to what many might already consider a "good" design.

In spite of its relatively short duration, FEL proactively seeks to implement the best possible design and execution plan. This changing environment requires people of many widely differing disciplines and functions to work together and communicate effectively. An integrated project team always seems to perform best during FEL, if it has well-established, informal, and personal interfaces between project groups and organizations. Additional important attributes of FEL phases are listed below.

- Focuses on owner's business objectives
- Emphasizes proactive elimination of low or zero value scope
- Demands significant access to and interaction with downstream experience such as operations, maintenance, construction, commissioning, and start-up
- Demands more experienced staff when compared to EPC projects
- Has far shorter time scale than EPC projects
- Focuses on overall project profitability rather than only cost, schedule, and work hours
- Demands higher level and frequency of communication than EPC projects
- Has far more interfaces than EPC projects
- Has owner-contractor management interfaces that are informal, close, and effective
- Has projects co-led by the owner and contractor which are more successful
- Requires greater development of personal relationships that result in respect and trust than EPC projects
- Demands continuous realignment of owner's desires and requirements with contractor needs

Table 9-31 lists further differences between FEL and EPC projects. Understanding these many differences is very important in that awareness of them and the driving forces behind them will prepare the project team member for the challenging and rewarding environment of FEL projects.

**Parameters of FEL Phases** Other important aspects of each phase of FEL are cost estimate accuracy, cumulative engineering hours spent, and the contingency assigned to the cost estimate. Table 9-32 lists the typical parameters encountered industrywide. For the capital cost estimate, each operating company may request a slightly different accuracy, which is often project-specific. What is important is the level of engineering required to support such estimating accuracy. This determination is the responsibility of both the owner and the engineering contractor. Agreement on this is critical prior to initiating project work.

FEL engineering hours spent are typically proportional to the project scope and equipment count. These engineering hours also vary widely between small and large projects apart from equipment count and project scope. Further, they tend to be proportional to the project complexity, extent of interfaces with other parties, whether new or emerging technology is being applied, or whether higher throughput capacities are being applied than previously commercially demonstrated. Projects such as these may require additional engineering to achieve the desired estimate accuracy, level of engineering definition, and project contingency desired.

**Best FEL Project Performance Characteristics** Overall project performance can be enhanced by ensuring that the following characteristics are emphasized during the FEL phases.

- Methodical business and project execution planning
- Effective integration of owner and engineering contractor workforces
- Projects with an integrated management team (owner and engineering contractor) have the lowest number of design changes at any project stage
- Engineering contractor should be brought onto the project in early FEL phases
- Clear roles for project team members which relate to the expertise of both owner and contractor staff
- Effective personal communication between owner and contractor organizations and their project team representatives, ensuring extensive site and manufacturing input
- Schedule and cost goals set by an integrated business and technical project team composed of owner and contractor representatives

Best FEL performance targets should be actively pursued by the project management team because the level of FEL definition is a leading indicator of post-FID project performance. When benchmarking projects, consultants such as IPA measure numerous aspects of the project to allow statistical comparison to previously completed projects. IPA's FEL Index is one of the most important such indices. The target for this index is the "Best Practical" rating whose characteristics or indicators are described briefly below.

IPA defines their Best Practical FEL Index rating by ensuring that the project has identified all potential project risks and has captured those risks within the project's authorization cost estimate. Based on industry historical performance, the project is, therefore, well positioned to achieve a better level of capital effectiveness with lower costs than industry norms. Their FEL Index is measured by the level of definition of the three equally weighted categories listed below.

1. Site-specific factors
2. EPC phase project execution planning
3. Level of engineering completeness

Figure 9-20 provides more details of what is measured in each FEL Index category.

Figure 9-21 illustrates the benefit of improving FEL performance or thoroughness on overall project costs and shows that these economic benefits increase as the project size increases.

Figure 9-22 illustrates the benefit of good FEL performance on cost growth and schedule slip. Here the negative impacts become evident if the FEL effort is compromised. IPA statistics indicate that significant project financial and schedule benefits can be realized by implementing a thorough FEL effort, prior to the EPC phase.

Figure 9-23 shows how the level of FEL definition can drive the EPC phase critical path schedule predictability.

Figure 9-24 presents the benefits of having an integrated project team during FEL on the overall project performance. IPA project data indicate that a well-integrated FEL team can produce significantly better project performance in terms of lower capital investment and more predictable execution schedule, when compared to projects where FEL teams were not properly integrated. An integrated FEL project team produces fewer late changes in the EPC phase. The performance of the individual team member is best measured by the performance of the entire integrated FEL project team. FEL is a team sport, not an individual performance. This illustrates the benefits for each engineering team member working closely with other team members, to produce the most profitable overall project results.

**Investment in FEL for Best Project Performance** The cost and schedule required to optimally complete the FEL phase are always under pressure and must be justified. This is especially true for "fast-track" projects where the time pressures can be significant. The Construction Industry Institute (CII) has shown that projects with good scope definition (i.e., well-defined FEL deliverables) prior to FID outperformed projects with poorly defined FEL scope.

This is also supported by Table 9-33 where a CII study of 62 industrial projects showed that a higher level of FEL effort resulted in a reduction

**TABLE 9-31 FEL Projects versus EPC Projects**

| Parameter | FEL | EPC |
|---|---|---|
| Project state | Undefined | Defined |
| Changes | Actively seeks changes | Actively resists changes |
| Impact of change | Low | High |
| Opportunity for change | High | Low |
| Contract type | Typically reimbursable | Typically lump sum |
| Value improvement potential | High | Low |
| Client participation | Encouraged | Discouraged |
| Philosophy | Information driven | Deliverable driven |

|---|---|---|
| **Site-Specific Factors** | *Plot Plans and Unit Configurations* | • All equipment has been placed.<br>• All large-bore piping and one-line drawings for smaller bore piping have been provided.<br>• Plot plans have been approved by the owner.<br>• All major pipe routings have been identified and inspected.<br>• Plot plans include major equipment, piping, and associated utilities. |
| | *Soils and Hydrology* | • Comprehensive understanding of the site is evident including knowledge of overhead and underground interferences and contamination issues.<br>• Full geotechnical investigation completed for load-bearing capacity and soil contamination. |
| | *Environmental Regulatory Requirements* | • Grassroots or Greenfield projects – all known requirements addressed – all permit applications submitted to agencies.<br>• Revamp projects – all environmental and building permits received or have been incontrovertibly established that permits are not needed to execute the project. |
| | *Health and Safety Requirements* | • Completed detailed, but not necessarily final, Hazard and Operability (HAZOP) reviews using advanced P&IDs and detailed equipment layouts.<br>• HAZOP recommendations incorporated into design and EPC Phase cost estimate.<br>• HAZOPs conducted with full participation of plant operations and maintenance personnel. |
| *EPC Phase Project Execution Planning* | | • Full project team members assigned and all understand their roles and responsibilities.<br>• Detailed EPC Phase Project Execution Plan with project charter, communication plans, and turnaround strategy.<br>• Detailed EPC contracting strategy.<br>• Detailed and integrated resource-loaded critical-path project schedule including effects of equipment delivery dates, interferences, successor and predecessor activities, and turnover and commissioning sequences for start-up. |
| *Level of Engineering Completeness* | | • Project engineering 15% to 30% complete.<br>• Owner/operator provided extensive input into design at time of estimate preparation.<br>• For revamp projects, process tie-ins field-verified and approved by owner operations staff.<br>• Completed electrical single lines and process control strategy. |

**FIG. 9-20** IPA's FEL index-best practical parameters.

in total EPC phase project design and construction cost of as much as 20 percent versus the FID authorized cost estimate. Further, the study indicated a reduction also in total project design and construction schedule by as much as 39 percent versus the FID authorized schedule.

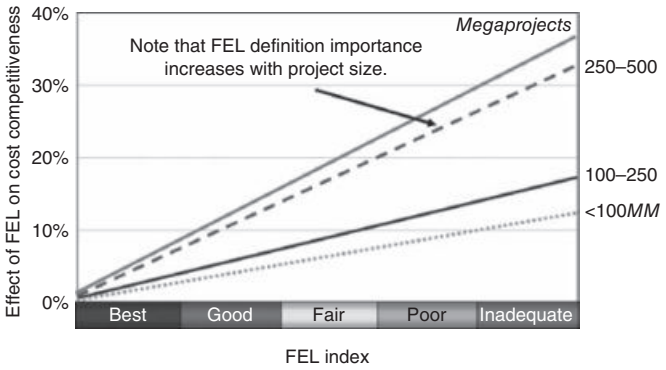

**FIG. 9-21** Importance of FEL definition on project cost.

The level of definition of a project during the FEL phases has a direct influence on the ultimate project's outcome in terms of the number and impacts of changes in the EPC phase. This level of FEL performance translates to fewer major changes during detail engineering, construction, commissioning, and start-up. These conclusions are depicted by Fig. 9-25 where IPA has defined a major late change to mean changes made after the start of detail engineering and involving impacts greater than either 0.5 percent of the total project capital investment or 1 month in the critical path project schedule.

This graph illustrates why better project performance is produced through proactively seeking profitability-improving changes as early as possible. One of the reasons for this observation is that operation, maintenance, and construction expertise must be incorporated into the project team in every FEL phase.

This means that the design engineer should be working closely with these "real-world" experts as they design processes and their support systems. This also means that in order to improve overall project performance, achieving the best practical or highest level of definition during FEL is critical. Finally, this high level of definition results in a reduced number of changes during the EPC phase. These observations should be the critical goals of all project teams.

**Typical FEL Deliverables and Level of Definition** FEL phases are most accurately defined by the product or deliverables for each FEL phase. This is a very good means to determine in which phase(s) the project is actually conducting work. FEL phase deliverables are always customized to

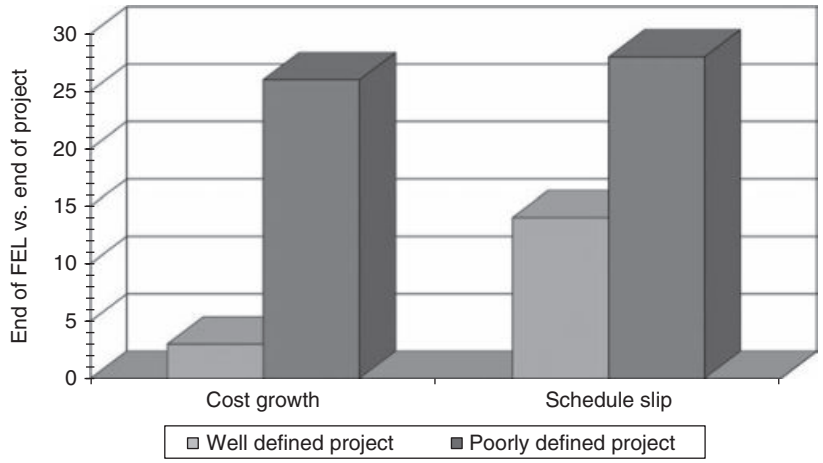

**FIG. 9-22** FEL quality vs. project cost and schedule performance.

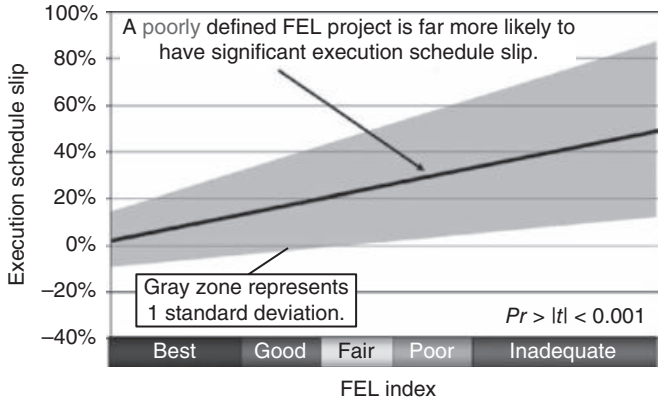

**FIG. 9-23** FEL drives schedule predictability.

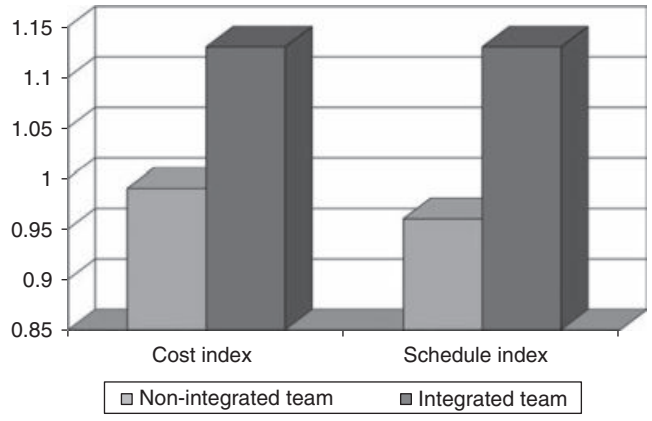

**FIG. 9-24** Team integration vs. project cost and schedule performance.

suit the particular project's scope and business drivers. However, there are certain FEL deliverables and their levels of definition that actually define the FEL phase themselves. These deliverables are listed in Table 9-34.

Since there is no such thing as a "standard" FEL, every FEL project team member should be very aware of which deliverables or end products are required by those who have commissioned their work. Therefore, all project team members must understand the detailed expectations for each deliverable for each FEL phase. They should also confirm at the outset what information will be available to them prior to starting their work, the expected deliverable format, content, level of detail, and due dates. Further, the splits of work or division of work (who will do which aspect of the work) must be well understood by all as they are likely to be interdependent.

**TABLE 9-33 Project Performance vs. Level of FEL Effort**

| Level of FEL effort | Cost | Schedule |
|---|---|---|
| High | –4% | –13% |
| Medium | –2% | +8% |
| Low | +16% | +26% |
| Difference | 20% | 39% |

SOURCE: Construction Industry Institute, University of Texas at Austin, CII Special Publication 268-3, *Adding Value Through Front-End Planning*, 2012.

Today, it is common to see multiple operating companies form a joint venture to authorize major projects. It is also common for multiple engineering contractors to form joint ventures to execute the FEL and/or EPC phases of those major projects. These situations require an even more heightened understanding of information flow, project interfaces, deliverables work requiring multiple disciplines (i.e., discipline interdependence), divisions of work, who will be reviewing the work products, and what their expectations are.

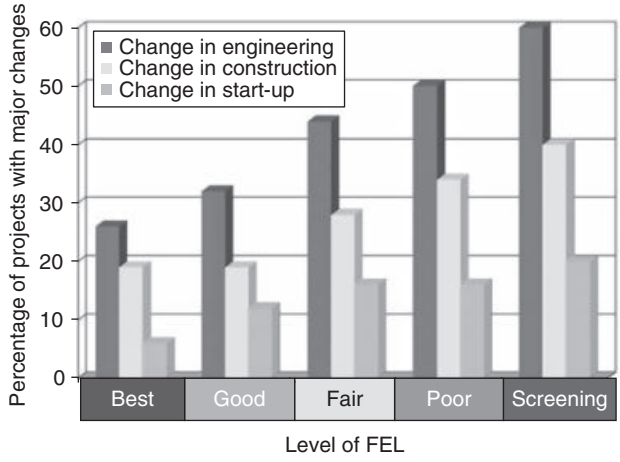

**FIG. 9-25** Good FEL drives late charges down.

**TABLE 9-34 Typical FEL Deliverables by Phase**

| FEL-1 (Conceptual phase) | FEL-2 (Feasibility phase) | FEL-3 (Definition phase) |
|---|---|---|
| Strategic business assessment | Updated strategic business assessment | Updated strategic business assessment |
| Preliminary project milestone schedule (level 1) | Level 2 EPC phase project schedule | Level 3 EPC phase project schedule |
| Key technology selected and risk identified | Cost estimate (+/−25%) | Completed environment permit submittal |
| Market assessment for feed, products, and capacity | Overall project execution strategy | EPC phase project execution plan |
| Potential sites identified and under evaluation | Contracting and purchasing strategies | EPC phase cash flow plan |
| Cost estimate (+/−40%) | Permitting and regulatory compliance plan | EPC phase training, commissioning, and startup plans |
| Block flow diagrams completed | Degree of economic off-site pre-assembly (modularization) determined | EPC phase contracting plans |
| Process cases identified | Soil survey and report | EPC phase materials management plan |
| Critical long lead equipment identified | Project alternatives analysis | EPC phase safety process and quality management plan |
| Construction strategy | Process flow diagrams (PFDs) for selected option(s) | EPC phase cost estimate (+/−10%) |
| FEL-1 phase VIP reports | Preliminary utility flow diagrams and balances | Finalized utility flow diagrams and balances |
| | Preliminary equipment list and equipment load sheets | P&IDs—includes owner review and preliminary hazards analysis changes |

**Introduction** Value-improving practices (VIPs) are formal structured work processes applied to capital projects to improve profitability or value above that which can be attained through the application of good engineering and project management practices. VIPs provide an objective forum for formal analyses of project characteristics and features and are performed by small multidisciplinary teams of subject matter experts and conducted at optimum times during the engineering design and development of capital projects.

VIPs that have been statistically verified by Independent Project Analysis, Inc. (IPA) benchmarking of capital projects are listed below. Each has a different purpose and focus, but all produce project profitability improvements that the project team cannot achieve on their own.

- Classes of Facility Quality
- Technology Selection
- Process Simplification
- Constructability
- Customization of Standards and Specifications
- Energy Optimization
- Predictive Maintenance
- Waste Minimization
- Process Reliability Simulation
- Value Engineering
- Design to Capacity
- 3D-CAD

Application of VIPs to capital projects has been statistically proved to significantly improve project profitability according to IPA and the Construction Industry Institute (CII). IPA data presented in Fig. 9-26 have been gathered from thousands of capital projects since 1987 and illustrate that up to 10 percent reduction in project CAPEX can be realized in high-performing projects by conducting VIPs while also conducting rigorous FEL work processes—7.5 percent from VIPs and 2.5 percent from FEL. The better-performing projects are often referred to as Best Practical or Best in Class projects and represent the upper 20 percent of projects benchmarked by IPA.

Some organizations' VIP programs have documented far higher CAPEX reduction in addition to project profitability improvements from OPEX reduction, critical path schedule improvement, improved facility throughput, and improved facility availability. These improved results are often due to continual adaptation and improvement of the VIP work processes to maintain their relevance and ability to technically and economically improve projects above that accomplished through good project management practices (KBR VIP Program).

**Characteristics of VIPs** VIPs are often described by their characteristics as listed below.

- Out-of-the-ordinary practices are used to improve cost, schedule, and/or reliability of capital projects.
- Statistical links exist between the use of the practice and better project performance which are demonstrated, systematic, repeatable, and proven correlations.
- Formal and documented practices involve repeatable work processes.
- All involve stated explicit support from the owner's corporate executive team.
- These VIPs must be performed by a trained experienced VIP facilitator—someone who is not a full-time member of the project team.
- VIPs are used primarily during FEL project phases.
- All involve a formal facilitated workshop to confirm the value gained by the project and to formally approve vip team recommendations.

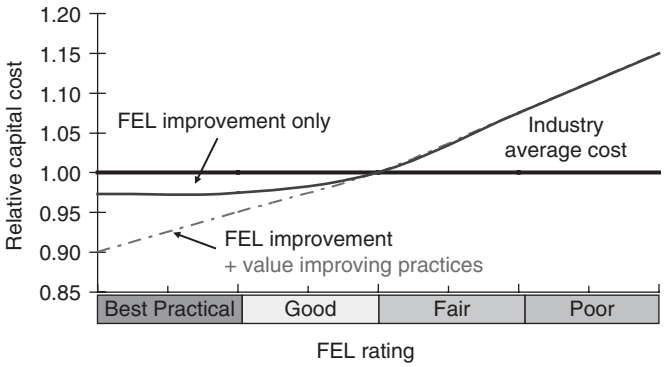

**FIG. 9-26** FEL and VIP's drive lower capital investment.

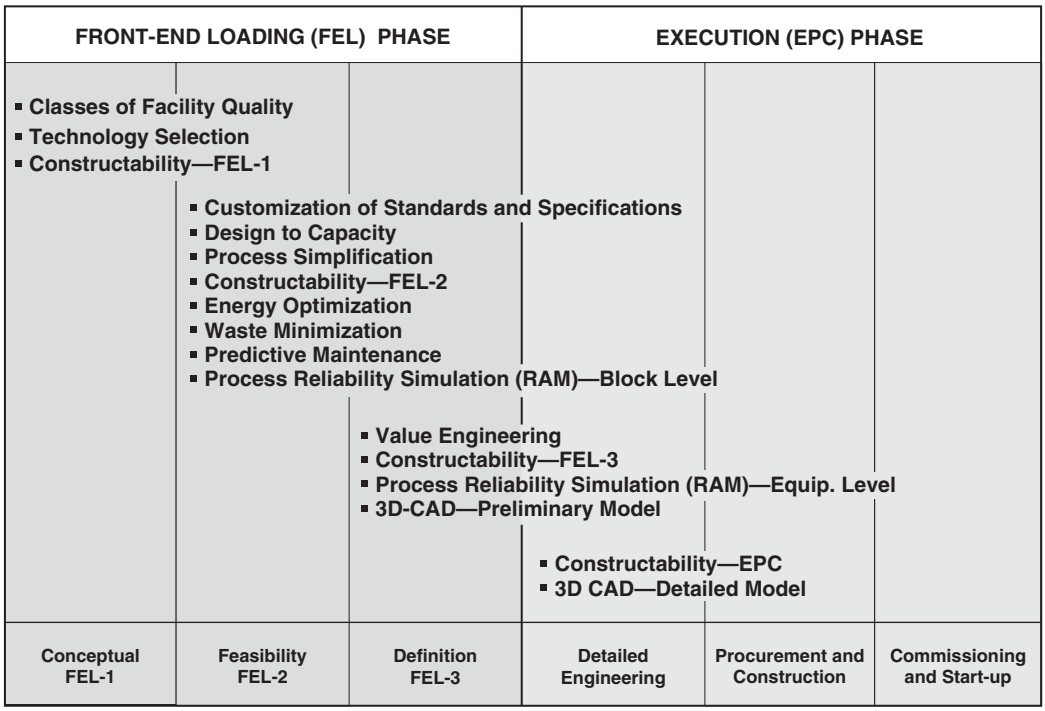

**FIG. 9-27** Implementation timing for value-improving practices.

VIPs are also further clarified by what they are *not*, as listed below.

- Just "good engineering"
- Simple brainstorming or strategy sessions
- Business as usual
- A special look at some aspect of the project
- Process flow diagram (PFD) reviews
- Piping & instrumentation diagram (P&ID) reviews
- Safety reviews
- Audits
- Project readiness reviews

**VIP Selection and Implementation** Execution of VIPs must be deliberately and carefully planned in the initial phase of the project just after the project kick-off. VIPs should be selected from those offered from both the engineering contractor and the owner organizations. It is important to ensure that those selecting the VIPs are fully aware of the project scope and proven benefits for each VIP. They should also be aware of the resources, preparation, and time required to implement each VIP. During the VIP selection meeting, the project management team and the selected experienced VIP facilitator should

- Confirm which VIPs should be applied to the project and when
- Incorporate the planned VIPs into the project scope of work and schedule
- Determine the required workshop resources and best combination of engineering, operations, maintenance, construction, and other expertise for each selected VIP workshop team

The implementation of VIPs to any project must have the explicit commitment of the owner organization and be evident in the integrated project management team. This is so because the VIPs inherently seek project changes that are deemed profitability improvements beyond that evident at the start of the VIP effort. In other words, VIPs drive change that improves project performance, but must be supported by the owner organization to provide the additional resources and time to incorporate the value improvement into the project scope and execution plan. Experience has shown that economic benefit from VIPs is directly proportional to the owner's active and sustained support for implementing the VIPs and especially incorporating the VIP recommendations into the project design, scope, and execution plan.

Experience has also shown that each VIP should be conducted at an optimum time in the project life cycle for best results. Therefore, it is important to incorporate the optimal VIP timing into the project schedule. Figure 9-27 presents the optimal times in the project life cycle for conducting VIPs.

When capital projects are benchmarked by third-party organizations such as IPA or through CII's Project Definition Rating Index (PDRI), the implementation of applicable VIPs to the project is an important part of that benchmarking process.

**Sources of Expertise** VIP workshops should be planned and led by a trained and experienced facilitator who has significant experience in conducting such workshops. Technical expertise for VIP workshops should be a combination of senior project team members and subject matter experts from the owner's organization, the engineering contractor's organization, licensed technology providers, and any key fabrication or installation subcontractors to be used. It is important for the VIP team makeup to include subject matter experts not involved in the project to provide a "cold eyes" or unbiased perspective to the VIP team. Figure 9-28 illustrates the best balance of expertise for VIP workshops.

**VIP Descriptions** The VIP descriptions below provide a basic understanding of the important elements of each practice. Customization of VIPs beyond the basics is an important means to keep these practices able to

**FIG. 9-28** Ideal team makeup.

consistently produce results above those of good engineering and management practices.

**Classes of Facility Quality VIP** The Classes of Facility Quality VIP determines with the owner organization the design philosophies that will produce the desired levels of overall plant performance and associated risk consistent with the highest long-term profitability. The minimum categories considered include:

- Capital Expense (CAPEX) or Total Installed Costs (TIC)
- Planned Facility Life
- Expandability
- Level of Automation
- Equipment Selection
- Operating Expense (OPEX)
- Environmental Controls
- Capacity
- Technology

Some organizations have applied additional categories listed below to provide a greater level of definition (KBR VIP Program, 2007 through 2016).

- Energy Intensity
- Raw Material Flexibility
- Product Mix Flexibility
- Product Availability
- Product Quality
- Project Schedule
- Site Integration

This VIP individually confirms the best overall design philosophy for the project team, for each of the parameters listed above. Here, the designer first learns by category how risk-averse the owner organization is with respect to how the facility is to be designed, operated, and maintained. For example, if the plant is to have only commercially proven technology that has been in operation within the owner organization for at least 2 years, then the engineer will need to confirm prior to starting the process design what technologies have been so used and in what services.

Alternatively, if the plant must be equipped with environmental controls that must be demonstrated Best Available Control Technology (BACT) on all waste streams, then this performance level and the associated unit operations and equipment must be well understood before the process design is begun. The results of this VIP are used by the project management team to update their Project Execution Plan for each FEL phase. The Classes of Facility Quality VIP provides the best results when conducted just following project kick-off in the FEL-1 phase.

**Technology Selection VIP** The Technology Selection VIP is the application of evaluation criteria aligned with the project's business objectives to identify manufacturing and processing technology that may be superior to that currently used. The goal is to ensure that the technology suite finally selected is the most competitive available. This requires a systematic search—both inside and outside the operating company's organization—to identify emerging technology alternatives.

This formal facilitated process is also meant to ensure due diligence for all parties involved and that all emerging and near-commercial alternative technologies for accomplishing a particular processing function are objectively considered. This VIP should not be confused with the routine engineering practice of evaluating and selecting the best processing and equipment options for a given project application. Its focus should be on the new and emerging technology for the intended function. This VIP is most commonly applied at the unit operation level, although it has also been successfully applied at the major equipment level and to help select competing processing schemes (KBR VIP Program). This VIP is particularly effective for combating the "not invented here" syndrome.

The goals of this VIP are to document which technology evaluation criteria are applicable and then to conduct a formal technology screening and evaluation assessment. The result is a prioritized listing of technology options for each selected application or function for the project. The preferred time to execute this VIP is the midpoint in the FEL-1 phase.

**Process Simplification VIP** The Process Simplification VIP uses the Value Methodology and is a formal, rigorous means to identify opportunities to eliminate or combine process and utility system steps or equipment, ultimately reducing investment and operating costs. The focus is the reduction of installed costs and critical path schedule while balancing these value improvements with expected facility operability, flexibility, and overall life cycle costs.

The Process Simplification VIP is far more than just evaluating and simplifying processing steps. This very productive VIP ensures that low- or zero-value system and equipment functions included in the project scope are challenged by subject matter experts and eliminated, if possible. This VIP tries to systematically differentiate "wants" from "needs" and remove the wants. It can be especially effective for providing a neutral professional environment for identifying and challenging sacred cows and then removing them. Removal of these low- or zero-value functions yields significant profitability improvements to the overall project. Process Simplification results in

- Reduced capital expense (CAPEX)
- Improved critical-path schedule
- Reduced process inventory
- Increased yields
- Reduced operating and maintenance expense (OPEX)
- Increased productivity
- Incremental capacity gains
- Reduced utility and support systems requirements
- Reduced waste generation

Process Simplification is executed in a formal workshop with a trained experienced facilitator. This VIP should always include key participants from each of the project owner's organizations, the engineering contractor organization, key third-party technology licensors, and equipment or systems vendors, where possible. One or more "cold eyes" reviewers or subject matter experts, who have extensive experience, should also be included to provide an objective and unbiased perspective.

This VIP also provides a means for integrating overall plantwide systems. The Process Simplification VIP is typically performed during the FEL-2 phase after the preliminary PFDs and heat and material balances become available. However, for very large and complex projects, considerable value has been gained by also performing this VIP at the midpoint or later in the FEL-1 phase.

**Constructability VIP** The Constructability VIP is the systematic implementation of the latest engineering, procurement, and construction concepts and lessons learned consistent with the facility's intended operations and maintenance requirements. The goal is to enhance construction safety, scope, predictability, cost, schedule, and quality.

Since constructability has seen widespread implementation in industry for over 30 years, in order for constructability to remain consistent with the definition of a VIP (i.e., above what project teams can do on their own), something formal must be added to the standard work process. One large engineering and construction company has enhanced the standard constructability work process to include a formal facilitated workshop in each project phase. This formal VIP workshop seeks profitability improvements above those already identified by the project team in the course of their normal work (KBR VIP Program, 2000 through 2016). These formal VIP workshops and the standard work process are mutually additive, flexible, and compatible.

The traditional constructability work process includes the following characteristics:

- An ongoing structured work process that starts in the FEL-1 phase and continues through facility start-up
- Systematic implementation of the latest engineering, procurement, and construction lessons learned
- Optimized use of operations, maintenance, engineering, procurement, key vendors, and construction knowledge and experience
- Enhanced achievement of project objectives
- Construction experts working with engineering and procurement resulting in profitability improvements in construction safety, cost, schedule, and quality

The enhanced Constructability VIP workshops add the following to the traditional work process:

- Conducts formal facilitated workshops in every engineering phase of the project focused on the pertinent aspects of that phase
- Identifies additional design and execution options that improve project profitability above those already being considered by the traditional constructability work process
- Involves a detailed review of planning, design, procurement, fabrication, and installation functions to achieve the best overall project safety performance, lowest CAPEX, and the shortest reasonable schedule
- Includes considerations for operability and maintainability
- Uses on-project and off-project subject matter experts

Conducting a formal Constructability VIP workshop in the FEL-1 phase should focus on confirming the best overall project construction strategies. These strategies should cover the overall plot plan, equipment arrangements, potential congestion areas, construction and turnaround laydown areas, site access for equipment and modules, economic driving forces for modularization, heavy lifts, procurement limitations, fabrication and transport limitations, area labor limitations, and coordination with existing structures and facilities. The conceptual plot plan and satellite views of the site should be used.

Conducting a formal Constructability VIP workshop in the FEL-2 phase should focus on more specific topics of layout optimization using a preliminary plot plan, equipment layouts, and satellite views of the site. Considerations should include optimum site layout in terms of construction laydown areas; optimum equipment arrangement to reduce piping and steel for structures and pipe racks; specific sizes and weights for modules; which

components will be included in each module; module sequencing; crane locations for heavy lifts; equipment requiring early purchase to support the project critical path schedule; further analysis of procurement limitations; fabrication limitations; area labor availability; and pre-commissioning, commissioning, and start-up considerations. A preliminary 3D model should also be used, if available.

Conducting a formal Constructability VIP workshop in the FEL-3 phase focuses on even more detail for what was discussed above. If available, the preliminary 3D model will have more details than in FEL-2, especially if the project is a revamp or expansion. For these projects, incorporating tie-in details from laser scanning surveys into the 3D model should be strongly considered. This will then allow a more realistic determination of the scope of work that should be done before, during, and after a major planned maintenance turnaround.

In the detail engineering stage of the EPC phase, considerable detailed information will be available regarding engineering design and procurement, construction, and commissioning plans and schedules. In addition, the detailed 3D model and plot plans are recommended to be used as visual depictions of equipment and package systems footprints based on final vendor/supplier data as well as near-final pipe routings, steel detail, cable details, etc. The best timing for the Constructability VIP workshops is usually about three weeks ahead of the formal 3D model reviews, to allow workshop recommendations to be incorporated into the model before the formal reviews. Constructability VIP workshops should be formal and facilitated and should draw on personnel from operations, maintenance, and construction in addition to project and owner organization representation.

**Customization of Standards and Specifications VIP** The Customization of Standards and Specifications VIP is a direct and systematic method to improve project value by selecting aspects of applicable codes, standards, and specifications most appropriate for the project. The goal is to make needed changes to meet project performance requirements by ensuring that the codes, standards, and specifications selected do not exceed the minimum required for the project consistent with owner operation goals. Figure 9-29 shows the typical hierarchy of project guidelines and specifications and the focus areas of this VIP.

This VIP is beyond typical good engineering practices and should not be confused with ongoing systematic improvements to corporate standards and specifications, nor with required identification of applicable equipment and materials procurement specifications to be used for the project. This formal VIP takes a combination of project owner and engineering contractor corporate specifications and aggressively seeks profitability improvements consistent with the project's goals and limitations. This VIP promotes the procurement of off-the-shelf equipment over equipment customized for the project. This VIP is best performed early in the FEL-2 phase and should include project team members involved from the project owner and engineering contractor as well as appropriate suppliers of major packaged subsystems, modularized equipment, etc.

**Energy Optimization VIP** The Energy Optimization VIP is the systematic evaluation and economic optimization of energy use within a process or multiple subunits within a larger process or facility. This optimization starts by using the "Pinch" technology branch of process energy integration (energy pinch) to identify better process energy exchange options.

Energy pinch (usually just called *pinch*) is a methodology for the conceptual design of process heating, utility, and power systems. Pinch identifies the maximum theoretical energy use within a process, while minimizing the use of plant utilities. Such minimization is achieved by reusing energy via heat exchange between process streams. Once the minimum theoretical energy requirements and applicable process options have been determined, a formal facilitated workshop follows to determine which process options are operationally and economically supported by the owner's stakeholders.

This methodology is most profitably applied to processes where energy costs are a large fraction of the OPEX and to optimize high-value complex mass flow circuits, such as refinery crude unit pump-around circuits, refinery hydrogen networks (hydrogen pinch), and wastewater minimization (water pinch). This VIP is commonly applied to both Greenfield (new or grassroots plants) and Brownfield projects (revamps and expansions). This VIP should be implemented in the FEL-2 phase when preliminary PFDs and heat and material balances are available.

**Predictive Maintenance VIP** The Predictive Maintenance VIP is the proactive use of sensors and associated controls to monitor machinery mechanical "health," using both current-state and historical trends. This allows more effective planning of shutdowns and maintenance, thereby detecting equipment abnormalities and diagnosing potential problems before they cause permanent equipment damage. Examples include

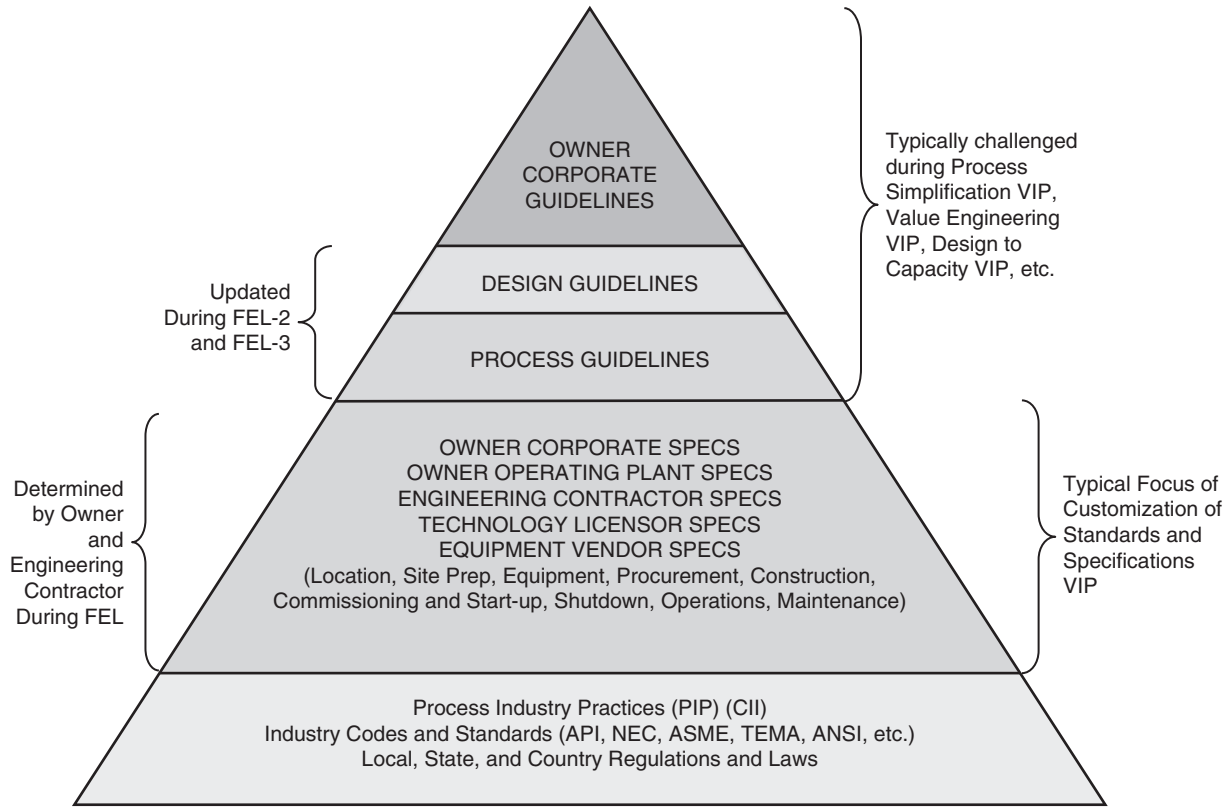

**FIG. 9-29** Typical hierarchy of project guidelines and specifications.

real-time corrosion monitoring and equipment vibration monitoring. This additional instrumentation is generally economically justified in the case of critical equipment items and key operations.

Predictive maintenance reduces maintenance costs, improves the confidence of extending time between turnarounds, improves reliability, and provides a more predictable maintenance schedule for key process equipment. It also minimizes the amount of remaining equipment life that is lost through using only preventive maintenance practices. Preventive maintenance is an older practice which is limited to periodic inspections and repairs to avoid unplanned equipment breakdowns.

For the Predictive Maintenance VIP to be effective, maintenance personnel from the project owner's organization must be involved in determining key predictive maintenance requirements. Suppliers of critical equipment items (e.g., compressors, turbines, large pumps) are also important participants in this process. Today, this VIP is considered by some operating companies and engineering contractors to be standard practice. Whether standard practice or not, consideration of the provisions required for portable and permanent predictive maintenance technology should be initiated in the FEL-2 phase and concluded prior to purchase of the equipment systems involved.

**Waste Minimization VIP** The Waste Minimization VIP involves a formal analysis of each process stream to identify ways to eliminate or reduce the waste streams generated by a chemical processing facility. For those waste streams not eliminated, reduced, or converted into saleable by-products, this VIP provides a formal method to identify ways to manage the resulting waste streams. Waste Minimization incorporates environmental requirements into the facility design and combines life cycle environmental benefits and positive economic returns through energy reduction, reduced end-of-pipe treatment requirements, and improved yield of products from feedstocks or raw materials. The waste reduction hierarchy used is as follows:

- Eliminate or minimize the generation of waste at the source (i.e., source reduction).
- Recycle by use, reuse, or reclamation those potential waste streams or materials that cannot be eliminated or minimized (i.e., recycle/reuse).
- Treat generated wastes to reduce volume, toxicity, or mobility prior to storage or disposal (i.e., end-of-pipe treatment).

This VIP is executed in a formal workshop with an experienced facilitator and with owner organization and engineering contractor representatives involved. A cold-eyes reviewer with extensive experience should also be included to add a nonbiased perspective. Today, this VIP is considered by many operating companies and engineering contractors to be standard practice. However, there still appears to be benefit in confirming the best handling, transportation, and final disposition of wastes generated. The best results are achieved when implemented in the FEL-2 phase.

**Process Reliability Simulation VIP** The Process Reliability Simulation VIP is the use of *reliability, availability, and maintainability* (RAM) computer simulation modeling of the process and the mechanical reliability of the facility. A principal goal is to optimize the engineering design in terms of life cycle cost, thereby maximizing the project's potential profitability. The objective is to determine the optimum relationships between maximum production rates and design and operational factors. Process reliability simulation is also applied for safety and environmental purposes, since it considers the consequences of specific equipment failures and failure modes.

This VIP is typically led by an engineer experienced in plant operations and use of the RAM simulation modeling software. The VIP should also directly involve the owner organization since they would most often supply the historical operating and maintenance information required for the development of the RAM model. This process provides the project team with a more effective means of assessing, early in the design, the economic impact of changes in process design, the technical and economic justification for installed spare equipment, identification of bottlenecks in the system, simulation of key operating scenarios, and training and maintenance requirements of a facility.

The Process Reliability Simulation VIP should be initiated in the FEL-2 phase to produce a block-level RAM model. Based on the results of that model, a more detailed equipment-level RAM model should be developed starting in the FEL-3 phase.

**Value Engineering VIP** The Value Engineering VIP applies the value methodology, which is a systematic and structured team approach to analyze the functions and essential characteristics of a program, project, process, technology, work process, or system in order to satisfy those functions and essential characteristics at the lowest life cycle cost. The value methodology helps achieve balance between required functions, performance, quality, safety, and scope with the cost and other resources necessary to accomplish those requirements. The proper balance results in the maximum value for the project.

This VIP tries to systematically differentiate wants from needs and remove the wants. It also tests for non-income-producing investments including redundancy, overdesign, manufacturing add-ons, upgraded materials of construction, and customized designs versus vendor standards. The Value Engineering VIP also ensures that low- or zero-value functions or equipment included in the project scope are challenged to be the highest value possible for the project. Removal of these low- or zero-value functions from the project scope, if possible, has been proven to yield significant economic improvements to the overall project. These can encompass the following:

- Misalignment of unit or system capacity or operations capability with respect to the overall facility
- Overly conservative assumptions of the basic design data
- Overly conservative interpretation of how the facilities will be used during peak, seasonal, or upset conditions
- Traditional design, layout, and operations approaches
- Preinvestment included in the project scope that may not be value added
- Overdesign of equipment or systems to provide uneconomic added flexibility

The Value Engineering VIP is executed in a formal workshop with an experienced technical workshop facilitator/leader. Both the owner organization and the engineering contractor are always involved. Third-party licensors and equipment/systems vendors should be included where applicable. A cold-eyes reviewer with extensive experience is also included to add a nonbiased perspective.

This VIP leverages the growing accumulation of more detailed project knowledge to test the value of earlier more generalized scope assumptions. It also tests the presumed added value of different stakeholder requirements, which have influenced the evolution of the project scope.

This highly adaptable VIP results in reduced CAPEX, improved critical-path schedule, reduced process inventory, increased yields, reduced OPEX, increased productivity, incremental capacity gains, reduced utility and support systems requirements, and reduced waste generation. The Value Engineering VIP is easily the most productive of the VIPs in terms of CAPEX reduction and the most adaptive. Results are best achieved when conducted early in the FEL-3 phase.

**Design to Capacity VIP** The Design to Capacity VIP systematically evaluates the maximum capacity of processing systems, major equipment, ancillary piping, valving, instrumentation, and associated engineering calculations and guidelines. This VIP reduces project capital investment by confirming minimum required system and equipment capacities and flexibility necessary to meet project business objectives. Design to Capacity drills down to each process system and subsystem and scrutinizes the design of each equipment item. The goal is to improve life cycle costs or project profitability by eliminating preinvestment and overdesign not supported by project economics. This VIP produces the best results when conducted in the FEL-2 phase as a facilitated workshop with both owner and engineering contractor representation.

**3D-CAD VIP** The 3D-CAD VIP is the creation of a detailed three-dimensional (3D) computer-aided design (CAD) model depicting the proposed process and associated equipment along with the optimized plant layout and specific equipment arrangements and orientations.

The principal benefit is to produce an electronic model of the intended facility to enable project teams and owner operations and maintenance staff to review and agree on the planned plant layout and equipment arrangements. The goals of this VIP are to reduce engineering and construction rework, improve operability and maintainability, and confirm the incorporation into the design of advantageous human factors (a.k.a. ergonomics) focused on ease of operation and maintenance.

Application of this VIP during the FEL phases involves creation of conceptual or preliminary level models to gain early stakeholder acceptance of plant layouts, multilevel structures such as modules, tie-in point details for revamp or expansion projects, and improved inputs to project cost estimate generation.

Application in the EPC phase involves more detailed 3D models based on specific equipment supplier information where engineering and construction rework can be reduced by supporting interference checks by the engineering disciplines involved prior to issuing fabrication or construction drawings. Development of 3D models throughout the project life cycle has become standard practice for most operating companies and major engineering and construction contractors.

**VIPs That Apply the Value Methodology** Many of the VIPs are conducted only once in a project at a "sweet spot" where maximum benefit is found. For some, they are conducted in each project phase using the same overall methodology, but with more detailed information and a slightly different mix of subject matter experts. The best such example is the Constructability VIP. Other VIPs such as Process Simplification and Value Engineering apply a more rigorous and adaptive methodology known as the *value methodology*. This methodology has produced excellent results in industry for more than 65 years [Society of American Value Engineers International (SAVE)].

Some organizations have applied the value methodology to additional VIPs such as Design to Capacity, Technology Selection, Waste Minimization, and Constructability to produce far better results (McCuish and Kaufman, 2016). Other organizations have applied VIPs in combination to better solve highly complex situations evident in large or complex projects where the owner is a joint venture or the engineering contractor is a joint venture (KBR VIP Program). For those VIPs where the value methodology is to be applied, a typical sequential approach is described below.

**Value Methodology Job Plan** The value methodology job plan focuses on the analysis of the "function" of each unit, unit operation, system, and equipment of the process—how it is expected to perform and to what expected degree of efficiency. Project execution functions are also identified and analyzed to validate them and identify value improvements. This analysis covers all aspects of the project including execution strategies, permitting issues, engineering and design issues, unresolved issues, construction execution issues, and project risks. Before the formal VIP workshop begins, the goals, objectives, and scheduled time for the workshop must be agreed to by the integrated project management team. The workshop facilitator/leader must ensure that all the information required for the workshop is available and the workshop team members are briefed on the objectives, methodology, and expectations.

**The Formal Workshop** The formal workshop should always be structured to make maximum use of the multidisciplinary team's time and effort. Such workshops typically require no less than 2 days and as many as 5 days depending on the size and complexity of the project. The required workshop length should be determined by the VIP facilitator. The workshop includes the following six phases of a typical "job plan" that are supported by the Society of American Value Engineers International.

***Information Phase*** Important project background information is reviewed to confirm understanding of the basis for design, project constraints, owner cost and reliability targets, and the sensitivity of expected plant capital and operating costs. Discussions of these issues' validity and basis are completed during the morning of the first workshop day. Experience consistently shows that the information phase overlaps significantly with the function analysis phase and the creative phase. That is, workshop attendees tend to generate ideas in the form of questions as they are being informed of the project basis and when updating the *function analysis system technique* (FAST) diagram. Such spontaneous idea generation should be encouraged.

***Function Analysis Phase*** The team analyzes the project scope to understand and clarify the required processing and execution functions. To enable this, a draft project FAST diagram is prepared prior to the workshop. This function analysis diagramming illustrates the logical or functional relationships and dependencies between different process systems and project activities and their associated costs. In the workshop, the team reviews, discusses, and modifies the draft "overall project" FAST diagram to identify the highest-value functions that offer the greatest potential to improve project value or profitability. These highest-value functions present targets of opportunity where brainstorming should be focused.

***Creative or Speculation Phase*** Once the pertinent information and issues have been reviewed and the important functions of each process and project step identified, the team is encouraged to speculate or brainstorm for alternative means to accomplish the targeted functions. A creative environment is strictly maintained to encourage the unconstrained flow of new ideas and to encourage the team to strive for fresh, innovative ideas. All ideas generated are listed—no ideas are deleted. Most importantly, no analysis or judgment of ideas is allowed in this phase. Ideas are then generated as the team reviews process and utility flow diagrams and plot plans with simultaneous focus on the project functions previously identified. In this way, the "targets of opportunity" or functions within the project FAST diagram allow the team to focus all their effort on the targets most likely to reveal realistic value improvement ideas.

***Evaluation or Analytical Phase*** The team reviews the ideas against relevant project criteria such as potential impact on long-term economics, impact on plant operations and maintenance costs, effect on capital cost, applicability to the project scope of work, technical and execution risks associated with implementation, impact on project schedule, and cost and resources required to implement the improvement. Each workshop has specific criteria against which proposed alternatives are judged. The ideas are weighted, sorted, grouped, linked, and ranked so that the best of the technically viable ideas are efficiently identified for further study.

***Development or Proposal Phase*** The VIP team selects and expands the ideas ranked highest (i.e., best potential value to be gained) to obtain additional technical and economic insights and information to support those ideas. Each selected idea is assigned to a workshop team member best equipped to render an objective analysis of the idea when compared to the current project scope and premises. This analysis involves written proposals where potential benefits, costs, and risks are estimated in the workshop. Experience indicates that having the VIP team perform this stage within the formal workshop produces the best results. The written proposals are then presented to the other workshop team members by those who prepared them and are discussed sufficiently to reach consensus on whether the ideas retain sufficient technical and economic merit to become workshop value recommendations.

***Presentation Phase*** The workshop team presents orally and with supporting available materials the agreed value recommendations to the project stakeholders. These stakeholders are often the integrated project management team. Ideally, higher-level owner stakeholders arrive near the end of the workshop to hear the workshop team's recommendations. The owner stakeholders then approve only those recommendations that pass muster and authorize the project team to begin the implementation effort. For team recommendations that offer insufficient value improvement, the owner stakeholder rationales for not approving those recommendations are noted. In some cases, the owner has given workshop team members the authority to approve or reject workshop team recommendations. Often, this approval is conditional on early validation by owner subject matter experts. Approval is meant to provide support to the project team for additional resources and schedule consideration to incorporate fully the value improvements into the project scope of work.

**Reporting and Follow-Up** After completing the formal VIP workshop, the workshop facilitator/leader completes and issues the written VIP workshop report for the project record. During this time, the project management team assigns each approved recommendation to a member of the project team and estimates the engineering time and resources required to incorporate the improvement into the project scope of work. The assigned team member evaluates further each workshop recommendation to confirm both technical and economic viability. Important considerations are the potential impact on the project schedule and the timely development and completion of key project deliverables. If the recommendation remains attractive following this evaluation, it is presented to the owner management team for final approval. If approved, the project scope is revised accordingly via the project Management of Change protocol. The management team then communicates the results of the VIP effort within the integrated project team. This follow-up action plan creates a very positive and cost-conscious attitude within the project team that leads to further improvements in project value.

# GLOSSARY

***Accounts payable*** The value of purchased goods and services that are being used but have not been paid.

***Accounts receivable*** Credit extended to customers, usually on a 30-day basis. Cash is set aside to take care of the probability that some customers may not pay their bills.

***Accrual basis*** The accounting method that recognizes revenues and disbursement of funds by receipt of bills or orders and not by cash flow, distinguished from cash basis.

***Administrative expense*** An overhead expense due to the general direction of a company beyond the plant level. It includes administrative and office salaries, rent, auditing, accounting, legal, central purchasing and engineering, etc., expenses.

***Allocation of expenses*** A procedure whereby overhead expenses and other indirect charges are assigned back to processing units or to products on what is expected to be an equitable basis. All allocations are somewhat arbitrary.

***Amortization*** Often used interchangeably with *depreciation*, but there is a slight difference depending on whether the life of an asset is known. If the period of time is known to be usually more than a year, this annual expense is amortization; however, if the life is estimated, then it is depreciation.

***Annual net sales*** Pounds of product sold times the net selling price. Net means that any allowances have been subtracted from the gross selling price.

***Annual report*** Management's report to the stockholders and other interested parties at the end of a year of operation showing the status of the company, its activities, funds, income, profits, expenses, and other information.

***Appurtenances*** The auxiliaries to either process or nonprocess equipment: piping, electrical, insulation, instrumentation, etc.

***Assets*** The list of money on hand, marketable securities, monies due, investments, plants, properties, intellectual property, inventory, etc., at cost or market value, whichever is smaller. The assets are what a company (or person) owns.

***Balance sheet*** This is an accounting, historical tabulation of assets, liabilities, and stockholders' equity for a company. The assets must equal the liabilities plus the stockholders' equity.

***Battery limit*** A geographic boundary defining the coverage of a specific project. Usually it takes in the manufacturing area of a proposed plant, including all process equipment but excluding provision for storage, site preparation, utilities, administrative buildings, or auxiliary facilities.

***Bonds*** When one purchases a bond, the company (or person) acquires an interest in debt and becomes a creditor of the company. The purchaser receives the right to receive regular interest payments and the subsequent repayment of the principal.

***Book value*** Current investment value on the company books as the original installed cost less depreciation accruals.

***Book value of common stock*** Net worth of a firm divided by the number of shares of common stock issued at the time of a report.

***Break-even chart*** An economic production chart depicting total revenue and total expenses as functions of operation of a processing facility.

***Break-even point*** The percentage of capacity at which income equals all fixed and variable expenses at that level of operation.

***By-product*** A product made as a consequence of the production of a main product. The by-product may have a market value or a value as a raw material.

***Capacity*** The estimated maximum level of production on a sustained basis.

***Capital ratio*** Ratio of capital investment to sales dollars; the reciprocal of capital turnover.

***Capital recovery*** The process by which original investment in a project is recovered over its life.

***Capital turnover*** The ratio of sales dollars to capital investment; the reciprocal of capital ratio.

***Cash*** Money that is on hand to pay for operating expenses, e.g., wages, salaries, raw materials, supplies, etc., to maintain a liquid financial position.

***Cash basis*** The accounting basis whereby revenue and expense are recorded when cash is received and paid, distinguished from accrual basis.

***Cash flow*** Net income after taxes plus depreciation (and depletion) flowing into the company treasury.

***Code of accounts*** A system in which items of expense or fixed capital such as equipment and material are identified with numerical figures to facilitate accounting and cost control.

***Common stock*** Money paid into a corporation for the purchase of shares of common stock that becomes the permanent capital of the firm. Common stockholders have the right to transfer ownership and may sell the stock to individuals or firms. Common stockholders have the right to vote at annual meetings on company business or may do so by proxy.

***Compound interest*** The interest charges under the condition that interest is charged on previous interest plus principal.

***Contingencies*** An allowance for unforeseeable elements of cost in fixed investment estimates that previous experience has shown to exist.

***Continuous compounding*** A mathematical procedure for evaluating compound interest based upon continuous interest function rather than discrete interest periods.

***Conversion expense*** The expense of converting raw materials to finished product.

***Corporation*** In 1819, defined by Chief Justice Marshall of the Supreme Court as "an artificial being, invisible, intangible and existing only in contemplation of law." It exists by the grace of a state, and the laws of a state govern the procedure for its formation.

***Cost of capital*** The cost of borrowing money from all sources, namely, loans, bonds, and preferred and common stock. It is expressed as an interest rate.

***Cost center*** For accounting purposes, a grouping of equipment and facilities comprising a product manufacturing system.

***Cost of sales*** The sum of the fixed and variable (direct and indirect) expenses for manufacturing a product and delivering it to a customer.

***Decision or decision making*** A program of action undertaken as a result of (1) an established policy or (2) an analysis of variables that can be altered to influence a final result.

***Depletion*** A provision in the tax regulations that allows a business to charge as current expense a noncash expense representing the portion of limited natural resources consumed in the conduct of business.

***Depreciation*** A reasonable allowance by the Internal Revenue Service for the exhaustion, wear and tear, and normal obsolescence of equipment used in a trade or business. The property must have a useful life of more than 1 year. Depreciation is a noncash expense deductible from income for tax purposes.

***Design to cost*** A management technique to achieve system designs that meet cost parameters. Cost as a design parameter is considered on a continuous basis as part of a system's development and production processes.

***Direct expense*** An expense directly associated with the production of a product such as utilities, labor, and maintenance.

***Direct labor expense*** The expense of labor involved in the manufacture of a product or in the production of a service.

***Direct material expense*** The expense associated with materials consumed in the manufacture of a product or the production of a service.

***Distribution expense*** Expense including advertising, preparation of samples, travel, entertainment, freight, warehousing, etc., to distribute a sample or product.

***Dollar volume*** Dollar's worth of a product manufactured per unit of time.

***Earnings*** The difference between income and operating expenses.

***Economic life*** The period of commercial use of a product or facility. It may be limited by obsolescence, physical life of equipment, or changing economic conditions.

***Economic value added*** The period dollar profit above the cost of capital. It is a means to measure an organization's value and a way to determine how management's decisions contribute to the value of a company.

***Effective interest*** The true value of interest computed by equations for the compound interest rate for a period of 1 year.

***Equity*** The owner's actual capital held by a company for its operations.

***Escalation*** A provision in actual or estimated cost for an increase in equipment cost, material, labor, expenses, etc., over those specified in an original estimate or contract due to inflation.

***External funds*** Capital obtained by selling stocks or bonds or by borrowing.

***FEL (front-end loading)*** The process by which a company develops a detailed definition of the scope of a capital project that meets corporate business objectives.

***FIFO (first in, first out)*** The valuation of raw material and supplies inventory, meaning first into the company or process is the first used or out.

***Financial expense*** The charges for use of borrowed funds.

***Fixed assets*** The real or material facilities that represent part of the capital in an economic venture.

***Fixed capital*** Item including the equipment and buildings.

***Fixed expense*** An expense that is independent of the rate of output, e.g., depreciation and plant indirect expenses.

***Fringe benefits*** Employee welfare benefits; expenses of employment over and above compensation for actual time worked, such as holidays, vacations, sick leave, and insurance.

***Full-cost accounting*** Method of pricing goods and services to reflect their true costs, including production, use, recycling, and disposal.

***Future worth*** The expected value of capital in the future according to some predetermined method of computation.

***Goods manufactured, cost of*** Total expense (direct and indirect expenses) including overhead charges.

***Goods-in-process inventory*** The holdup of product in a partially finished state.

***Goods sold, cost of*** The total of all expenses before income taxes that is deducted from income (revenue).

***Grass-roots plant*** A complete plant erected on new site including land, site preparation, battery-limits facilities, and auxiliary facilities.

***Gross domestic product*** An indicator of a country's economic activity. It is the sum of all goods and services produced by a nation within its borders.

***Gross margin (profit)*** Total revenue minus cost of goods manufactured.

***Gross national product*** An economic indicator of a country's economic activity. It is the sum of all the goods and services produced by a nation both within and outside its borders.

***Income*** Profit before income taxes or gross income from sales before deduction of expenses.

***Income statement*** The statement of earnings of a firm as approximated by accounting practices, usually covering a 1-year period.

***Income tax*** The tax imposed on corporate profits by the federal and/or state governments.

***Indirect expenses*** Part of the manufacturing expense of a product not directly related to the amount of product manufactured, e.g., depreciation, local taxes, and insurance.

***Internal funds*** Capital available from depreciation and accumulated retained earnings.

***Inventory*** The quantity of raw materials and/or supplies held in a process or in storage.

***Last in, first out (LIFO)*** The valuation of raw materials and supplies, meaning the last material into a process or storage is the first used or out.

***Leverage*** The influence of debt on the earning rate of a company.

***Liabilities*** An accounting term for capital owed by a company.

***Life cycle cost*** Cost of development, acquisition, support, and disposal of a system over its full life.

***Manufacturing expense*** The sum of the raw material, labor, utilities, maintenance, depreciation, local taxes, etc., expenses. It is the sum of the direct and indirect (fixed and variable) manufacturing expenses.

***Marginal cost*** The incremental cost of making one additional unit without additional investment in facilities.

***Market capitalization*** The product of the number of shares of common stock outstanding and the share price.

***Market value added*** A certain future economic value added for a company. It is the present value of the future economic value (EVA) generated by a company. It is a measure of how much value a firm has created.

***Minimum acceptable rate of return (MARR)*** The level of return on investment, at or above the cost of capital, chosen as acceptable for discounting or cutoff purposes.

***Net sales price*** Gross sales price minus freight adjustments.

***Net worth*** The sum of the stockholders' investment plus surplus, or total assets minus total liabilities.

***Nominal interest*** The number applied loosely to describe the annual interest rate.

***Obsolescence*** The occurrence of decreasing value of physical assets due to technological changes rather than physical deterioration.

***Operating expense*** The sum of the manufacturing expenses for a product and the general, administrative, and selling expenses.

***Operating margin*** The gross margin minus the general, administrative, and selling expenses.

***Opportunity cost*** The estimate of values that are forgone by undertaking one alternative instead of another one.

***Payout time (payback period)*** The time to recover the fixed capital investment from profit plus depreciation. It is usually after taxes but not always.

***Preferred stock*** Stock having claims that it commands over common stock, with the preference related to dividends. The holders of such stock receive dividends before any distribution is made to common stockholders. Preferred stockholders usually do not have voting rights as common stockholders do.

***Present worth*** The value at some datum time (present time) of expenditures, costs, profits, etc., according to a predetermined method of computation. It is the current value of cash flow obtained by discounting.

***Production rate*** The amount of product manufactured in a given time period.

***Profitability*** A term generally applied in a broad sense to the economic feasibility of a proposed venture or an ongoing operation. It is generally considered to be related to return on investment.

***Rate of return on investment*** The efficiency ratio relating profit or cash flow to investment.

***Replacement*** A new facility that takes the place of an older facility with no increase in capacity.

***Revenue*** The net sales received from the sale of a product or a service to a customer.

***Sales, administration, research, and engineering expenses (SARE)*** Overhead expenses incurred as a result of maintaining sales offices and administrative offices and the expense of maintaining research and engineering departments. This item is usually expressed as a percentage of annual net sales.

***Sales volume*** The amount of sales expressed in pounds, gallons, tons, cubic feet, etc., per unit of time.

***Salvage value*** The value that can be realized from equipment or other facilities when taken out of service and sold.

***Selling expense*** Salaries and commissions paid to sales personnel.

***Simple interest*** The interest charges in any time period that is charged on only the principal.

***Sinking fund*** An accounting procedure computed according to a specified procedure to provide capital to replace an asset.

***Surplus*** The excess of earnings over expenses that is not distributed to stockholders.

***Tax credit*** The amount available to a firm as part of its annual return because of deductible expenses for tax purposes. Examples have been research and development expenses, energy tax credit, etc.

***Taxes*** In a manufacturing cost statement, usually property taxes. In an income statement, usually federal and state income taxes.

***Time value of money*** The expected interest rate that capital should or would earn. Money has value with respect to time.

***Total operating investment*** The fixed capital investment, backup capital, auxiliary capital, utilities and services capital, and working capital.

***Utilities and services capital*** Electrical substations, plant sewers, water distribution facilities, and occasionally the steam plant.

***Value added*** The difference between the raw material expense and the selling price of that product.

***Value-improving practices (VIPs)*** Formal structured practices applied to capital projects to improve profitability ("or value") above that which is attained through the application of proven good engineering and project management practices.

***Variable expense*** Any expense that varies directly with production output.

***Working capital*** In the accounting sense, the current assets minus the current liabilities. It consists of the total amount of money invested in raw materials, supplies, goods in process, product inventories, accounts receivable, and cash minus those liabilities due within 1 year.

# Transport and Storage of Fluids

**Meherwan P. Boyce, Ph.D., P.E.** *(Deceased) Chairman and Principal Consultant, The Boyce Consultancy Group, LLC; Fellow, American Society of Mechanical Engineers (U.S.); Fellow, National Academy Forensic Engineers (U.S.); Fellow, Institution of Mechanical Engineers (U.K.); Fellow, Institution of Diesel and Gas Turbine Engineers (U.K.); Registered Professional Engineer (Texas), Chartered Engineer (U.K.); Sigma Xi, Tau Beta Pi, Tau Beta Pi, Phi Kappa Phi. Section Editor, Perry's Chemical Engineering Handbook, Measurement of Flow, Pumps and Compressors, Piping, Storage and Process Vessels, 7th ed.; and Joint Section Editor, 8th and 9th eds.*

**Victor H. Edwards, Ph.D., P.E.** *Principal, VHE Technical Analysis; Fellow and Life Member, American Institute of Chemical Engineers; Member, American Association for the Advancement of Science, American Chemical Society, National Society of Professional Engineers; Life Member, New York Academy of Sciences; Registered Professional Engineer (Texas), Phi Lambda Upsilon, Sigma Tau; Joint Section Editor, 8th and 9th eds.*

**Roy A. Grichuk, P.E.** *Piping Director, Fluor, BSME, P.E.; Member, American Society of Mechanical Engineers, B31 Main Committee, B31MTC Committee, and B31.3 Committee; Registered Professional Engineer (Texas) (Piping)*

**Hugh D. Kaiser, P.E., B.S., M.B.A.** *Principal Engineer, WSP USA; Fellow, American Institute of Chemical Engineers; Registered Professional Engineer (Indiana, Nebraska, Oklahoma, and Texas) (Storage and Process Vessels)*

**Ronnie Montgomery,** *Technical Manager, Process Control Systems, IHI Engineering and Construction International Corporation; Member, Process Industries Practices, Process Controls Function Team; Member, International Society of Automation (Flow Measurement)*

## MEASUREMENT OF FLOW

Introduction ..... 10-6
Properties and Behavior of Fluids ..... 10-6
Total Temperature ..... 10-7
  Thermocouples ..... 10-7
  Resistive Thermal Detectors ..... 10-7
Static Temperature ..... 10-7
Dry- and Wet-Bulb Temperatures ..... 10-7
Pressure Measurements ..... 10-7
  Liquid-Column Manometers ..... 10-7
  Closed U Tubes ..... 10-8
  Tube Size for Manometers ..... 10-8
  Multiplying Gauges ..... 10-8
  Mechanical Pressure Gauges ..... 10-8
  Conditions of Use ..... 10-8
  Calibration of Gauges ..... 10-8
Static Pressure ..... 10-9
  Local Static Pressure ..... 10-9
  Average Static Pressure ..... 10-9
  Specifications for Piezometer Taps ..... 10-9
Velocity Measurements ..... 10-10
  Variables Affecting Measurement ..... 10-10
  Velocity Profile Effects ..... 10-10
  Other Flow Disturbances ..... 10-10
  Pitot Tubes ..... 10-10
  Special Tubes ..... 10-11
  Traversing for Mean Velocity ..... 10-11
Flowmeters ..... 10-12
Industry Guidelines and Standards ..... 10-13
Classification of Flowmeters ..... 10-14
  Differential Pressure Meters ..... 10-14
  Velocity Meters ..... 10-14
  Mass Meters ..... 10-14
  Volumetric Meters ..... 10-14
  Variable-Area Meters ..... 10-14
  Open-Channel Flow Measurement ..... 10-14
Differential Pressure Flowmeters ..... 10-14
  General Principles ..... 10-14
  Orifice Meters ..... 10-14
  Venturi Meters ..... 10-16
  Flow Nozzles ..... 10-17
  Critical Flow Nozzle ..... 10-17
  Elbow Meters ..... 10-18
  Accuracy ..... 10-18
Velocity Meters ..... 10-19
  Anemometers ..... 10-19
  Turbine Flowmeters ..... 10-19
Mass Flowmeters ..... 10-20
  General Principles ..... 10-20
  Axial-Flow Transverse-Momentum Mass Flowmeter ..... 10-20
  Inferential Mass Flowmeter ..... 10-20
  Coriolis Mass Flowmeter ..... 10-20
Variable-Area Meters ..... 10-20
  General Principles ..... 10-20
  Rotameters ..... 10-20
Two-Phase Systems ..... 10-21
  Gas-Solid Mixtures ..... 10-21
  Gas-Liquid Mixtures ..... 10-21
  Liquid-Solid Mixtures ..... 10-21
Flowmeter Selection ..... 10-21

## PUMPS AND COMPRESSORS

Introduction ... 10-22
Terminology ... 10-22
- Displacement ... 10-22
- Centrifugal Force ... 10-22
- Electromagnetic Force ... 10-22
- Transfer of Momentum ... 10-22
- Mechanical Impulse ... 10-22
- Measurement of Performance ... 10-22
- Capacity ... 10-22

Pumps ... 10-22
- Total Dynamic Head ... 10-22
- Total Suction Head ... 10-22
- Static Suction Head ... 10-23
- Total Discharge Head ... 10-23
- Static Discharge Head ... 10-23
- Velocity ... 10-23
- Velocity Head ... 10-24
- Viscosity ... 10-24
- Friction Head ... 10-24
- Work Performed in Pumping ... 10-24

Pump Selection ... 10-24
- Range of Operation ... 10-24

Net Positive Suction Head ... 10-24
- Suction Limitations of a Pump ... 10-24
- NPSH Requirements for Other Liquids ... 10-25
- Example 10-1 NPSH Calculation ... 10-25

Pump Specifications ... 10-25
Positive-Displacement Pumps ... 10-25
- Reciprocating Pumps ... 10-25
- Piston Pumps ... 10-25
- Plunger Pumps ... 10-25
- Diaphragm Pumps ... 10-25
- Rotary Pumps ... 10-27
- Gear Pumps ... 10-27
- Screw Pumps ... 10-27

Centrifugal Pumps ... 10-27
- Casings ... 10-27
- Action of a Centrifugal Pump ... 10-28
- Centrifugal Pump Characteristics ... 10-28
- System Curves ... 10-28
- Pump Selection ... 10-28
- Process Pumps ... 10-29
- Sealing the Centrifugal Chemical Pump ... 10-29
- Double-Suction, Single-Stage Pumps ... 10-31
- Close-Coupled Pumps ... 10-31
- Canned-Motor Pumps ... 10-31
- Vertical Pumps ... 10-31
- Sump Pumps ... 10-33
- Multistage Centrifugal Pumps ... 10-33

Propeller and Turbine Pumps ... 10-33
- Axial-Flow (Propeller) Pumps ... 10-33
- Turbine Pumps ... 10-33
- Regenerative Pumps ... 10-33

Jet Pumps ... 10-35
Pump Diagnostics ... 10-35

## COMPRESSORS

- Compressor Selection ... 10-37

Compression of Gases ... 10-38
- Theory of Compression ... 10-38
- Adiabatic Calculations ... 10-38
- Reciprocating Compressors ... 10-39

Fans and Blowers ... 10-42
- Axial-Flow Fans ... 10-43
- Centrifugal Blowers ... 10-44
- Forward-Curved Blade Blowers ... 10-44
- Backward-Curved Blade Blowers ... 10-44
- Fan Performance ... 10-45

Continuous-Flow Compressors ... 10-45
- Centrifugal Compressors ... 10-45
- Compressor Configuration ... 10-46
- Impeller Fabrication ... 10-47
- Axial-Flow Compressors ... 10-48
- Positive-Displacement Compressors ... 10-48
- Rotary Compressors ... 10-49

Ejectors ... 10-50
- Ejector Performance ... 10-50
- Uses of Ejectors ... 10-50

Vacuum Systems ... 10-51
- Vacuum Equipment ... 10-51

Sealing of Rotating Shafts ... 10-51
- Noncontacting Seals ... 10-51
- Labyrinth Seals ... 10-51
- Ring Seals ... 10-54
- Fixed Seal Rings ... 10-54
- Floating Seal Rings ... 10-54
- Packing Seal ... 10-55
- Mechanical Face Seals ... 10-55
- Mechanical Seal Selection ... 10-55
- Internal and External Seals ... 10-57
- Throttle Bushings ... 10-57
- Materials ... 10-57

Bearings ... 10-58
- Types of Bearings ... 10-58
- Thrust Bearings ... 10-58
- Thrust Bearing Power Loss ... 10-59

Centrifugal Compressor Problems ... 10-59
- Compressor Fouling ... 10-60
- Compressor Failures ... 10-61
- Impeller Problems ... 10-61
- Rotor Thrust Problems ... 10-61
- Journal Bearing Failures ... 10-62
- Thrust Bearing Failures ... 10-62
- Compressor Seal Problems ... 10-62

Rotor Dynamics ... 10-63
Vibration Monitoring ... 10-63
- Example 10-2 Vibration ... 10-64

## PROCESS PLANT PIPING

Introduction ... 10-65
Codes and Standards ... 10-65
- Units: Pipe and Tubing Sizes and Ratings ... 10-65
- Pressure-Piping Codes ... 10-65
- National Standards ... 10-65
- Government Regulations: OSHA ... 10-65
- International Regulations ... 10-65

Code Contents and Scope ... 10-65
Selection of Pipe System Materials ... 10-67
- General Considerations ... 10-67
- Specific Material Considerations—Metals ... 10-67
- Specific Material Considerations—Nonmetals ... 10-67

Metallic Piping System Components ... 10-67
- Seamless Pipe and Tubing ... 10-68
- Welded Pipe and Tubing ... 10-68
- Tubing ... 10-69
- Methods of Joining Pipe ... 10-69
- Flanged Joints ... 10-72
- Ring Joint Flanges ... 10-74
- Bolting ... 10-74
- Miscellaneous Mechanical Joints ... 10-74
- Pipe Fittings and Bends ... 10-78
- Valves ... 10-79

Cast Iron, Ductile Iron, and High-Silicon Iron Piping Systems ... 10-87
- Cast Iron and Ductile Iron ... 10-87
- High-Silicon Iron ... 10-87

Nonferrous Metal Piping Systems ... 10-88
- Aluminum ... 10-88
- Copper and Copper Alloys ... 10-88
- Nickel and Nickel Alloys ... 10-88
- Titanium ... 10-89
- Flexible Metal Hose ... 10-89

Nonmetallic Pipe and Metallic Piping Systems with Nonmetallic Linings ... 10-89
- Cement-Lined Carbon-Steel Pipe ... 10-89
- Concrete Pipe ... 10-89
- Glass Pipe and Fittings ... 10-91
- Glass-Lined Steel Pipe and Fittings ... 10-92
- Fused Silica or Fused Quartz ... 10-92
- Plastic-Lined Steel Pipe ... 10-92
- Rubber-Lined Steel Pipe ... 10-93
- Plastic Pipe ... 10-93
- Reinforced-Thermosetting-Resin (RTR) Pipe ... 10-94

Design of Piping-Systems ... 10-94
- Safeguarding ... 10-94
- Classification of Fluid Services ... 10-94
- Category D ... 10-94
- Category M ... 10-94
- Design Conditions ... 10-94
- Effects of Support, Anchor, and Terminal Movements ... 10-95
- Reduced Ductility ... 10-95
- Cyclic Effects ... 10-95
- Air Condensation Effects ... 10-95
- Design Criteria: Metallic Pipe ... 10-95
- Limits of Calculated Stresses due to Sustained Loads and Displacement Strains ... 10-96

Pressure Design of Metallic Components ... 10-96
Test Conditions ... 10-97
Thermal Expansion and Flexibility: Metallic Piping ... 10-99
Reactions: Metallic Piping ... 10-106
Pipe Supports ... 10-108
Design Criteria: Nonmetallic Pipe ... 10-108
Fabrication, Assembly, and Erection ... 10-110
Welding, Brazing, or Soldering ... 10-110
Bending and Forming ... 10-111
Preheating and Heat Treatment ... 10-111
Joining Nonmetallic Pipe ... 10-111
Assembly and Erection ... 10-111
Examination, Inspection, and Testing ... 10-111
Examination and Inspection ... 10-111
Examination Methods ... 10-112
Type and Extent of Required Examination ... 10-113
Impact Testing ... 10-115
Pressure Testing ... 10-115
Cost Comparison of Piping Systems ... 10-119
Forces of Piping on Process Machinery and Piping Vibration ... 10-119
Heat Tracing of Piping Systems ... 10-119
Types of Heat-Tracing Systems ... 10-119
Choosing the Best Tracing System ... 10-123

## STORAGE AND PROCESS VESSELS

Storage of Liquids ... 10-124
Atmospheric Tanks ... 10-124
Shop-Fabricated Storage Tanks ... 10-124
USTs versus ASTs ... 10-124
Aboveground Storage Tanks ... 10-124
Pressurized Tanks ... 10-127
Calculation of Tank Volume ... 10-127
Container Materials and Safety ... 10-128
Pond and Underground Storage ... 10-128
Underground Cavern Storage ... 10-129
Storage of Gases ... 10-131
Gas Holders ... 10-131
Solution of Gases in Liquids ... 10-131
Storage in Pressure Vessels, Bottles, and Pipelines ... 10-131
Materials ... 10-132
Cavern Storage ... 10-132
Cost of Storage Facilities ... 10-132
Bulk Transport of Fluids ... 10-133
Pipelines ... 10-133
Tanks ... 10-133
Tank Cars ... 10-134
Tank Trucks ... 10-134
Marine Transportation ... 10-134
Materials of Construction for Bulk Transport ... 10-134
Pressure Vessels ... 10-134
Code Administration ... 10-134
ASME Code Section VIII, Division 1 ... 10-135
ASME BPVC Section VIII, Division 2 ... 10-138
Additional ASME Code Considerations ... 10-139
Other Regulations and Standards ... 10-140
Standards of Tubular Exchanger Manufacturers Association (TEMA) ... 10-140
Vessels with Unusual Construction ... 10-140
ASME Code Developments ... 10-141
Vessel Codes Other than ASME ... 10-141
Vessel Design and Construction ... 10-141
Care of Pressure Vessels ... 10-141
Pressure-Vessel Cost and Weight ... 10-142

### Nomenclature and Units

In this list, symbols used in the section are defined in a general way, and appropriate SI and U.S. Customary System (USCS) units are given. Specific definitions, as denoted by subscripts, are stated at the place of application in the section. Some specialized symbols used in the section are defined only at the place of application.

| Symbol | Definition | SI units | U.S. customary units |
|---|---|---|---|
| $A$ | Area | $m^2$ | $ft^2$ |
| $A$ | Factor for determining minimum value of $R_1$ | | |
| $A_\infty$ | Free-stream speed of sound | | |
| $a$ | Area | $m^2$ | $ft^2$ |
| $a$ | Duct or channel width | m | ft |
| $a$ | Coefficient, general | | |
| $B$ | Height | m | ft |
| $b$ | Duct or channel height | m | ft |
| $b$ | Coefficient, general | | |
| $C$ | Coefficient, general | | |
| $C$ | Conductance | $m^3/s$ | $ft^3/s$ |
| $C$ | Sum of mechanical allowances (thread or groove depth) plus corrosion or erosion allowances | mm | in |
| $C$ | Cold-spring factor | | |
| $C$ | Constant | | |
| $C_a$ | Capillary number | Dimensionless | Dimensionless |
| $C_1$ | Estimated self-spring or relaxation factor | | |
| $c_p$ | Constant-pressure specific heat | J/(kg·K) | Btu/(lb·°R) |
| $c_v$ | Constant-volume specific heat | J/(kg·K) | Btu/(lb·°R) |
| $D$ | Diameter | m | ft |
| $D$, $D_0$ | Outside diameter of pipe | mm | in |
| $d$ | Diameter | m | ft |
| $E$ | Modulus of elasticity | $N/m^2$ | $lbf/ft^2$ |
| $E$ | Quality factor | | |
| $E_a$ | As-installed Young's modulus | MPa | $kip/in^2$ (ksi) |
| $E_c$ | Casting quality factor | | |
| $E_j$ | Joint quality factor | | |
| $E_m$ | Minimum value of Young's modulus | MPa | $kip/in^2$ (ksi) |
| $F$ | Force | N | lbf |
| $F$ | Friction loss | (N·m)/kg | (ft·lbf)/lb |
| $F$ | Correction factor | Dimensionless | Dimensionless |
| $f$ | Frequency | Hz | l/s |
| $f$ | Friction factor | Dimensionless | Dimensionless |
| $f$ | Stress-range reduction factor | | |
| $G$ | Mass velocity | $kg/(s·m^2)$ | $lb/(s·ft^2)$ |
| $g$ | Local acceleration due to gravity | $m/s^2$ | $ft/s^2$ |
| $g_c$ | Dimensional constant | 1.0 (kg·m)/(N·$s^2$) | 32.2 (lb·ft)/(lbf·$s^2$) |
| $H$ | Depth of liquid | m | ft |
| $H$, $h$ | Head of fluid, height | m | ft |
| $H_{ad}$ | Adiabatic head | N·m/kg | lbf·ft/lbm |
| $h$ | Flexibility characteristic | | |
| $h$ | Height of truncated cone; depth of head | m | in |
| $i$ | Specific enthalpy | J/kg | Btu/lb |
| $i$ | Stress-intensification factor | | |
| $i_i$ | In-plane stress-intensification factor | | |
| $i_o$ | Out-plane stress intensification factor | | |
| $I$ | Electric current | A | A |
| $J$ | Mechanical equivalent of heat | 1.0 (N·m)/J | 778 (ft·lbf)/Btu |
| $K$ | Index, constant or flow parameter | | |
| $K$ | Fluid bulk modulus of elasticity | $N/m^2$ | $lbf/ft^2$ |
| $K_1$ | Constant in empirical flexibility equation | | |
| $k$ | Ratio of specific heats | Dimensionless | Dimensionless |
| $k$ | Flexibility factor | | |
| $k$ | Adiabatic exponent $c_p/c_v$ | | |
| $L$ | Length | m | ft |
| $L$ | Developed length of piping between anchors | m | ft |
| $L$ | Dish radius | m | in |
| $M$ | Molecular weight | kg/mol | lb/mol |
| $M_p$, $m_i$ | In-plane bending moment | N·mm | in·lbf |
| $M_o$ | Out-plane bending moment | N·mm | in·lbf |
| $M_t$ | Torsional moment | N·mm | in·lbf |
| $M_\infty$ | Free stream Mach number | | |
| $m$ | Mass | kg | lb |
| $m$ | Thickness | m | ft |
| $N$ | Number of data points or items | Dimensionless | Dimensionless |
| $N$ | Frictional resistance | Dimensionless | Dimensionless |
| $N$ | Equivalent full temperature cycles | | |
| $N_S$ | Strouhal number | Dimensionless | Dimensionless |
| $N_{De}$ | Dean number | Dimensionless | Dimensionless |
| $N_{Fr}$ | Froude number | Dimensionless | Dimensionless |
| $N_{Re}$ | Reynolds number | Dimensionless | Dimensionless |
| $N_{We}$ | Weber number | Dimensionless | Dimensionless |
| NPSH | Net positive suction head | m | ft |
| $n$ | Polytropic exponent | | |
| $n$ | Pulsation frequency | Hz | 1/s |
| $n$ | Constant, general | | |
| $n$ | Number of items | Dimensionless | Dimensionless |
| $P$ | Design gauge pressure | kPa | $lbf/in^2$ |
| $P_{ad}$ | Adiabatic power | kW | hp |
| $p$ | Pressure | Pa | $lbf/ft^2$ |
| $p$ | Power | kW | hp |
| $Q$ | Heat | J | Btu |
| $Q$ | Volume | $m^3$ | $ft^3$ |
| $Q$ | Volume rate of flow (liquids) | $m^3/h$ | gal/min |
| $Q$ | Volume rate of flow (gases) | $m^3/h$ | $ft^3$/min (cfm) |
| $q$ | Volume flow rate | $m^3/s$ | $ft^3/s$ |
| $R$ | Gas constant | 8314 J/(K·mol) | 1545 (ft·lbf)/(mol·°R) |
| $R$ | Radius | m | ft |
| $R$ | Electrical resistance | Ω | Ω |
| $R$ | Head reading | m | ft |
| $R$ | Range of reaction forces or moments in flexibility analysis | N or N·mm | lbf or in·lbf |
| $R$ | Cylinder radius | m | ft |
| $R$ | Universal gas constant | J/(kg·K) | (ft·lbf)/(lbm·°R) |
| $R_a$ | Estimated instantaneous reaction force or moment at installation temperature | N or N·mm | lbf or in·lbf |
| $R_m$ | Estimated instantaneous maximum reaction force or moment at maximum or minimum metal temperature | N or N·mm | lbf or in·lbf |
| $R_1$ | Effective radius of miter bend | mm | in |

**Nomenclature and Units** (*Continued*)

| Symbol | Definition | SI units | U.S. customary units |
|---|---|---|---|
| $r$ | Radius | m | ft |
| $r$ | Pressure ratio | Dimensionless | Dimensionless |
| $r_c$ | Critical pressure ratio | | |
| $r_k$ | Knuckle radius | m | in |
| $r_2$ | Mean radius of pipe using nominal wall thickness $\overline{T}$ | mm | in |
| $S$ | Specific surface area | $m^2/m^3$ | $ft^2/ft^3$ |
| $S$ | Fluid head loss | Dimensionless | Dimensionless |
| $S$ | Specific energy loss | $m/s^2$ | lbf/lb |
| $S$ | Speed | $m^3/s$ | $ft^3/s$ |
| $S$ | Basic allowable stress for metals, excluding factor $E$, or bolt design stress | MPa | kip/in² (ksi) |
| $S_A$ | Allowable stress range for displacement stress | MPa | kip/in² (ksi) |
| $S_E$ | Computed displacement-stress range | MPa | kip/in² (ksi) |
| $S_L$ | Sum of longitudinal stresses | MPa | kip/in² (ksi) |
| $S_T$ | Allowable stress at test temperature | MPa | kip/in² (ksi) |
| $S_b$ | Resultant bending stress | MPa | kip/in² (ksi) |
| $S_c$ | Basic allowable stress at minimum metal temperature expected | MPa | kip/in² (ksi) |
| $S_h$ | Basic allowable stress at maximum metal temperature expected | MPa | kip/in² (ksi) |
| $S_t$ | Torsional stress | MPa | kip/in² (ksi) |
| $s$ | Specific gravity | | |
| $s$ | Specific entropy | J/(kg·K) | Btu/(lb·°R) |
| $T$ | Temperature | K (°C) | °R (°F) |
| $T_s$ | Effective branch-wall thickness | mm | in |
| $\overline{T}$ | Nominal wall thickness of pipe | mm | in |
| $\overline{T}_b$ | Nominal branch-pipe wall thickness | mm | in |
| $\overline{T}_h$ | Nominal header-pipe wall thickness | mm | in |
| $t$ | Head or shell radius | mm | in |
| $t$ | Pressure design thickness | mm | in |
| $t$ | Time | s | s |
| $t_m$ | Minimum required thickness, including mechanical, corrosion, and erosion allowances | mm | in |
| $t_r$ | Pad or saddle thickness | mm | in |
| $U$ | Straight-line distance between anchors | m | ft |
| $u$ | Specific internal energy | J/kg | Btu/lb |
| $u$ | Velocity | m/s | ft/s |
| $V$ | Velocity | m/s | ft/s |
| $V$ | Volume | $m^3$ | $ft^3$ |
| $v$ | Specific volume | $m^3/kg$ | $ft^3/lb$ |
| $W$ | Work | N·m | lbf·ft |
| $W$ | Weight | kg | lb |
| $w$ | Weight flow rate | kg/s | lb/s |
| $x$ | Weight fraction | Dimensionless | Dimensionless |
| $x$ | Distance or length | m | ft |
| $x$ | Value of expression $[(p_2/p_1)^{(k-1/k)} - 1]$ | | |
| $Y$ | Expansion factor | Dimensionless | Dimensionless |
| $y$ | Distance or length | m | ft |
| $y$ | Resultant of total displacement strains | mm | in |
| $Z$ | Section modulus of pipe | $mm^3$ | $in^3$ |
| $Z$ | Vertical distance | m | ft |
| $Z_e$ | Effective section modulus for branch | $mm^3$ | $in^3$ |
| $Z$ | Gas-compressibility factor | Dimensionless | Dimensionless |
| $z$ | Vertical distance | m | ft |

Greek symbols

| Symbol | Definition | SI units | U.S. customary units |
|---|---|---|---|
| $\alpha$ | Viscous-resistance coefficient | $1/m^2$ | $1/ft^2$ |
| $\alpha$ | Angle | ° | ° |
| $\sigma$ | Half-included angle | ° | ° |
| $\alpha, \beta, \theta$ | Angles | ° | ° |
| $\beta$ | Inertial-resistance coefficient | 1/m | 1/ft |
| $\beta$ | Ratio of diameters | Dimensionless | Dimensionless |
| $\Gamma$ | Liquid loading | kg/(s·m) | lb/(s·ft) |
| $\Gamma$ | Pulsation intensity | Dimensionless | Dimensionless |
| $\delta$ | Thickness | m | ft |
| $\varepsilon$ | Wall roughness | m | ft |
| $\varepsilon$ | Voidage—fractional free volume | Dimensionless | Dimensionless |
| $\eta$ | Viscosity, nonnewtonian fluids | Pa·s | lb/(ft·s) |
| $\eta_{ad}$ | Adiabatic efficiency | | |
| $\eta_p$ | Polytropic efficiency | | |
| $\theta$ | Angle | ° | ° |
| $\lambda$ | Molecular mean free-path length | m | ft |
| $\mu$ | Viscosity | Pa·s | lb/(ft·s) |
| $\nu$ | Kinematic viscosity | $m^2/s$ | $ft^2/s$ |
| $\rho$ | Density | $kg/m^3$ | $lb/ft^3$ |
| $\sigma$ | Surface tension | N/m | lbf/ft |
| $\sigma_c$ | Cavitation number | Dimensionless | Dimensionless |
| $\tau$ | Shear stress | $N/m^2$ | $lbf/ft^2$ |
| $\phi$ | Shape factor | Dimensionless | Dimensionless |
| $\phi$ | Angle | ° | ° |
| $\phi$ | Flow coefficient | | |
| $\psi$ | Pressure coefficient | | |
| $\psi$ | Sphericity | Dimensionless | Dimensionless |

## INTRODUCTION

The flow rate of fluids is a critical variable in most chemical engineering applications, ranging from flows in the process industries to environmental flows and to flows within the human body. *Flow* is defined as mass flow or volume flow per unit of time at specified temperature and pressure conditions for a given fluid. This subsection deals with the techniques of measuring the pressure, temperature, velocities, and flow rates of flowing fluids. For more detailed discussion of these variables, consult Sec. 8, which introduces methods of measuring flow rate, temperature, and pressure. This subsection builds on the coverage in Sec. 8 with emphasis on measurement of the flow of fluids.

## PROPERTIES AND BEHAVIOR OF FLUIDS

Transportation and the storage of fluids (gases and liquids) involve the understanding of the properties and behavior of fluids. The study of fluid dynamics is the study of fluids and their motion in a force field.

Flows can be classified into two major categories: (1) incompressible flow and (2) compressible flow. Most liquids fall into the incompressible flow category, while most gases are compressible. A *perfect fluid* can be defined as a fluid that is nonviscous and nonconducting. Fluid flow, compressible or incompressible, can be classified by the ratio of the inertial forces to the viscous forces. This ratio is represented by *Reynolds number* $N_{Re}$. At a low Reynolds number, the flow is considered to be laminar, and at high Reynolds numbers, the flow is considered to be turbulent. The limiting types of flow are the inertialess flow, sometimes called *Stokes' flow*, and the inviscid flow that occurs at an infinitely large Reynolds number. The Reynolds number (dimensionless) for flow in a pipe is given as

$$N_{Re} = \frac{\rho V D}{\mu} \tag{10-1}$$

where $\rho$ is the density of the fluid, $V$ the velocity, $D$ the diameter, and $\mu$ the viscosity of the fluid. In fluid motion where the friction forces interact with the inertia forces, it is important to consider the ratio of the viscosity $\mu$ to the density $\rho$. This ratio is known as the *kinematic viscosity* $\nu$. Tables 10-1 and 10-2 give the kinematic viscosity for several fluids. A flow is considered to be *adiabatic* when there is no transfer of heat between the fluid and its surroundings. An *isentropic* flow is one in which the entropy of each fluid element remains constant.

To fully understand the mechanics of flow, the following definitions explain the behavior of various types of fluids in both their static and flowing states.

A perfect fluid is a nonviscous, nonconducting fluid. An example of this type of fluid would be a fluid that has a very small viscosity and conductivity and is at a high Reynolds number. An ideal gas is one that obeys the equation of state:

$$\frac{P}{\rho} = RT \tag{10-2}$$

where $P$ = pressure, $\rho$ = density, $R$ is the gas constant per unit mass, and $T$ = absolute temperature.

A flowing fluid is acted upon by many forces that result in changes in pressure, temperature, stress, and strain. A fluid is said to be *isotropic* when the relations between the components of stress and those of the rate of strain are the same in all directions. The fluid is said to be *newtonian* when this relationship is linear. These pressures and temperatures must be fully understood so that the entire flow picture can be described.

The *static pressure* in a fluid has the same value in all directions and can be considered as a scalar point function. It is the pressure of a flowing fluid. It is normal to the surface on which it acts and at any given point has the same magnitude irrespective of the orientation of the surface. The static pressure arises because of the random motion in the fluid of the molecules that make up the fluid. In a diffuser or nozzle, there is an increase or decrease in the static pressure due to the change in velocity of the moving fluid.

*Total pressure* is the pressure that would occur if the fluid were brought to rest in a reversible adiabatic process. Many texts and engineers use the words *total* and *stagnation* to describe the flow characteristics interchangeably. To be accurate, the stagnation pressure is the pressure that would occur if the fluid were brought to rest isentropically.

Total pressure will change in a fluid only if shaft work or the work of extraneous forces is introduced. Therefore, total pressure would increase in the impeller of a compressor or pump; it would remain constant in the diffuser. Similarly, total pressure would decrease in the turbine impeller but would remain constant in the nozzles.

*Static temperature* is the temperature of the flowing fluid. Like static pressure, it arises because of the random motion of the fluid molecules. Static temperature is, in most practical installations, impossible to measure since it can be measured only by a thermometer or thermocouple at rest relative to the flowing fluid that is moving with the fluid. Static temperature will increase in a diffuser and decrease in a nozzle.

*Total temperature* is the temperature that would occur if the fluid were brought to rest in a reversible adiabatic manner. Just like its counterpart *total pressure, total* and *stagnation temperatures* are used interchangeably by many test engineers.

**TABLE 10-1 Density, Viscosity, and Kinematic Viscosity of Water and Air in Terms of Temperature**

| Temperature | | Water | | | Air at a pressure of 760 mm Hg (14.696 lbf/in$^2$) | | |
|---|---|---|---|---|---|---|---|
| (°C) | (°F) | Density $\rho$ (lbf·s$^2$/ft$^4$) | Viscosity $\mu \times 10^6$ (lbf·s/ft$^2$) | Kinematic viscosity $\nu \times 10^6$ (ft$^2$/s) | Density $\rho$ (lbf·s$^2$/ft$^4$) | Viscosity $\mu \times 10^6$ (lbf·s/ft$^2$) | Kinematic viscosity $\nu \times 10^6$ (ft$^2$/s) |
| −20 | −4 | — | — | — | 0.00270 | 0.326 | 122 |
| −10 | 14 | — | — | — | 0.00261 | 0.338 | 130 |
| 0 | 32 | 1.939 | 37.5 | 19.4 | 0.00251 | 0.350 | 140 |
| 10 | 50 | 1.939 | 27.2 | 14.0 | 0.00242 | 0.362 | 150 |
| 20 | 68 | 1.935 | 21.1 | 10.9 | 0.00234 | 0.375 | 160 |
| 40 | 104 | 1.924 | 13.68 | 7.11 | 0.00217 | 0.399 | 183 |
| 60 | 140 | 1.907 | 9.89 | 5.19 | 0.00205 | 0.424 | 207 |
| 80 | 176 | 1.886 | 7.45 | 3.96 | 0.00192 | 0.449 | 234 |
| 100 | 212 | 1.861 | 5.92 | 3.19 | 0.00183 | 0.477 | 264 |

Conversion factors: 1 kp·s$^2$/m$^4$ = 0.01903 lbf·s$^2$/ft$^4$ (= slug/ft$^3$)
1 lbf·s$^2$/ft$^4$ = 32.1719 lb/ft$^3$ (lb = lb mass; lbf = lb force)
1 kp·s$^2$/m$^4$ = 9.80665 kg/m$^3$ (kg = kg mass; kp = kg force)
1 kg/m$^3$ = 16.02 lb/ft$^3$

**TABLE 10-2 Kinematic Viscosity**

| Liquid | Temperature °C | Temperature °F | $\nu \times 10^6$ ($ft^2/s$) |
|---|---|---|---|
| Glycerine | 20 | 68 | 7319 |
| Mercury | 0 | 32 | 1.35 |
| Mercury | 100 | 212 | 0.980 |
| Lubricating oil | 20 | 68 | 4306 |
| Lubricating oil | 40 | 104 | 1076 |
| Lubricating oil | 60 | 140 | 323 |

*Dynamic temperature* and *dynamic pressure* are the difference between the total and static conditions.

$$P_d = P_T - P_s \tag{10-3}$$

$$T_d = T_T - T_s \tag{10-4}$$

where subscript $d$ refers to dynamic, $T$ to total, and $s$ to static.

Another helpful formula is

$$P_K = \frac{1}{2}\rho V^2 \tag{10-5}$$

For incompressible fluids, $P_K = P_d$.

## TOTAL TEMPERATURE

For most points requiring temperature monitoring, either thermocouples or *resistive thermal detectors* (RTDs) can be used. Each type of temperature transducer has its own advantages and disadvantages, and both should be considered when temperature is to be measured. Since there is considerable confusion in this area, a short discussion of the two types of transducers is necessary.

**Thermocouples** The various types of thermocouples provide transducers suitable for measuring temperatures from −330 to 5000°F (−201 to 2760°C). Thermocouples function by producing a voltage proportional to the temperature differences between two junctions of dissimilar metals. By measuring this voltage, the temperature difference can be determined. It is assumed that the temperature is known at one of the junctions; therefore, the temperature at the other junction can be determined. Since the thermocouples produce a voltage, no external power supply is required to the test junction; however, for accurate measurement, a reference junction is required. For a temperature monitoring system, reference junctions must be placed at each thermocouple, or similar thermocouple wire must be installed from the thermocouple to the monitor where there is a reference junction. Properly designed thermocouple systems can be accurate to approximately ±2°F (±1°C).

**Resistive Thermal Detectors** RTDs determine temperature by measuring the change in resistance of an element due to temperature. Platinum is generally utilized in RTDs because it remains mechanically and electrically stable, resists contaminations, and can be highly refined. The useful range of platinum RTDs is −454 to 1832°F (−270 to 1000°C). Since the temperature is determined by the resistance in the element, any type of electrical conductor can be utilized to connect the RTD to the indicator; however, an electric current must be provided to the RTD. A properly designed temperature monitoring system utilizing RTDs can be accurate to ±0.02°F (±0.01°C).

## STATIC TEMPERATURE

Since this temperature requires the thermometer or thermocouple to be at rest relative to the flowing fluid, it is impractical to measure. However, it can be calculated from the measurement of total temperature and total and static pressure.

$$T_S = \frac{T_o}{\left(\frac{P_o}{P_S}\right)^{(k-1)/k}} \tag{10-6}$$

## DRY- AND WET-BULB TEMPERATURES

The moisture content or humidity of air has an important effect on the properties of the gaseous mixture. Steam in air at any relative humidity less than 100 percent must exist in a superheated condition. The saturation temperature corresponding to the actual partial pressure of the steam in air is called the *dew point*. This term arose from the fact that when air at less than 100 percent relative humidity is cooled to the temperature at which it becomes saturated, the air has reached the minimum temperature to which it can be cooled without precipitation of the moisture (dew). *Dew point* can also be defined as that temperature at which the weight of steam associated with a certain weight of dry air is adequate to saturate that weight of air.

The *dry-bulb temperature* of air is the temperature indicated by an ordinary thermometer. In contrast to dry-bulb, or air, temperature, the term *wet-bulb temperature of the air*, or simply *wet-bulb temperature*, is employed. When a thermometer, with its bulb covered by a wick wetted with water, is moved through air unsaturated with water vapor, the water evaporates in proportion to the capacity of the air to absorb the evaporated moisture, and the temperature indicated by the thermometer drops below the dry-bulb, or air, temperature. The equilibrium temperature finally reached by the thermometer is known as the *wet-bulb temperature*. The purpose in measuring both the dry-bulb and wet-bulb temperatures of the air is to find the exact humidity characteristics of the air from the readings obtained, either by calculation or by use of a psychrometric chart. Instruments for measuring wet-bulb and dry-bulb temperatures are known as *psychrometers,* which are defined in Sec. 12. For other methods of measuring the moisture content of gases, see Sec. 8.

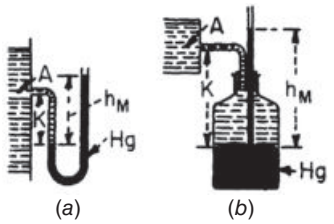

**FIG. 10-1** Open manometers.

## PRESSURE MEASUREMENTS

*Pressure* is defined as the force per unit area. Pressure devices measure with respect to the ambient atmospheric pressure: The *absolute pressure* $P_a$ is the pressure of the fluid (gauge pressure) plus the atmospheric pressure.

Process pressure-measuring devices may be divided into three groups:

1. Those based on the height of a liquid column (manometers)
2. Those based on the measurement of the distortion of an elastic pressure chamber (mechanical pressure gauges such as Bourdon-tube gauges and diaphragm gauges)
3. Electric sensing devices (strain gauges, piezoresistive transducers, and piezoelectric transducers)

This subsection contains an expanded discussion of manometric methods. See Sec. 8 for other methods.

**Liquid-Column Manometers** The *height,* or *head,* $p_n = \rho hg/g_c$ to which a fluid rises in an open vertical tube attached to an apparatus containing a liquid is a direct measure of the pressure at the point of attachment and is frequently used to show the level of liquids in tanks and vessels. This same principle can be applied with U tube gauges (Fig. 10-1*a*) and equivalent devices (such as that shown in Fig. 10-1*b*) to measure pressure in terms of the head of a fluid other than the one under test. Most of these gauges may be used either as *open* or as *differential manometers*. The manometric fluid that constitutes the measured liquid column of these gauges may be any liquid immiscible with the fluid under pressure. For high vacuums or for high pressures and large pressure differences, the gauge liquid is a high-density liquid, generally mercury; for low pressures and small pressure differences, a low-density liquid (e.g., alcohol, water, or carbon tetrachloride) is used.

The *open U tube* (Fig. 10-1*a*) and the *open gauge* (Fig. 10-1*b*) each show a reading $h_M$, which represents m (ft) of manometric fluid. If the interface of the manometric fluid and the fluid of which the pressure is wanted is $K$ m (ft) below the point of attachment $A$, $\rho_A$ is the density of the latter fluid at $A$, and $\rho_M$ is that of the manometric fluid, then gauge pressure $p_A$ ($lb_f/ft^2$) at $A$ is

$$p_A = (h_M \rho_M - K\rho_A)(g/g_c) \tag{10-7}*$$

where $g$ = local acceleration due to gravity and $g_c$ = dimensional constant. The head $h_A$ at $A$ as meters (feet) of the fluid at that point is

$$h_A = h_M(\rho_M/\rho_A) - K \tag{10-8}*$$

When a gas pressure is measured, unless it is very high, $\rho_A$ is so much smaller than $\rho_M$ that the terms involving $K$ in these formulas are negligible.

* The line leading from the pressure tap to the gauge is assumed to be filled with fluid of the same density as that in the apparatus at the location of the pressure tap. If this is not the case, $\rho_A$ is the density of the fluid actually filling the gauge line, and the value given for $h_A$ must be multiplied by $\rho_A/\rho$, where $\rho$ is the density of the fluid whose head is being measured.

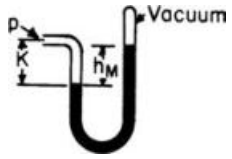

**FIG. 10-2** Closed U tube.

**Closed U Tubes** Closed U tubes (Fig. 10-2) using mercury as the manometric fluid serve to measure directly the absolute pressure $p$ of a fluid, provided that the space between the closed end and the mercury is substantially a perfect vacuum.

The *mercury barometer* (Fig. 10-3) indicates directly the absolute pressure of the atmosphere in terms of the height of the mercury column. Normal (standard) barometric pressure is 101.325 kPa by definition. Equivalents of this pressure in other units are 760 mm mercury (at 0°C), 29.921 in.Hg (at 0°C), 14.696 lbf/in$^2$, and 1 atm. For cases in which barometer readings, when expressed by the height of a mercury column, must be corrected to standard temperature (usually 0°C), appropriate temperature correction factors are given in ASME, *Performance Test Code,* 1997, pp. 23–26, and Weast, *Handbook of Chemistry and Physics,* 65th ed., Chemical Rubber, Cleveland, Ohio, 1985, pp. E36–E37.

**Tube Size for Manometers** To avoid capillary error, the tube diameter should be sufficiently large and the manometric fluids of such densities that the effect of capillarity is negligible in comparison with the gauge reading. The effect of capillarity is practically negligible for tubes with inside diameters of 12.7 mm (0.5 in) or larger (see ASME, *Performance Test Code,* 1997, p. 15). Small diameters are generally permissible for U tubes because the capillary displacement in one leg tends to cancel that in the other leg.

The capillary rise in a small vertical open tube of circular cross section dipping into a pool of liquid is given by

$$h = \frac{4\sigma g_c \cos\theta}{gD(\rho_1 - \rho_2)} \tag{10-9}$$

Here $\sigma$ = surface tension, $D$ = inside diameter, $\rho_1$ and $\rho_2$ are the densities of the liquid and gas (or light liquid), respectively, $g$ = local acceleration due to gravity, $g_c$ = dimensional constant, and $\theta$ = the contact angle subtended by the heavier fluid. For most organic liquids and water, the contact angle $\theta$ is zero against glass, provided the glass is wet with a film of the liquid; for mercury against glass, $\theta$ = 140° (*International Critical Tables,* vol. 4, McGraw-Hill, New York, 1928, pp. 434–435). For further discussion of capillarity, see Schwartz, *Ind. Eng. Chem.* **61**(1): 10–21 (1969).

**Multiplying Gauges** To attain the requisite precision in measurement of small pressure differences by liquid-column manometers, means must often be devised to magnify the readings. The inclined U tube (Fig. 10-4) and the draft gauge may give 10-fold multiplication. The two-fluid U tube can magnify small pressure measurements by as much as 30-fold (*Perry's Chemical Engineers' Handbook*, 8th ed., McGraw-Hill, New York, 2008, p. 10-9). In general, the greater the multiplication, the more elaborate must be the precautions in the use of the gauge if the gain in precision is not to be illusory.

1. *Change of manometric fluid.* In open manometers, choose a fluid of lower density. In differential manometers, choose a fluid such that the difference between its density and that of the fluid being measured is as small as possible.

2. *Inclined U tube* (Fig. 10-4). If the reading $R$ m ( ft) is taken as shown and $R_0$ m ( ft) is the zero reading, by making the substitution $h_M = (R - R_0) \sin\theta$, the formulas of preceding paragraphs give $p_A - p_B$ when the corresponding upright U tube is replaced by an inclined one. For precise work, the gauge should be calibrated because of possible variations in tube diameter and slope.

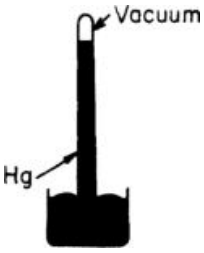

**FIG. 10-3** Mercury barometer.

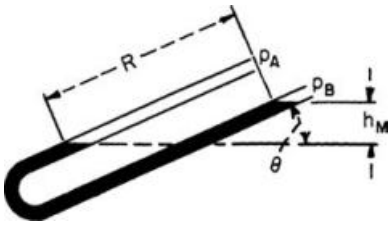

**FIG. 10-4** Inclined U tube.

Several *micromanometers,* based on the liquid-column principle and possessing extreme precision and sensitivity, have been developed for measuring minute gas pressure differences and for calibrating low-range gauges. Some of these micromanometers are available commercially. These micromanometers are free from errors due to capillarity and, aside from checking the micrometer scale, require no calibration.

**Mechanical Pressure Gauges** The *Bourdon-tube gauge* indicates pressure by the amount of flection under internal pressure of an oval tube bent in an arc of a circle and closed at one end. These gauges are commercially available for all pressures below atmospheric and for pressures up to 700 MPa (about 100,000 lbf/in$^2$) above atmospheric. Details on Bourdon-type gauges are given by Harland [*Mach. Des.* **40**(22): 69–74 (Sept. 19, 1968)].

A *diaphragm gauge* depends for its indication on the deflection of a diaphragm, usually metallic, when subjected to a difference of pressure between the two faces. These gauges are available for the same general purposes as Bourdon gauges but are not usually employed for high pressures. The aneroid barometer is a type of diaphragm gauge.

Small *pressure transducers with flush-mounted diaphragms* are commercially available for the measurement of either steady or fluctuating pressures up to 100 MPa (about 15,000 lbf/in$^2$). The metallic diaphragms are as small as 4.8 mm ($\frac{3}{16}$ in) in diameter. The transducer is mounted on the apparatus containing the fluid whose pressure is to be measured so that the diaphragm is flush with the inner surface of the apparatus. Deflection of the diaphragm is measured by unbonded strain gauges and recorded electrically.

With nonnewtonian fluids the pressure measured at the wall with nonflush-mounted pressure gauges may be in error (see the subsection Static Pressure).

Bourdon and diaphragm gauges that show both pressure and vacuum indications on the same dial are called *compound gauges.*

**Conditions of Use** Bourdon tubes should not be exposed to temperatures over about 65°C (about 150°F) unless they are specifically designed for such operation. When the pressure of a hotter fluid is to be measured, some type of liquid seal should be used to keep the hot fluid from the tube. In using either a Bourdon or a diaphragm gauge to measure gas pressure, if the gauge is below the pressure tap of the apparatus so that liquid can collect in the lead, then the gauge reading will be too high by an amount equal to the hydrostatic head of the accumulated liquid.

For measuring pressures of corrosive fluids, slurries, and similar process fluids which may foul Bourdon tubes, a *chemical gauge,* consisting of a Bourdon gauge equipped with an appropriate flexible diaphragm to seal off the process fluid, may be used. The combined volume of the tube and the connection between the diaphragm and the tube is filled with an inert liquid. These gauges are available commercially.

Further details on pressure-measuring devices can be found in Sec. 8.

**Calibration of Gauges** Simple *liquid-column manometers* do not require calibration if they are so constructed as to minimize errors due to capillarity (see the subsection Liquid-Column Manometers). If the scales used to measure the readings have been checked against a standard, the accuracy of the gauges depends solely on the precision of determining the position of the liquid surfaces. Hence liquid-column manometers are primary standards used to calibrate other gauges.

For *high pressures* and, with commercial mechanical gauges, even for quite moderate pressures, a deadweight gauge (see ASME, *Performance Test Code,* 1997, pp. 36–41) is commonly used as the primary standard because it is safer and more convenient than use of manometers. When manometers are used as high-pressure standards, an extremely high mercury column may be avoided by connecting a number of the usual U tubes in series. Multiplying gauges are standardized by comparing them with a micromanometer. The procedure in the calibration of a gauge consists merely of connecting it, in parallel with a standard gauge, to a reservoir wherein constant pressure may be maintained. Readings of the unknown gauge are then made for various reservoir pressures as determined by the standard.

Calibration of *high-vacuum gauges* is described by Sellenger [*Vacuum* **18**(12): 645–650 (1968)].

## STATIC PRESSURE

**Local Static Pressure** In a moving fluid, the local static pressure is equal to the pressure on a surface which moves with the fluid or to the normal pressure ( for newtonian fluids) on a stationary surface that parallels the flow. The pressure on such a surface is measured by making a small hole perpendicular to the surface and connecting the opening to a pressure-sensing element (Fig. 10-5*a*). The hole is known as a *piezometer opening* or *pressure tap*.

Measurement of local static pressure is frequently difficult or impractical. If the channel is so small that introduction of any solid object disturbs the flow pattern and increases the velocity, there will be a reduction and redistribution of the static pressure. If the flow is in straight parallel lines, aside from the fluctuations of normal turbulence, the flat disk (Fig. 10-5*b*) and the bent tube (Fig. 10-5*c*) give satisfactory results when properly aligned with the stream. Slight misalignments can cause serious errors. The diameter of the disk should be 20 times its thickness and 40 times the static opening; the face must be flat and smooth, with the knife edges made by bevelling the underside. The piezometer tube, such as that in Fig. 10-5*c,* should have openings with size and spacing as specified for a pitot-static tube (Fig. 10-9).

Readings given by open straight tubes (Fig. 10-5*d* and *e*) are too low due to flow separation. Readings of closed tubes oriented perpendicular to the axis of the stream and provided with side openings (Fig. 10-5*e*) may be low by as much as two velocity heads.

**Average Static Pressure** In most cases, the object of a static pressure measurement is to obtain a suitable average value for substitution in Bernoulli's theorem or in an equivalent flow formula. This can be done simply only when the flow is in straight lines parallel to the confining walls, such as in straight ducts at sufficient distance downstream from bends (2 diameters) or other disturbances. For such streams, the sum of the static head and gravitational potential head is the same at all points in a cross section taken perpendicular to the axis of flow. Thus the exact location of a piezometer opening about the periphery of such a cross section is immaterial, provided its elevation is known. However, in stating the static pressure, the custom is to give the value at the elevation corresponding to the centerline of the stream.

With flow in curved passages or with swirling flow, determination of a true average static pressure is, in general, impractical. In metering, straightening vanes are often placed upstream of the pressure tap to eliminate swirl. Figure 10-6 shows various flow equalizers and straighteners.

**Specifications for Piezometer Taps** The size of a static opening should be small compared with the diameter of the pipe and yet large compared with the scale of surface irregularities. For reliable results, it is essential that (1) the surface in which the hole is made be substantially smooth and parallel to the flow for some distance on either side of the opening and (2) the opening be flush with the surface and possess no "burr" or other irregularity around its edge. Rounding of the edge is often employed to ensure absence of a burr. Pressure readings will be high if the tap is inclined upstream, is rounded excessively on the upstream side, has a burr on the downstream side, or has an excessive countersink or recess. Pressure readings will be low if the tap is inclined downstream, is rounded excessively on the downstream side, has a burr on the upstream side, or protrudes into the flow stream. Errors resulting from these faults can be large.

Recommendations for *pressure-tap dimensions* are summarized in Table 10-3. Data from several references were used in arriving at these composite values. The length of a pressure-tap opening prior to any enlargement in the tap channel should be at least 2 tap diameters, preferably 3 or more.

A *piezometer ring* is a toroidal manifold into which are connected several sidewall static taps located around the perimeter of a common cross section. Its intent is to give an average pressure if differences in pressure exist around the perimeter other than those due to static head. However, there is generally no assurance that a true average is provided thereby. The principal advantage of the ring is that use of several holes in place of a single hole reduces the possibility of completely plugging the static openings.

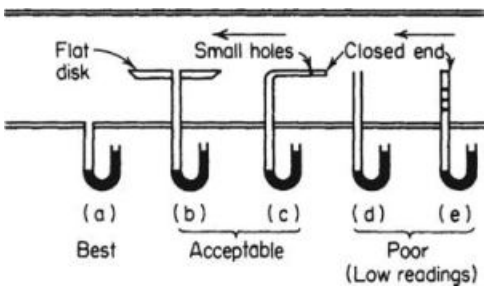

**FIG. 10-5** Measurement of static pressure.

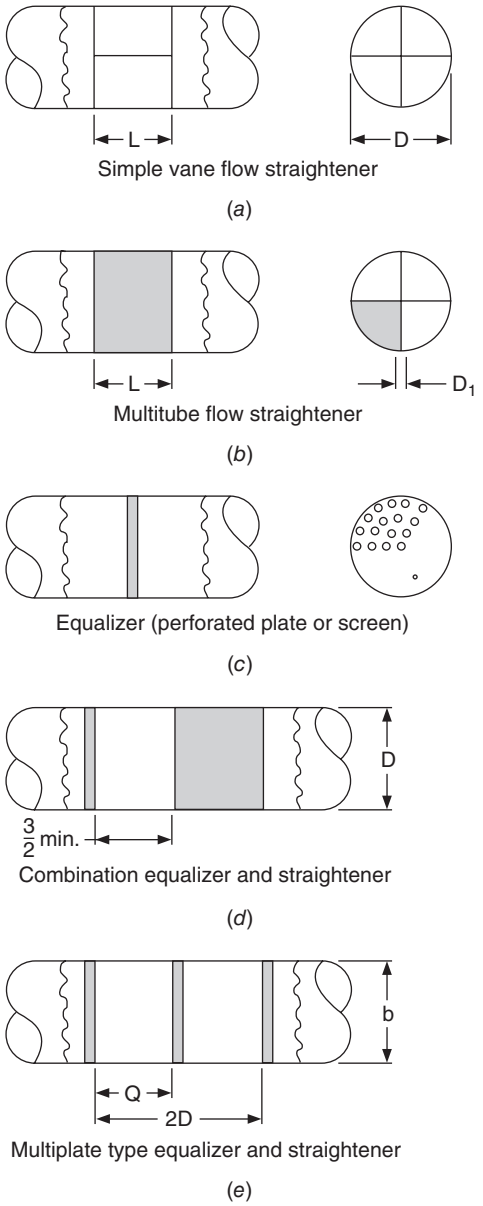

**FIG. 10-6** Flow equalizers and straighteners. [*Power Test Code 10, Compressors and Exhausters,* ASME, 1997]

For information on prediction of static-hole error, see Shaw, *J. Fluid Mech.* **7:** 550–564 (1960); Livesey, Jackson, and Southern, *Aircr. Eng* **34:** 43–47 (February 1962).

For nonnewtonian fluids, pressure readings with taps may also be low because of fluid-elasticity effects. This error can be largely eliminated by using flush-mounted diaphragms.

For information on the pressure-hole error for nonnewtonian fluids, see Han and Kim, *Trans. Soc. Rheol.* **17:** 151–174 (1973); Novotny and Eckert, *Trans. Soc. Rheol.* **17:** 227–241 (1973); and Higashitani and Lodge, *Trans. Soc. Rheol.* **19:** 307–336 (1975).

**TABLE 10-3 Pressure-Tap Holes**

| Nominal inside pipe diameter, in | Maximum diameter of pressure tap, mm (in) | Radius of hole-edge rounding, mm (in) |
|---|---|---|
| 1 | 3.18 (⅛) | <0.40 (1/64) |
| 2 | 6.35 (¼) | 0.40 (1/64) |
| 3 | 9.53 (⅜) | 0.40–0.79 (1/64 – 1/32) |
| 4 | 12.7 (½) | 0.79 (1/32) |
| 8 | 12.7 (½) | 0.79–1.59 (1/32–1/16) |
| 16 | 19.1 (¾) | 0.79–1.59 (1/32–1/16) |

## VELOCITY MEASUREMENTS

Measurement of flow can be based on the measurement of velocity in ducts or pipes by using devices such as pitot tubes and hot wire anemometers. The local velocity is measured at various sections of a conduit and then averaged for the area under consideration.

$$\frac{\dot{m}}{\rho} = A \times V = \dot{Q} \tag{10-10}$$

where $\dot{m}$ = mass flow rate, lbm/s, kg/s
$\rho$ = density, lbm/ft$^3$, kg/m$^3$
$A$ = area, ft$^2$, m$^2$
$V$ = velocity, ft/s, m/s
$\dot{Q}$ = volumetric flow rate, ft$^3$/s, m$^3$/s

Equation (10-10) shows that the fluid density directly affects the relationship between mass flow rate and both the velocity and volumetric flow rates. Liquid temperature affects liquid density and hence volumetric flow rate at a constant mass flow rate. Liquid density is relatively insensitive to pressure. Both temperature and pressure affect gas density and thus volumetric flow rate.

**Variables Affecting Measurement** Flow measurement methods may sense local fluid velocity, volumetric flow rate, total or cumulative volumetric flow (the integral of volumetric flow rate with respect to elapsed time), mass flow rate, and total mass flow.

**Velocity Profile Effects** Many variables can influence the accuracy of specific flow measurement methods. For example, the velocity profile in a closed conduit affects many types of flow-measuring devices. The velocity of a fluid varies from zero at the wall and at other stationary solid objects in the flow channel to a maximum at a distance from the wall. In the entry region of a conduit, the velocity field may approach plug flow and a constant velocity across the conduit, dropping to zero only at the wall. As a newtonian fluid progresses down a pipe, a velocity profile develops that is parabolic for laminar flow [Eq. (6-41)] and that approaches plug flow for highly turbulent flow. Once a steady flow profile has developed, the flow is said to be *fully developed*; the length of conduit necessary to achieve fully developed flow is called the *entrance region.* For long cylindrical, horizontal pipe ($L < 40D$, where $D$ is the inside diameter of the pipe and $L$ is the upstream length of pipe), the velocity profile becomes fully developed. Velocity profiles in flowing fluids are discussed in greater detail in Sec. 6 (p. 6-XX).

For steady-state, isothermal, single-phase, uniform, fully developed newtonian flow in straight pipes, the velocity is greatest at the center of the channel and symmetric about the axis of the pipe. Of those flowmeters that are dependent on the velocity profile, they are usually calibrated for this type of flow. Thus any disturbances in flow conditions can affect flowmeter readings.

Upstream and downstream disturbances in the flow field are caused by valves, elbows, and other types of fittings. Two upstream elbows in two perpendicular planes will impart swirl in the fluid downstream. Swirl, similar to atypical velocity profiles, can lead to erroneous flow measurements. Although the effect is not as great as in upstream flow disturbances, downstream flow disturbances can also lead to erroneous flow measurements.

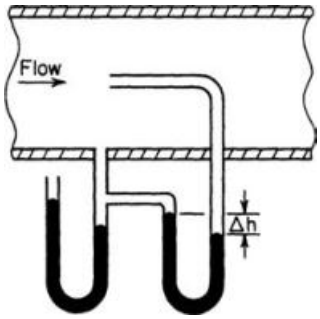

**FIG. 10-7** Pitot tube with sidewall static tap.

**Other Flow Disturbances** Other examples of deviations from fully developed, single-phase newtonian flow include nonnewtonian flow, pulsating flow, cavitation, multiphase flow, boundary layer flows, and nonisothermal flows. See Sec. 6.

**Pitot Tubes** The combination of pitot tubes in conjunction with sidewall static taps measures local or point velocities by measuring the difference between the total pressure and the static pressure. The pitot tube shown in Fig. 10-7 consists of an impact tube whose opening faces directly into the stream to measure impact pressure, plus one or more sidewall taps to measure local static pressure.

Dynamic pressure may be measured by use of a pitot tube that is a simple impact tube. These tubes measure the pressure at a point where the velocity of the fluid is brought to zero. Pitot tubes must be parallel to the flow. The pitot tube is sensitive to yaw or angle attack. In general, angles of attack over 10° should be avoided. In cases where the flow direction is unknown, it is recommended to use a Kiel probe. Figure 10-8 shows a Kiel probe. This probe will read accurately to an angle of about 22° with the flow.

The combined pitot-static tube shown in Fig. 10-9 consists of a jacketed impact tube with one or more rows of holes, 0.51 to 1.02 mm (0.02 to 0.04 in) in diameter, in the jacket to measure the static pressure. Velocity $V_0$ m/s (ft/s) at the point where the tip is located is given by

$$V_0 = C\sqrt{2g_c\,\Delta h} = C\sqrt{2g_c(p_T - p_s)/\rho_0} \tag{10-11}$$

where $C$ = coefficient, dimensionless; $g_c$ = dimensional constant; $\Delta h$ = dynamic pressure ($\Delta h_s g/g_c$), expressed in (N · m)/kg [(ft · lbf)/lb or ft of fluid flowing]; $\Delta h_s$ = differential height of static liquid column corresponding

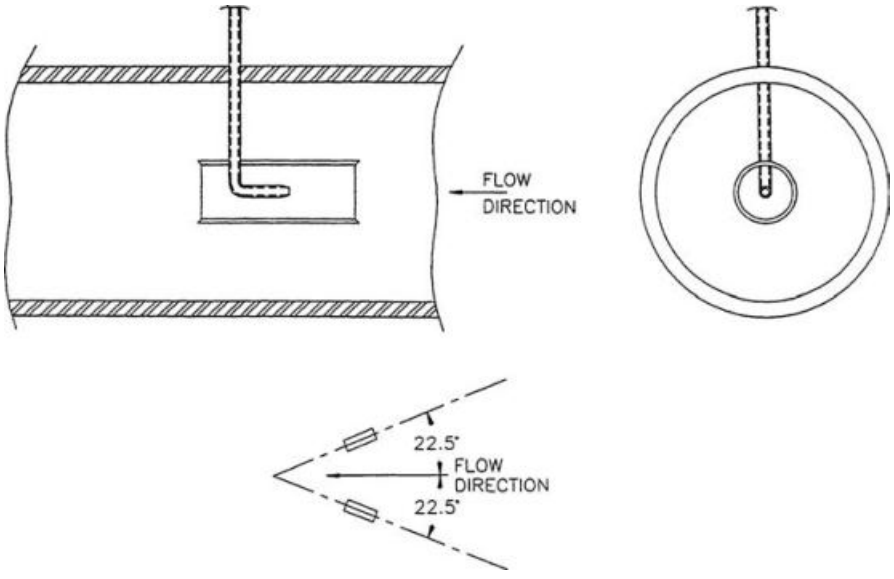

**FIG. 10-8** Kiel probe. Accurate measurements can be made at angles up to 22.5° with the flow stream.

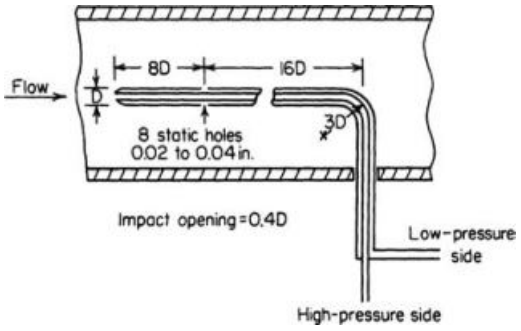

**FIG. 10-9** Pitot-static tube.

to $\Delta h$; $g$ = local acceleration due to gravity; $g_c$ = dimensional constant; $p_i$ = impact pressure; $p_0$ = local static pressure; and $\rho_0$ = fluid density measured at pressure $p_0$ and the local temperature. With gases at velocities above 60 m/s (about 200 ft/s), compressibility becomes important, and the following equation should be used:

$$V_0 = C\sqrt{\frac{2g_c k}{k-1}\left(\frac{p_0}{\rho_0}\right)\left[\left(\frac{p_i}{p_0}\right)^{(k-1)/k} - 1\right]} \tag{10-12}$$

where $k$ is the ratio of specific heat at constant pressure to that at constant volume. (See ASME, *Report of the ASME Research Committee on Fluid Meters*, p. 105.) Coefficient $C$ is usually close to 1.00 (±0.01) for simple pitot tubes (Fig. 10-7) and generally ranges between 0.98 and 1.00 for pitot-static tubes (Fig. 10-9).

There are certain limitations on the range of usefulness of pitot tubes. With gases, the differential is very small at low velocities; e.g., at 4.6 m/s (15.1 ft/s) the differential is only about 1.30 mm (0.051 in) of water (20°C) for air at 1 atm (20°C), which represents a lower limit for 1 percent error even when one uses a micromanometer with a precision of 0.0254 mm (0.001 in) of water. The equation does not apply for Mach numbers greater than 0.7 because of the interference of shock waves. For supersonic flow, local Mach numbers can be calculated from a knowledge of the dynamic and true static pressures. The *free stream Mach number* $M_\infty$ is defined as the ratio of the speed of the stream $V_\infty$ to the speed of sound in the free stream:

$$A_\infty = \sqrt{\left(\frac{\partial P}{\partial \rho}\right)_{s=c}} \tag{10-13}$$

$$M_\infty = \frac{V_\infty}{\sqrt{\left(\frac{\partial P}{\partial \rho}\right)_{s=c}}} \tag{10-14}$$

where $s$ is the entropy. For isentropic flow, this relationship and pressure can be written as

$$M_\infty = \frac{V_\infty}{\sqrt{kRT_s}} \tag{10-15}$$

The relationships between total and static temperature and pressure are given by the following:

$$\frac{T_T}{T_S} = 1 + \frac{k-1}{2}M^2 \tag{10-16}$$

$$\frac{P_T}{P_S} = \left(1 + \frac{k-1}{2}M^2\right)^{(k-1)/k} \tag{10-17}$$

With *liquids* at low velocities, the effect of the Reynolds number upon the coefficient is important. The coefficients are appreciably less than unity for Reynolds numbers less than 500 for pitot tubes and for Reynolds numbers less than 2300 for pitot-static tubes [see Folsom, *Trans. Am. Soc. Mech. Eng.* **78:** 1447–1460 (1956)]. Reynolds numbers here are based on the probe outside diameter. Operation at low Reynolds numbers requires prior calibration of the probe.

The pitot-static tube is also more sensitive to *yaw* or *angle of attack* than is the simple pitot tube because of the sensitivity of the static taps to orientation. The error involved is strongly dependent on the exact probe dimensions. In general, angles greater than 10° should be avoided if the velocity error is to be 1 percent or less.

*Disturbances* upstream of the probe can cause large errors, in part because of the turbulence generated and its effect on the static-pressure measurement. A calming section of at least 50 pipe diameters is desirable. If this is not possible, the use of straightening vanes or a honeycomb is advisable.

The effect of *pulsating flow* on pitot-tube accuracy is treated by E. Ower in his article "On the response of a vane anemometer to an air-stream of pulsating speed," *The London and Edinburgh, and Dublin Philosophical Magazine and Journal of Science* Series 7, **23**(157) (1937), now available online https://doi.org/10.1080/14786443708561870. For sinusoidal velocity fluctuations, the ratio of indicated velocity to actual mean velocity is given by the factor $\sqrt{1+\lambda^2/2}$, where $\lambda$ is the velocity excursion as a fraction of the mean velocity ±50 percent, and pulsations greater than ±20 percent should be damped to avoid errors greater than 1 percent. The error increases as the frequency of flow oscillations approaches the natural frequency of the pitot tube and the density of the measuring fluid approaches the density of the process fluid [see Horlock and Daneshyar, *J. Mech. Eng. Sci.* **15:** 144–152 (1973)].

Pressures substantially lower than true impact pressures are obtained with pitot tubes in turbulent flow of dilute polymer solutions [see Halliwell and Lewkowicz, *Phys. Fluids* **18:** 1617–1625 (1975)].

**Special Tubes** A variety of special forms of the pitot tube have evolved. Richard Gilman Folsom [*Trans. Am. Soc. Mech. Eng.* **78:** 1447–1460 (1956)] gives a description of many of these special types of pitot tubes together with a comprehensive bibliography. Included are the impact tube for *boundary-layer* measurements and *shielded total-pressure tubes*. The latter are insensitive to angle of attack up to 40°.

Chue [*Prog. Aerosp. Sci.* **16:** 147–223 (1975)] reviews the use of the pitot tube and allied pressure probes for impact pressure, static pressure, dynamic pressure, flow direction and local velocity, skin friction, and flow measurements.

A reversed pitot tube, also known as a *pitometer*, has one pressure opening facing upstream and the other facing downstream. Coefficient $C$ for this type is on the order of 0.85. This gives about a 40 percent increase in pressure differential compared with standard pitot tubes and is an advantage at low velocities. There are commercially available very compact types of pitometers which require relatively small openings for their insertion into a duct.

The *pitot-venturi* flow element is capable of developing a pressure differential 5 to 10 times that of a standard pitot tube. This is accomplished by employing a pair of concentric venturi elements in place of the pitot probe. The low-pressure tap is connected to the throat of the inner venturi, which in turn discharges into the throat of the outer venturi. For a discussion of performance and application of this flow element, see Stoll, *Trans. Am. Soc. Mech. Eng.* **73:** 963–969 (1951).

**Traversing for Mean Velocity** The mean velocity in a duct can be obtained by dividing the cross section into a number of equal areas, finding the local velocity at a representative point in each, and averaging the results. In the case of *rectangular passages,* the cross section is usually divided into small squares or rectangles, and the velocity is found at the center of each. In circular pipes, the cross section is divided into several equal annular areas, as shown in Fig. 10-10. Readings of velocity are made at the intersections of a diameter and the set of circles which bisect the annuli and the central circle.

For an $N$-point traverse on a circular cross section, make readings on each side of the cross section at

$$100 \times \sqrt{(2n-1)/N} \text{ percent} \qquad (n = 1, 2, 3 \text{ to } N/2)$$

of the pipe radius from the center. Traversing several diameters spaced at equal angles about the pipe is required if the velocity distribution is unsymmetrical. With a normal velocity distribution in a circular pipe, a 10-point traverse theoretically gives a mean velocity 0.3 percent high; a 20-point traverse, 0.1 percent high.

For normal velocity distribution in straight circular pipes at locations preceded by runs of at least 50 diameters without pipe fittings or other obstructions, the graph in Fig. 10-10 shows the ratio of mean velocity $V$ to velocity at the center $u_{max}$ plotted versus the Reynolds number, where $D$ = inside pipe diameter, $\rho$ = fluid density, and $\mu$ = fluid viscosity, all in consistent units. Mean velocity is readily determined from this graph and a pitot reading at the center of the pipe if the quantity $Du_{max}\rho/\mu$ is less than 2000 or greater than 5000. The method is unreliable at intermediate values of the Reynolds number.

Methods for determining the mean flow rate from probe measurements under nonideal conditions are described by Mandersloot, Hicks, and Langejan [*Chem. Eng.* (*London*), no. 232, CE370–CE380 (1969)].

The *hot-wire anemometer* consists essentially of an electrically heated fine wire (generally platinum) exposed to the gas stream whose velocity

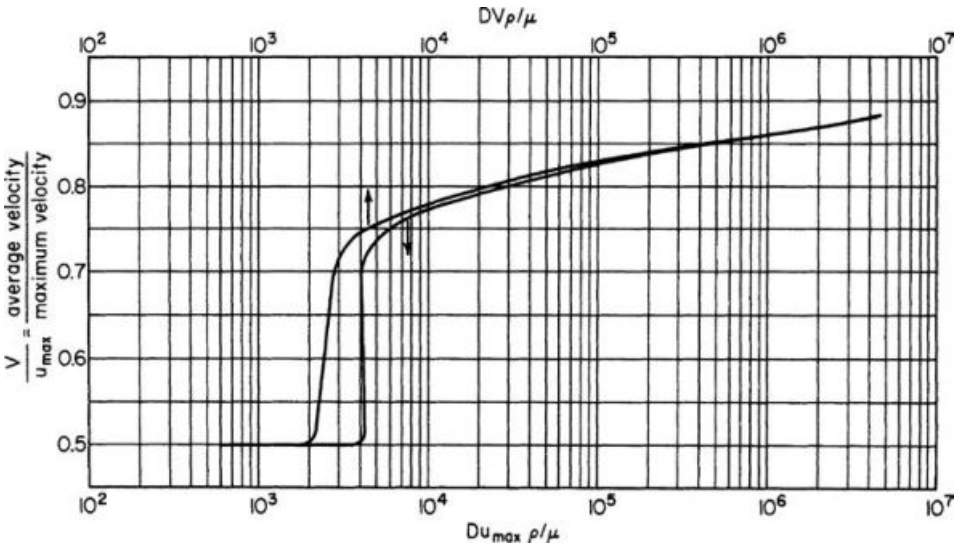

**FIG. 10-10** Velocity ratio versus Reynolds number for smooth circular pipes. [Based on data from Rothfus, Archer, Klimas, and Sikchi, *Am. Inst. Chem. Eng. J.* **3:** 208 (1957).]

is being measured. An increase in fluid velocity, other things being equal, increases the rate of heat flow from the wire to the gas, thereby tending to cool the wire and alter its electrical resistance. In a constant-current anemometer, the gas velocity is determined by measuring the resulting wire resistance; in the constant-resistance type, the gas velocity is determined from the current required to keep the wire temperature, and thus the resistance, constant. The difference in the two types is primarily in the electric circuits and instruments employed.

The hot-wire anemometer, with suitable calibration, can accurately measure velocities from about 0.15 m/s (0.5 ft/s) to supersonic velocities and can detect velocity fluctuations with frequencies up to 200,000 Hz. Fairly rugged, inexpensive units can be built for the measurement of mean velocities in the range of 0.15 to 30 m/s (about 0.5 to 100 ft/s). More elaborate, compensated units are commercially available for use in unsteady flow and turbulence measurements. In calibrating a hot-wire anemometer, it is preferable to use the same gas, temperature, and pressure as will be encountered in the intended application. In this case the quantity $I^2R_w/\Delta t$ can be plotted against $\sqrt{V}$, where $I$ = hot-wire current, $R_w$ = hot-wire resistance, $\Delta t$ = difference between the wire temperature and the gas bulk temperature, and $V$ = mean local velocity. A procedure is given by Wasan and Baid [*Am. Inst. Chem. Eng. J.* **17:** 729–731 (1971)] for use when it is impractical to calibrate with the same gas composition or conditions of temperature and pressure. Andrews, Bradley, and Hundy [*Int. J. Heat Mass Transfer* **15:** 1765–1786 (1972)] give a calibration correlation for measurement of small gas velocities. The hot-wire anemometer is treated in considerable detail in the following articles: The I.S.V.R. Constant Temperature **Hot Wire Anemometer**, ISVR Tech. Rep. No. 66. University of Southampton, United Kingdom. Davis, J. G. (1977). *IEEE Trans. Biomed. Eng.* **24:** 484–486. **Dean**, J. W., Brennan, J. A., Mann, D. B., and Kneebone, C. H. (1971). Natl. Bur. Stand. (U.S.), Tech. Note 606. **Dean**, J. W., Brennan ...; in Ladenburg et al., art. F-2; Grant and Kronauer, *Symposium on Measurement in Unsteady Flow,* ASME, New York, 1962, pp. 44–53; ASME, *Report of Research Committee on Fluid Meters*, op. cit., pp. 105–107; and Compte-Bellot, *Ann. Rev. Fluid Mech.* **8:** 209–231 (1976).

The hot-wire anemometer can be modified for liquid measurements, although difficulties are encountered because of bubbles and dirt adhering to the wire. See the articles for hydraulic flows by Stevens, Borden, and Strausser, David Taylor Model Basin Rep. 953, December 1956; Middlebrook and Piret, in the journal of *Industrial and Engineering Chemistry Research* **42:** 1511–1513 (1950); and Piret et al., *Ind. Eng. Chem.* **39:** 1098–1103 (1947).

The *hot-film anemometer* has been developed for applications in which use of the hot-wire anemometer presents problems. It consists of a platinum-film sensing element deposited on a glass substrate. Various geometries can be used. The most common involves a wedge with a 30° included angle at the end of a tapered rod. The wedge is commonly 1 mm (0.039 in) long and 0.2 mm (0.0079 in) wide on each face. Compared with the hot wire, it is less susceptible to fouling by bubbles or dirt when used in liquids, has greater mechanical strength when used with gases at high velocities and high temperatures, and can give a higher signal-to-noise ratio. For additional information see Ling and Hubbard, *J. Aeronaut. Sci.* **23:** 890–891 (1956); and Ling, *J. Basic Eng.* **82:** 629–634 (1960).

The *heated-thermocouple anemometer* measures gas velocity from the cooling effect of the gas stream flowing across the hot junctions of a thermopile supplied with constant electric power input. Alternate junctions are maintained at ambient temperature, thus compensating for the effect of ambient temperature. For details see Bunker, *Proc. Instrum. Soc. Am.* **9:** paper 54-43-2 (1954).

A glass-coated bead *thermistor anemometer* can be used for the measurement of low fluid velocities, down to 0.001 m/s (0.003 ft/s) in air and 0.0002 m/s (0.0007 ft/s) in water [see Murphy and Sparks, *Ind. Eng. Chem. Fundam.* **7:** 642–645 (1968)].

The *laser-Doppler anemometer* measures local fluid velocity from the change in frequency of radiation, between a stationary source and a receiver, due to scattering by particles along the wave path. A laser is commonly used as the source of incident illumination. The measurements are essentially independent of local temperature and pressure. This technique can be used in many different flow systems with transparent fluids containing particles whose velocity is actually measured. For a brief review of the laser-Doppler technique see Goldstein, *Appl. Mech. Rev.* **27:** 753–760 (1974). For additional details see Durst, Melling, and Whitelaw, *Principles and Practice of Laser-Doppler Anemometry,* Academic, New York, 1976.

## FLOWMETERS

In the process industries, flow measurement devices are the largest market in the process instrumentation field. Two web sites for process equipment and instrumentation, www.globalspec.com and www.thomasnet.com, both list more than 800 companies that offer flow measurement products. There are more than 100 types of flowmeters commercially available. The aforementioned web sites not only facilitate selection and specification of commercial flowmeters, but also provide electronic access to manufacturers' technical literature.

Devices that measure flow can be categorized in two areas as follows:

1. All types of measuring devices in which the material passes without being divided into isolated quantities. Movement of the material is usually sensed by a primary measuring element which activates a secondary device. The flow rate is then inferred from the response of the secondary device by means of known physical laws or from empirical relationships.
2. A positive-displacement meter, which applies to a device in which the flow is divided into isolated measured volumes. The number of fillings of these known volumes is measured with respect to time.

The most common application of flow measurement in process plants is flow in pipes, ducts, and tubing. Table 10-4 lists widely used flowmeters for these closed conduits as well as the two major classes of open-channel flowmeters. Table 10-4 also lists many other types of flowmeters that are discussed later in this subsection.

**TABLE 10-4 Comparison of Flowmeter Technologies**

| Flowmeter technology | Accuracy* (+/–) | Turndown | Fluids† | Pipe sizes,‡ in | Maximum pressure,‡ psig | Temperature range,‡ °F | Pipe run | Relative pressure loss |
|---|---|---|---|---|---|---|---|---|
| Differential Pressure Meters | | | | | | | | |
| Pitot | | 8:1 | L, G | 1 to 96 | 2.76E-4 to 200 | –200 to 750 | | L |
| Averaging pitot | 1% R | 8:1 | L, G, S | 0.25 to 72 | 8800 | –20 to 2370 | | L |
| Orifice | | | | | | | Long | |
| Square-edged | 0.5 to 1.5% R | 4:1 | L, G, S | 0.5 to 40 | 8800 | –4 to 2300 | | M |
| Eccentric | 2% R | 4:1 | L, G, S | 0.5 to 40 | 8800 | –4 to 2300 | | M |
| Segmental | 2% R | 4:1 | L, G, S, SL | 0.5 to 40 | 8800 | –4 to 2300 | | M |
| Orifice and multi-variable flow transmitter | 0.5 to 1% R | 10:1 | L, G, S | > 0.5 | 4000 | 1000 | | M |
| Venturi | 0.5 to 1.5% R | 10:1 | L, G, S, SL | 1 to 120 | 8800 | –4 to 2300 | | L |
| Flow nozzle | 0.5 to 2% R | 8:1 | L, G, S | 2 to 80 | >1000 | <1000 | | M |
| V cone | 0.5% F | 10:1 | L, G, S, SL | 0.25 to 120 | 6000 | To 400 | | M |
| Wedge | 0.5 to 5% R | 10:1 | L, G, S, SL | 0.5 to 24 | >600 | ‡ | | M |
| Velocity Meters | | | | | | | | |
| Correlation | 0.5% R | 10:1 | L, G, SL | 1 to 60 | Piping limits | To 600 | Long | L |
| Electromagnetic | 0.2 to 2% R | 10:1 | L | 0.15 to 60 | 5000 | –40 to 350 | Short | L |
| Propeller | 2% R | 15:1 | L | 2 to 12 | 230 | 0 to 300 | | M |
| Turbine | 0.15 to 1% R | 10:1 | L, G | 0.5 to 30 | 6000 | –450 to 600 | Short | M |
| Ultrasonic Doppler | 1 to 30% R | 50:1 | L, G, SL | 0.5 to 200 | 6000 | –40 to 250 | Long | L |
| Ultrasonic transit time | 0.5 to 5% R | Down to zero flow | L, G | 1 to 540 | 6000 | –40 to 650 | Long | L |
| Vortex | 0.5 to 2% R | 20:1 | L, G, S | 0.5 to 16 | 1500 | –330 to 800 | Short | M |
| Mass Meters | | | | | | | | |
| Coriolis | 0.1 to 0.3% R | 10:1 to 80:1 | L, G | 0.06 to 12 | 5700 | –400 to 800 | None | L, M |
| Thermal ( for gases) | 1% F | 50:1 | G | 0.125 to 8 | 4500 | 32 to 572 | Short | L |
| Thermal ( for liquids) | 0.5% F | 50:1 | L | 0.06 to 0.25 | 4500 | 40 to 165 | Short | L |
| Volumetric | 0.15 to 2% R | 10:1 | L | 0.25 to 16 | 2000 | –40 to 600 | None | M to H |
| Variable area | 1 to 5% F | 10:1 | L, G | 0.125 to 6 | 6000 | <1000 | None | M |
| Open-Channel Flowmeters | | | | | | | | |
| Weirs | 2 to 5% R | 25:1 | L | Wide range | NA | NA | | L |
| Flumes | 3 to 10% R | 40:1 | L | Wide range | NA | NA | | L |

*F = full scale, R = rate.
†L = liquid, G = gas, S = steam, SL = slurry.

Baker, *Introductory Guide to Flow Measurement*, American Society of Mechanical Engineers, New York, 2003; R. W. Miller, *Flow Measurement Engineering Handbook*, 3d ed., McGraw-Hill, New York, 1996; D. W. Spitzer, *Industrial Flow Measurement*, 3d ed., The Instrumentation, Systems, and Automation Society, Research Triangle Park, N.C., 2005; and manufacturers' literature at www.globalspec.com.

This subsection summarizes selection and installation of flowmeters, including the measurement of pressure and velocities of fluids when the flow measurement technique requires it.

## INDUSTRY GUIDELINES AND STANDARDS

Because flow measurement is important, many engineering societies and trade organizations have developed flow-related guidelines, standards, and other publications (Table 10-5). The reader should consult the appropriate standards when specifying, installing, and calibrating flow measurement systems.

There are also numerous articles in scholarly journals, trade magazines, and manufacturers' literature related to flow measurement.

Different types of flowmeters vary markedly in their degrees of sensitivity to flow disturbances. In the most extreme cases, obtaining highly accurate flow measurements with certain types of flowmeters may require 60*D* upstream straight pipe and 20*D* downstream. Valves can be particularly problematic because their effects on a flowmeter vary with valve position. Numerous types of flow straighteners or conditioners, as shown in Fig. 10-6, can significantly reduce the required run of straight pipe upstream of a given flowmeter.

## CLASSIFICATION OF FLOWMETERS

Table 10-4 lists the major classes of flowmeters, along with common examples of each. Brief descriptions are provided in this subsection, followed by more details in subsequent subsections.

**Differential Pressure Meters** Differential pressure meters or head meters measure the change in pressure across a special flow element. The differential pressure increases with increasing flow rate. The pitot tubes described previously work on this principle. Other examples include orifices [see also Eqs. (6-111) and (8-102) and Fig. 10-11], nozzles (Fig. 10-16), targets, venturis (see also Sec. 8 and Fig. 10-14), and elbow meters. Averaging pitot tubes produce a pressure differential that is based on multiple measuring points across the flow path.

Differential pressure meters are widely used. Temperature, pressure, and density affect gas density and readings of differential pressure meters. For that reason, many commercial flowmeters that are based on measurement of differential pressure often have integral temperature and absolute pressure measurements in addition to differential pressure. They also frequently have automatic temperature and pressure compensation.

**Velocity Meters** Velocity meters measure fluid velocity. Examples include electromagnetic, propeller, turbine, ultrasonic Doppler, ultrasonic transit time, and vortex meters. Section 8 describes the principles of operation of electromagnetic, turbine, ultrasonic, and vortex flowmeters.

**Mass Meters** Mass flowmeters measure the rate of mass flow through a conduit. Examples include Coriolis flowmeters and thermal mass flowmeters. Coriolis flowmeters can measure fluid density simultaneously with mass flow rate. This permits calculation of the volumetric flow rate as well. Section 8 includes brief descriptions of Coriolis and thermal mass flowmeters.

**Volumetric Meters** Volumetric meters (also called *positive-displacement flowmeters*) are devices that mechanically divide a fluid stream into discrete, known volumes and count the number of volumes that pass through the device. See Spitzer (2005, op. cit.).

**Variable-Area Meters** Variable-area meters, which are also called *rotameters*, offer popular and inexpensive flow measurement devices. These meters employ a float inside a tube that has an internal cross-sectional area which increases with distance upward in the flow path through the tube. As the flow rate increases, the float rises in the tube to provide a larger area for the flowing fluid to pass.

**Open-Channel Flow Measurement** Open-channel flow measurements are usually based on measurement of liquid level in a flow channel constructed of a specified geometry. The two most common flow channels used are weirs and flumes. See Spitzer, op. cit., 2005.

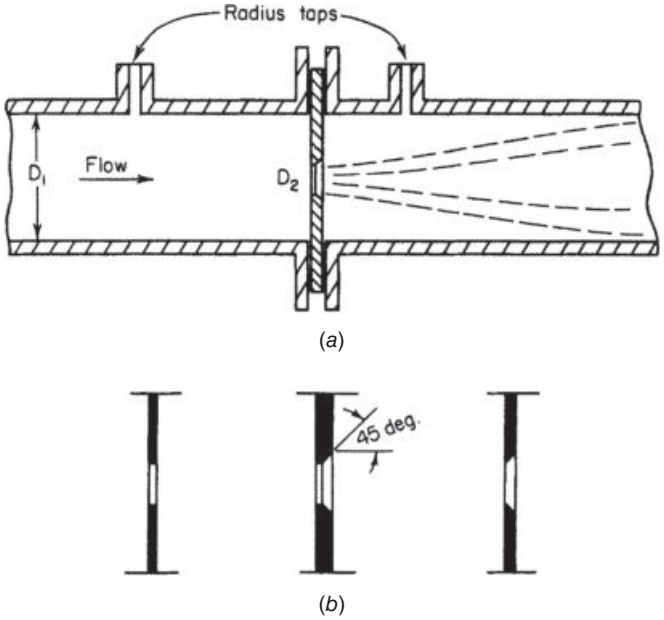

**FIG. 10-11** Square-edged or sharp-edged orifices. The plate at the orifice opening must not be thicker than one-thirtieth of the pipe diameter, one-eighth of the orifice diameter, or one-fourth of the distance from the pipe wall to the edge of the opening. (*a*) Pipeline orifice. (*b*) Types of plates.

## DIFFERENTIAL PRESSURE FLOWMETERS

**General Principles** If a constriction is placed in a closed channel carrying a stream of fluid, there will be an increase in velocity, and hence an increase in kinetic energy, at the point of constriction. From an energy balance, as given by Bernoulli's theorem [see Sec. 6, subsection Energy Balance, Eq. (6-16)], there must be a corresponding reduction in pressure. The rate of discharge from the constriction can be calculated by knowing this pressure reduction, the area available for flow at the constriction, the density of the fluid, and the coefficient of discharge *C*. The coefficient of discharge is defined as the ratio of actual flow to the theoretical flow and makes allowance for stream contraction and frictional effects. The metering characteristics of commonly used differential pressure meters are reviewed and grouped by Halmi [*J. Fluids Eng.* **95:** 127–141 (1973)].

The term *static head* generally denotes the pressure in a fluid due to the head of fluid above the point in question. Its magnitude is given by the application of Newton's law ( force = mass × acceleration). In the case of *liquids* (constant density), the static head $P_h$ (lbf/ft$^2$) is given by

$$P_h = h\rho g/g_c \tag{10-18}$$

where $h$ = head of liquid above the point, m ( ft); $\rho$ = liquid density; $g$ = local acceleration due to gravity; and $g_c$ = dimensional constant.

The head developed in a compressor or pump is the energy force per unit mass. In the measuring systems it is often misnamed as feet while the units are really ft · lb$_f$/lbm or kilojoules (kJ).

For a compressor or turbine, it is represented by the following relationship:

$$E = U_1 V_{\theta 1} - U_2 V_{\theta 2} \tag{10-19}$$

where $U$ is the blade speed and $V_\theta$ is the tangential velocity component of absolute velocity. This equation is known as the *Euler equation.*

**Orifice Meters** A *square-edged* or *sharp-edged* orifice, as shown in Fig. 10-11, is a clean-cut square-edged hole with straight walls perpendicular to the flat upstream face of a thin plate placed crosswise to the channel. The stream issuing from such an orifice attains its minimum cross section (vena contracta) at a distance downstream of the orifice which varies with the ratio $\beta$ of orifice to pipe diameter (see Fig. 10-12).

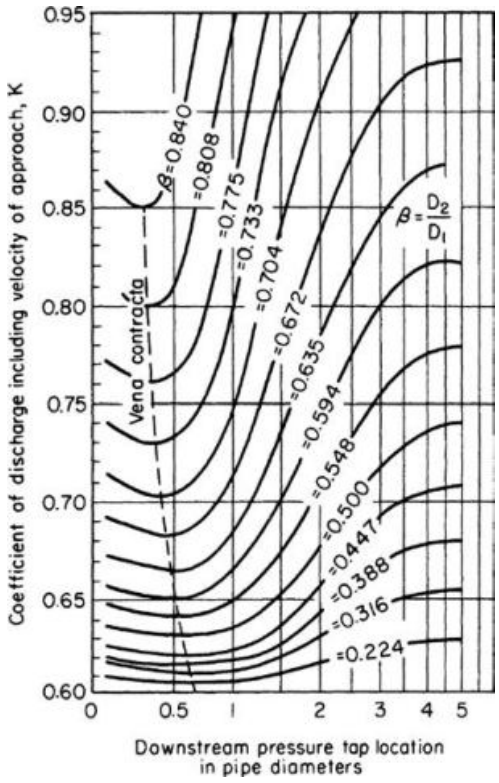

**FIG. 10-12** Coefficient of discharge for square-edged circular orifices for $N_{Re} > 30{,}000$ with the upstream tap located between 1 and 2 pipe diameters from the orifice plate. [Spitzglass, *Trans. Am. Soc. Mech. Eng.* **44:** 919 (1922).]

For a centered circular orifice in a pipe, the pressure differential is customarily measured between one of the following pressure-tap pairs. Except in the case of flange taps, all measurements of distance from the orifice are made from the upstream face of the plate.

1. *Corner taps.* Static holes are drilled, one in the upstream and one in the downstream flange, with the openings as close as possible to the orifice plate.
2. *Radius taps.* Static holes are located 1 pipe diameter upstream and 0.5 pipe diameter downstream from the plate.
3. *Pipe taps.* Static holes are located 2½ pipe diameters upstream and 8 pipe diameters downstream from the plate.
4. *Flange taps.* Static holes are located 25.4 mm (1 in) upstream and 25.4 mm (1 in) downstream from the plate.
5. *Vena contracta taps.* The upstream static hole is 0.5 to 2 pipe diameters from the plate. The downstream tap is located at the position of minimum pressure (see Fig. 10-12).

Radius taps are best from a practical standpoint; the downstream pressure tap is located at about the mean position of the vena contracta, and the upstream tap is sufficiently far upstream to be unaffected by distortion of the flow in the immediate vicinity of the orifice (in practice, the upstream tap can be as much as 2 pipe diameters from the plate without affecting the results). Vena contracta taps give the largest differential head for a given rate of flow but are inconvenient if the orifice size is changed from time to time. Corner taps offer the sometimes great advantage that the pressure taps can be built into the plate carrying the orifice. Thus the entire apparatus can be quickly inserted in a pipeline at any convenient flanged joint without having to drill holes in the pipe.

Flange taps are similarly convenient since by merely replacing standard flanges with special orifice flanges, suitable pressure taps are made available. Pipe taps give the lowest differential pressure, the value obtained being close to the permanent pressure loss.

The practical working equation for flow rate ($\dot{m}$) of discharge, adopted by the ASME Research Committee on Fluid Meters for use with either gases or liquids, is

$$\dot{m} = q_1\rho_1 = CYA_2\sqrt{\frac{2g_c(p_1-p_2)\rho_1}{1-\beta^4}} = KYA_2\sqrt{2g_c(p_1-p_2)\rho_1} \tag{10-20}$$

where $A_2$ = cross-sectional area of throat; $C$ = coefficient of discharge, dimensionless; $g_c$ = dimensional constant; $K = C/\sqrt{1-\beta^4}$, dimensionless; $p_1$, $p_2$ = pressure at upstream and downstream static pressure taps, respectively; $q_1$ = volumetric rate of discharge measured at upstream pressure and temperature; $\dot{m}$ = weight rate of discharge; $Y$ = expansion factor, dimensionless; $\beta$ = ratio of throat diameter to pipe diameter, dimensionless; and $\rho_1$ = density at upstream pressure and temperature.

For the case of subsonic flow of a gas ($r_c < r < 1.0$), the expansion factor $Y$ for orifices is approximated by

$$Y = 1 - [(1-r)/k]\,(0.41 + 0.35\beta^4) \tag{10-21}$$

where $r$ = ratio of downstream to upstream static pressure ($p_2/p_1$), $k$ = ratio of specific heats ($c_p/c_v$), and $\beta$ = diameter ratio. (See also Fig. 10-15.) Values of $Y$ for supercritical flow of a gas ($r < r_c$) through orifices are given by Benedict [*J. Basic Eng.* **93:** 121–137 (1971)]. For the case of *liquids*, expansion factor $Y$ is unity, and Eq. (10-25) should be used, since it allows for any difference in elevation between the upstream and downstream taps.

Coefficient of discharge $C$ for a given orifice type is a function of the Reynolds number $N_{Re}$ (based on orifice diameter and velocity) and diameter ratio $\beta$. At Reynolds numbers greater than about 30,000, the coefficients are substantially constant. For square-edged or sharp-edged concentric circular orifices, the value will fall between 0.595 and 0.620 for vena contracta or radius taps for $\beta$ up to 0.8 and for flange taps for $\beta$ up to 0.5. Figure 10-12 gives the coefficient of discharge $K$, including the velocity-of-approach factor $1/\sqrt{1-\beta^4}$, as a function of $\beta$ and the location of the downstream tap. Precise values of $K$ are given in ASME, *PTC*, 1997, pp. 20–39, for flange taps, radius taps, vena contracta taps, and corner taps. Precise values of $C$ are given in ASME, *Report of the Research Committee on Fluid Meters,* 1971, pp. 202–207, for the first three types of taps.

The discharge coefficient of sharp-edged orifices was shown by Benedict, Wyler, and Brandt [*J. Eng. Power* **97:** 576–582 (1975)] to increase with edge roundness. Typical as-purchased orifice plates may exhibit deviations on the order of 1 to 2 percent from ASME values of the discharge coefficient.

In the transition region ($N_{Re}$ between 50 and 30,000), the coefficients are generally higher than the above values. Although calibration is generally advisable in this region, the curves given in Fig. 10-13 for corner and vena

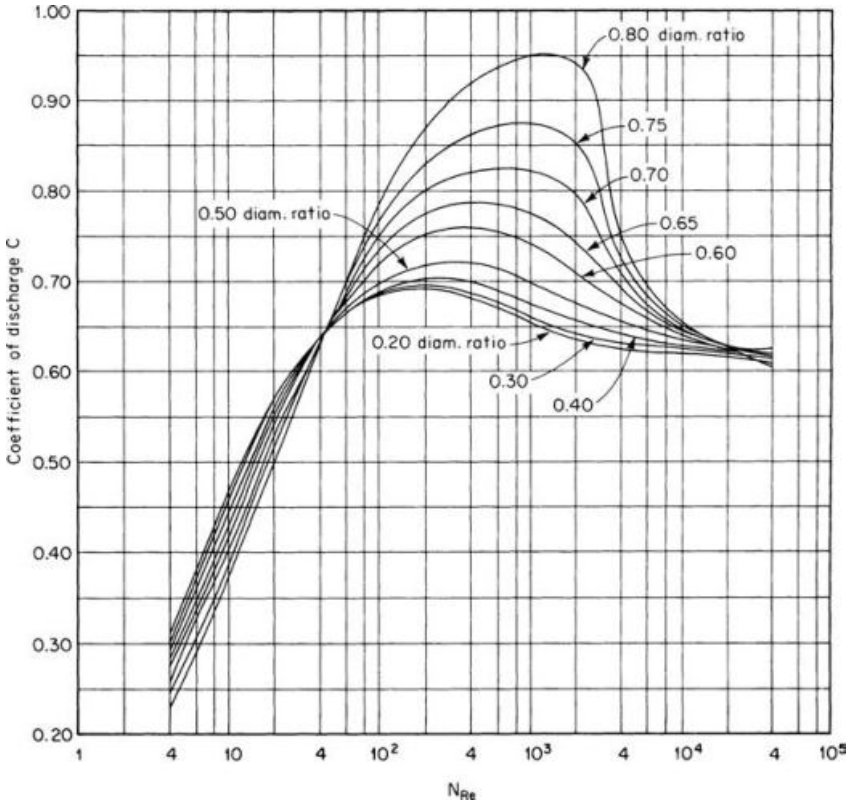

**FIG. 10-13** Coefficient of discharge for square-edged circular orifices with corner taps. [Tuve and Sprenkle, *Instruments* **6:** 201 (1933).]

contracta taps can be used as a guide. In the laminar-flow region ($N_{Re} < 50$), the coefficient $C$ is proportional to $\sqrt{N_{Re}}$. For $1 < N_{Re} < 100$, Johansen [*Proc. R. Soc.* (*London*), **A121:** 231–245 (1930)] presents discharge coefficient data for sharp-edged orifices with corner taps. For $N_{Re} < 1$, Miller and Nemecek [ASME Paper 58-A-106 (1958)] present correlations giving coefficients for sharp-edged orifices and short-pipe orifices ($L/D$ from 2 to 10). For short-pipe orifices ($L/D$ from 1 to 4), Dickerson and Rice [*J. Basic Eng.* **91:** 546–548 (1969)] give coefficients for the intermediate range ($27 < N_{Re} < 7000$). See also the subsection Contraction and Entrance Losses.

*Permanent pressure loss* across a concentric circular orifice with radius or vena contracta taps can be approximated for turbulent flow by

$$(p_1 - p_4)/(p_1 - p_2) = 1 - \beta^2 \tag{10-22}$$

where $p_1, p_2$ = upstream and downstream pressure-tap readings, respectively, $p_4$ = fully recovered pressure (4 to 8 pipe diameters downstream of the orifice), and $\beta$ = diameter ratio. See ASME, *PTC,* 1997, fig. 5.

See Benedict, *J. Fluids Eng.* **99:** 245–248 (1977), for a general equation for pressure loss for orifices installed in pipes or with plenum inlets. Orifices show higher loss than nozzles or ventura's. Permanent pressure loss for laminar flow depends on the Reynolds number in addition to $\beta$. See Alvi, Sridharan, and Rao, *J. Fluids Eng.* **100**(3): 99–307 (1978).

For the case of *critical flow* through a square- or sharp-edged concentric circular orifice (where $r \le r_c$, as discussed earlier in this subsection), use Eqs. (10-29), (10-30), and (10-31) as given for critical-flow nozzles. However, unlike with nozzles, the flow through a sharp-edged orifice continues to increase as the downstream pressure drops below that corresponding to the critical pressure ratio $r_c$. This is due to an increase in the cross section of the vena contracta as the downstream pressure is reduced, giving a corresponding increase in the coefficient of discharge. At $r = r_c$, $C$ is about 0.75, while at $r = 0$, $C$ has increased to about 0.84. See Benedict, *J. Basic Eng.* **93:** 99–120 (1971).

Measurements by Harris and Magnall [*Trans. Inst. Chem. Eng.* (*London*), **50:** 61–68 (1972)] with a venturi ($\beta = 0.62$) and orifices with radius taps ($\beta = 0.60$ to 0.75) indicate that the discharge coefficient for nonnewtonian fluids, in the range of $N_{Re}$ (generalized Reynolds number) from 3500 to 100,000, is approximately the same as for newtonian fluids at the same Reynolds number.

*Quadrant-edge orifices* have holes with rounded edges on the upstream side of the plate. The quadrant-edge radius is equal to the thickness of the plate at the orifice location. The advantages claimed for this type versus the square- or sharp-edged orifice are constant-discharge coefficients extending to lower Reynolds numbers and less possibility of significant changes in coefficient because of erosion or other damage to the inlet shape.

Values of discharge coefficient $C$ and Reynolds number limits for constant $C$ are presented in Table 10-6, based on Ramamoorthy and Seetharamiah [*J. Basic Eng.* **88:** 9–13 (1966)] and Bogema and Monkmeyer (*J. Basic Eng.* **82:** 729–734 (1960)]. At Reynolds numbers above those listed for the upper limits, the coefficients rise abruptly. As Reynolds numbers decrease below those listed for the lower limits, the coefficients pass through a hump and then drop off. According to Bogema, Spring, and Ramamoorthy [*J. Basic Eng.* **84:** 415–418 (1962)], the hump can be eliminated by placing a fine-mesh screen about 3 pipe diameters upstream of the orifice. This reduces the lower $N_{Re}$ limit to about 500.

Permanent pressure loss across quadrant-edge orifices for turbulent flow is somewhat lower than that given by Eq. (10-22). See Alvi, Sridharan, and Rao, loc. cit., for values of the discharge coefficient and permanent pressure loss in laminar flow.

*Slotted orifices* offer significant advantages over a standard square-edged orifice with an identical open area for homogeneous gases or liquids [Morrison and Hall, *Hydrocarbon Processing* **79:** 12, 65–72 (2000)]. The slotted orifice flowmeter only requires compact header configurations with very short upstream pipe lengths and maintains accuracy in the range of 0.25 percent with no flow conditioner. Permanent head loss is less than or equal to that of a standard orifice that has the same $\beta$ ratio. Discharge coefficients for the slotted orifice are much less sensitive to swirl or to axial velocity profiles. A slotted orifice plate can be a "drop-in" replacement for a standard orifice plate.

**TABLE 10-6 Discharge Coefficients for Quadrant-Edge Orifices**

| | | | Limiting $N_{Re}^*$ for constant coefficient† | |
|---|---|---|---|---|
| $\beta$ | $C$‡ | $K$‡ | Lower | Upper |
| 0.225 | 0.770 | 0.771 | 5000 | 60,000 |
| 0.400 | 0.780 | 0.790 | 5000 | 150,000 |
| 0.500 | 0.824 | 0.851 | 4000 | 200,000 |
| 0.600 | 0.856 | 0.918 | 3000 | 120,000 |
| 0.630 | 0.885 | 0.964 | 3000 | 105,000 |

*Based on pipe diameter and velocity.
†For a precision of about ±0.5 percent.
‡Can be used with corner taps, flange taps, or radius taps.

*Segmental* and *eccentric orifices* are frequently used for gas metering when there is a possibility that entrained liquids or solids would otherwise accumulate in front of a concentric circular orifice. This can be avoided if the opening is placed on the lower side of the pipe. For liquid flow with entrained gas, the opening is placed on the upper side. The pressure taps should be located on the opposite side of the pipe from the opening.

Coefficient $C$ for a square-edged eccentric circular orifice (with opening tangent to pipe wall) varies from about 0.61 to 0.63 for $\beta$ values from 0.3 to 0.5, respectively, and pipe Reynolds numbers > 10,000 for either vena contracta or flange taps (where $\beta$ = diameter ratio). For square-edged segmental orifices, coefficient $C$ falls generally between 0.63 and 0.64 for $0.3 \le \beta \le 0.5$ and pipe Reynolds numbers > 10,000, for vena contracta or flange taps, where $\beta$ = diameter ratio for an equivalent circular orifice = $\sqrt{\alpha}$ ($\alpha$ = ratio of orifice to pipe cross-sectional areas). Values of expansion factor $Y$ are slightly higher than for concentric circular orifices, and the location of the vena contracta is moved farther downstream as compared with concentric circular orifices. For further details, see ASME, *Report of the Research Committee on Fluid Meters*, 1971, pp. 210–213.

For permanent pressure loss with segmental and eccentric orifices with laminar pipe flow see Lakshmana Rao and Sridharan, *Proc. Am. Soc. Civ. Eng., J. Hydraul. Div.* **98**(HY 11): 2015–2034 (1972).

*Annular orifices* can also be used to advantage for gas metering when there is a possibility of entrained liquids or solids and for liquid metering with entrained gas present in small concentrations. Coefficient $K$ was found by Bell and Bergelin [*Trans. Am. Soc. Mech. Eng.* **79:** 593–601 (1957)] to range from about 0.63 to 0.67 for annulus Reynolds numbers in the range of 100 to 20,000, respectively, for values of $2L/(D - d)$ less than 1 where $L$ = thickness of orifice at outer edge, $D$ = inside pipe diameter, and $d$ = diameter of orifice disk. The *annulus Reynolds number* is defined as

$$N_{Re} = (D - d)\,(G/\mu) \tag{10-23}$$

where $G$ = mass velocity $\rho V$ through orifice opening and $\mu$ = fluid viscosity. The above coefficients were determined for $\beta$ values (= $d/D$) in the range of 0.95 to 0.996 and with pressure taps located 19 mm (¾ in) upstream of the disk and 230 mm (9 in) downstream in a 5.25-in-diameter pipe.

**Venturi Meters** The standard Herschel-type venturi meter consists of a short length of straight tubing connected at either end to the pipeline by conical sections (see Fig. 10-14). Recommended proportions (ASME, *PTC*, 1997, p. 17) are entrance cone angle $\alpha_1 = 21 \pm 2°$, exit cone angle $\alpha_2 = 5$ to 15°, throat length = 1 throat diameter, and upstream tap located 0.25 to 0.5 pipe diameter upstream of the entrance cone. The straight and conical sections should be joined by smooth curved surfaces for best results. *Rate of discharge* of either gases or liquids through a venturi meter is given by Eq. (10-20).

For the flow of *gases,* expansion factor $Y$, which allows for the change in gas density as it expands adiabatically from $p_1$ to $p_2$, is given by

$$Y = \sqrt{r^{2/k}\left(\frac{k}{k-1}\right)\left(\frac{1-r^{(k-1)/k}}{1-r}\right)\left(\frac{1-\beta^4}{1-\beta^4 r^{2/k}}\right)} \tag{10-24}$$

for venturi meters and flow nozzles, where $r = p_2/p_1$ and $k$ = specific heat ratio $c_p/c_v$. Values of $Y$ computed from Eq. (10-24) are given in Fig. 10-15 as a function of $r$, $k$, and $\beta$.

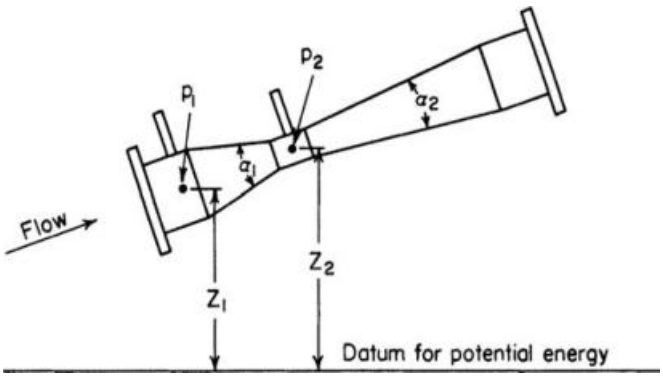

**FIG. 10-14** Herschel-type venturi tube.

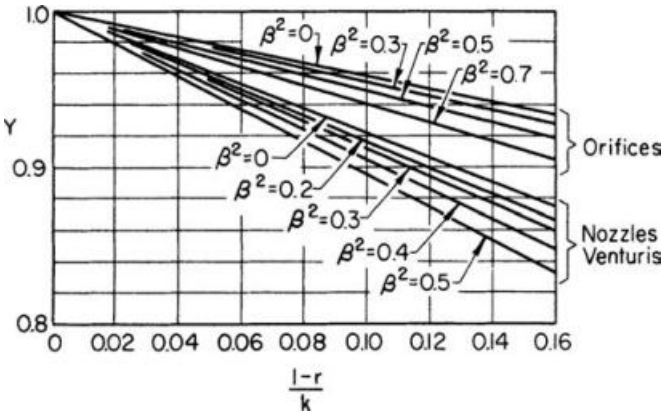

**FIG. 10-15** Values of expansion factor $Y$ for orifices, nozzles, and venturis.

For the flow of *liquids,* expansion factor $Y$ is unity. The change in potential energy in the case of an inclined or vertical venturi meter must be allowed for. Equation (10-20) is accordingly modified to give

$$\dot{m} = q_1\rho = CA_2\sqrt{\frac{[2g_c(p_1 - p_2) + 2g\rho(Z_1 - Z_2)]\rho}{1-\beta^4}} \tag{10-25}$$

where $g$ = local acceleration due to gravity and $Z_1, Z_2$ = vertical heights above an arbitrary datum plane corresponding to the centerline pressure-reading locations for $p_1$ and $p_2$, respectively.

The value of the *discharge coefficient C* for a *Herschel-type venturi meter* depends on the Reynolds number and to a minor extent on the size of the venturi, increasing with diameter. A plot of $C$ versus pipe Reynolds number is given in ASME, *PTC,* 1997, p. 19. A value of 0.984 can be used for pipe Reynolds numbers larger than 200,000.

*Permanent pressure loss* for a Herschel-type venturi tube depends on the diameter ratio β and discharge cone angle $\alpha_2$. It ranges from 10 to 15 percent of the pressure differential $p_1 - p_2$ for small angles (5° to 7°) and from 10 to 30 percent for large angles (15°), with the larger losses occurring at low values of β (see ASME, *PTC,* 1997, p. 12). See Benedict, *J. Fluids Eng.* **99:** 245–248 (1977), for a general equation for pressure loss for venturis installed in pipes or with plenum inlets.

For flow measurement of *steam and water mixtures* with a Herschel-type venturi in 2½-in- and 3-in-diameter pipes, see Collins and Gacesa, *J. Basic Eng.* **93:** 11–21 (1971).

A variety of *short-tube* venturi meters are available commercially. They require less space for installation and are generally (although not always) characterized by a greater pressure loss than the corresponding Herschel-type venturi meter. Discharge coefficients vary widely for different types, and individual calibration is recommended if the manufacturer's calibration is not available. Results of tests on the Dall flow tube are given by Miner [*Trans. Am. Soc. Mech. Eng.* **78:** 475–479 (1956)] and Dowdell [*Instrum. Control Syst.* **33:** 1006–1009 (1960)]; and on the Gentile flow tube (also called the Beth flow tube or Foster flow tube) by Hooper [*Trans. Am. Soc. Mech. Eng.* **72:** 1099–1110 (1950)].

The use of a *multiventuri system* (in which an inner venturi discharges into the throat of an outer venturi) to increase both the differential pressure for a given flow rate and the signal-to-loss ratio is described by Klomp and Sovran [*J. Basic Eng.* **94:** 39–45 (1972)].

**Flow Nozzles** A simple form of flow nozzle is shown in Fig. 10-16. It consists essentially of a short cylinder with a flared approach section.

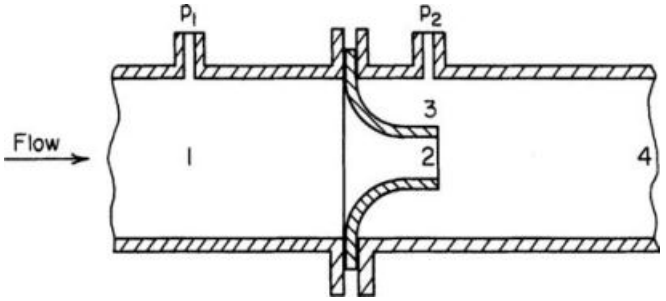

**FIG. 10-16** Flow nozzle assembly.

The approach cross section is preferably elliptical but may be conical. Recommended contours for long-radius flow nozzles are given in ASME, *PTC,* 1997, p. 13. In general, the length of the straight portion of the throat is about one-half the throat diameter, the upstream pressure tap is located about 1 pipe diameter from the nozzle inlet face, and the downstream pressure tap is about ½ pipe diameter from the inlet face. For subsonic flow, the pressures at points 2 and 3 will be practically identical. If a conical inlet is preferred, the inlet and throat geometry specified for a Herschel-type venturi meter can be used, omitting the expansion section.

The *rate of discharge* through a flow nozzle for subcritical flow can be determined by the equations given for venturi meters, Eq. (10-20) for gases and Eq. (10-25) for liquids. The expansion factor $Y$ for nozzles is the same as that for venturi meters [Eq. (10-24), Fig. 10-15]. The value of the discharge coefficient $C$ depends primarily on the pipe Reynolds number and to a lesser extent on the diameter ratio β. Curves of recommended coefficients for long-radius flow nozzles with pressure taps located 1 pipe diameter upstream and ½ pipe diameter downstream of the inlet face of the nozzle are given in ASME, *PTC,* 1997, p. 15. In general, coefficients range from 0.95 at a pipe Reynolds number of 10,000 to 0.99 at 1,000,000.

The performance characteristics of pipe wall-tap nozzles (Fig. 10-16) and throat-tap nozzles are reviewed by Wyler and Benedict [*J. Eng. Power* **97:** 569–575 (1975)].

*Permanent pressure loss* across a subsonic flow nozzle is approximated by

$$p_1 - p_4 = \frac{1-\beta^2}{1+\beta^2}(p_1 - p_2) \tag{10-26}$$

where $p_1$, $p_2$, $p_4$ = static pressures measured at the locations shown in Fig. 10-16 and β = ratio of nozzle throat diameter to pipe diameter, dimensionless. Equation (10-26) is based on a momentum balance assuming constant fluid density (see Lapple et al., *Fluid and Particle Mechanics,* University of Delaware, Newark, 1951, p. 13).

See Benedict, R. P., "On the Determination and Combination of Loss. Coefficients for Compressible Fluid Flows," *J. Eng. Power, ASME Trans.*, vol. 88, for a general equation for pressure loss for nozzles installed in pipes or with plenum inlets. Nozzles show higher loss than venturis. Permanent pressure loss for laminar flow depends on the Reynolds number in addition to β. For details, see Alvi, Sridharan, and Lakshamana Rao, *J. Fluids Eng.* **100:** 299–307 (1978).

**Critical Flow Nozzle** For a given set of upstream conditions, the rate of discharge of a gas from a nozzle will increase for a decrease in the absolute pressure ratio $p_2/p_1$ until the linear velocity in the throat reaches that of sound in the gas at that location. The value of $p_2/p_1$ for which the acoustic velocity is just attained is called the *critical pressure ratio* $r_c$. The actual pressure in the throat will not fall below $p_1 r_c$ even if a much lower pressure exists downstream.

The critical pressure ratio $r_c$ can be obtained from the following theoretical equation, which assumes a perfect gas and a frictionless nozzle:

$$r_c^{(1-k)/k} + \left(\frac{k-1}{2}\right)\beta^4 r_c^{2/k} = \frac{k+1}{2} \tag{10-27}$$

This reduces, for $\beta \le 0.2$, to

$$r_c = \left(\frac{2}{k+1}\right)^{k/(k-1)} \tag{10-28}$$

where $k$ = ratio of specific heats $c_p/c_v$ and β = diameter ratio. A table of values of $r_c$ as a function of $k$ and β is given in ASME, *Report of the Research Committee on Fluid Meters,* New York, 1971, p. 68. For small values of β, $r_c = 0.487$ for $k = 1.667$, $r_c = 0.528$ for $k = 1.40$, $r_c = 0.546$ for $k = 1.30$, and $r_c = 0.574$ for $k = 1.15$.

Under *critical flow conditions,* only the upstream conditions $p_1$, $\upsilon_1$, and $T_1$ need be known to determine the flow rate, which, for $\beta \le 0.2$, is given

$$\dot{m}_{max} = CA_2\sqrt{g_c k\left(\frac{p_1}{\upsilon_1}\right)\left(\frac{2}{k+1}\right)^{(k+1)/(k-1)}} \tag{10-29}$$

For a *perfect gas,* this corresponds to

$$\dot{m}_{max} = CA_2 p_1\sqrt{g_c k\left(\frac{M}{RT_1}\right)\left(\frac{2}{k+1}\right)^{(k+1)/(k-1)}} \tag{10-30}$$

For air, Eq. (10-30) reduces to

$$\dot{m}_{max} = C_1 CA_2 p_1/\sqrt{T_1} \tag{10-31}$$

where $A_2$ = cross-sectional area of throat; $C$ = coefficient of discharge, dimensionless; $g_c$ = dimensional constant; $k$ = ratio of specific heats $c_p/c_v$; $M$ = molecular weight; $p_1$ = pressure on upstream side of nozzle; $R$ = gas constant;

$T_1$ = absolute temperature on upstream side of nozzle; $v_1$ = specific volume on upstream side of nozzle; $C_1$ = dimensional constant, 0.0405 SI unit (0.533 U.S. Customary System unit); and $\dot{m}_{max}$ = maximum-weight flow rate.

Discharge coefficients for critical flow nozzles are, in general, the same as those for subsonic nozzles. See Grace and Lapple, *Trans. Am. Soc. Mech. Eng.* **73:** 639–647 (1951); and Szaniszlo, *J. Eng. Power* **97:** 521–526 (1975). Arnberg, Britton, and Seidl [*J. Fluids Eng.* **96:** 111–123 (1974)] present discharge coefficient correlations for circular-arc venturi meters at critical flow. For the calculation of the flow of natural gas through nozzles under critical-flow conditions, see Johnson, *J. Basic Eng.* **92:** 580–589 (1970).

**Elbow Meters** A pipe elbow can be used as a flowmeter for liquids if the differential centrifugal head generated between the inner and outer radii of the bend is measured by means of pressure taps located midway around the bend. Equation (10-25) can be used, except that the pressure difference term $p_1 - p_2$ is now taken to be the differential centrifugal pressure and β is taken as zero, if one assumes no change in cross section between the pipe and the bend. The discharge coefficient should preferably be determined by calibration, but as a guide it can be estimated within ±6 percent for circular pipe for Reynolds numbers greater than $10^5$ from $C = 0.98\sqrt{R_c/2D}$, where $R_c$ = radius of curvature of the centerline and $D$ = inside pipe diameter in consistent units. See Murdock, Foltz, and Gregory, *J. Basic Eng.* **86:** 498–506 (1964); or ASME, *Report of the Research Committee on Fluid Meters*, 1971, pp. 75–77.

**Accuracy** Square-edged orifices and venturi tubes have been so extensively studied and standardized that reproducibility within 1 to 2 percent can be expected between standard meters when new and clean. This is therefore the order of reliability to be had, if one assumes (1) accurate measurement of meter differential, (2) selection of the coefficient of discharge from recommended published literature, (3) accurate knowledge of fluid density, (4) accurate measurement of critical meter dimensions, (5) smooth upstream face of orifice, and (6) proper location of the meter with respect to other flow-disturbing elements in the system. Care must also be taken to avoid even slight corrosion or fouling during use.

Presence of *swirling flow* or an *abnormal velocity distribution* upstream of the metering element can cause serious metering error unless calibration in place is employed or sufficient straight pipe is inserted between the meter and the source of disturbance. Table 10-7 gives the minimum lengths of straight pipe required to avoid appreciable error due to the presence of certain fittings and valves either upstream or downstream of an orifice or nozzle. These values were extracted from plots presented by Sprenkle [*Trans. Am. Soc. Mech. Eng.* **67:** 345–360 (1945)]. Table 10-7 also shows the reduction in spacing made possible by the use of straightening vanes between the fittings and the meter. Entirely adequate straightening vanes can be provided by fitting a bundle of thin-wall tubes within the pipe. The center-to-center distance between tubes should not exceed one-fourth of the pipe diameter, and the bundle length should be at least 8 times this distance.

**TABLE 10-7 Locations of Orifices and Nozzles Relative to Pipe Fittings**

Distances in pipe diameters $D_1$

| Type of fitting upstream | $\frac{D_2}{D_1}$ | Distance, upstream fitting to orifice | | Distance, vanes to orifice | Distance, nearest downstream fitting from orifice |
|---|---|---|---|---|---|
| | | Without straightening vanes | With straightening vanes | | |
| Single 90° ell, tee, or cross used as ell | 0.2 | 6 | | | 2 |
| | 0.4 | 6 | | | |
| | 0.6 | 9 | 9 | | |
| | 0.8 | 20 | 12 | 8 | 4 |
| 2 short-radius 90° ells in form of S | 0.2 | 7 | | | 2 |
| | 0.4 | 8 | 8 | | |
| | 0.6 | 13 | 10 | 6 | |
| | 0.8 | 25 | 15 | 11 | 4 |
| 2 long- or short-radius 90° ells in perpendicular planes | 0.2 | 15 | 9 | 5 | 2 |
| | 0.4 | 18 | 10 | 6 | |
| | 0.6 | 25 | 11 | 7 | |

The distances specified in Table 10-7 will be conservative if applied to venturi meters. For specific information on requirements for venturi meters, see a discussion by Pardoe appended to Sprenkle [*Trans. Am. Soc. Mech. Eng.* **67:** 345–360 (1945)]. Extensive data on the effect of installation on the coefficients of venturi meters are given elsewhere by Pardoe [*Trans. Am. Soc. Mech. Eng.* **65:** 337–349 (1943)].

As a general rule, a concentric orifice plate is the most economical solution to flow measurement for most applications if the calculated permanent pressure loss is acceptable and the upstream and downstream piping configuration provides for a stabilized flow pattern. Unique designs such as the conditioning orifice plate offered by Emerson Rosemount Pak or a flow tube with an integral flow stabilization design such as the FlowPak flow tube assembly offered by Fluidic Techniques provide optional considerations for areas where straight lengths of upstream and downstream piping are problematic.

1. Conditioning orifice plate (see Fig. 10-17)

This copyrighted design requires only 2 pipe diameters upstream and downstream from a flow disturbance and is suitable for most liquids, gases, and steam. Refer to the Emerson Rosemount web site for more details.

2. The high head recovery FlowPak (see Fig. 10-18) is a patented flow tube design with a uniquely designed flow-conditioning translineal flow plate which eliminates the requirement of straight pipe between the upstream disturbances while providing the known properties of the flow tube characteristics including constant discharge coefficient, low uncertainty, and low permanent pressure loss. Refer to the Fluidics Techniques web site for more details.

In the presence of *flow pulsations,* the indications of head meters such as orifices, nozzles, and venturis will often be undependable for several reasons. First, the measured pressure differential will tend to be high, since the pressure differential is proportional to the square of the flow rate for a head meter, and the square root of the mean differential pressure is always greater than the mean of the square roots of the differential pressures. Second, there is a phase shift as the wave passes through the metering restriction, which can affect the differential. Third, pulsations can be set up in the manometer leads themselves. Frequency of the pulsation also plays a part. At low frequencies, the meter reading can generally faithfully follow the flow pulsations, but at high frequencies it cannot. This is due to inertia of the fluid in the manometer leads or of the manometric fluid, whereupon the meter would give a reading intermediate between the maximum and minimum flows but having no readily predictable relation to the mean flow. Pressure transducers with flush-mounted diaphragms can be used together

**FIG. 10-17** Rosemont 1595 Conditioning Orifice Plate. (*Courtesy of Rosemont.*)

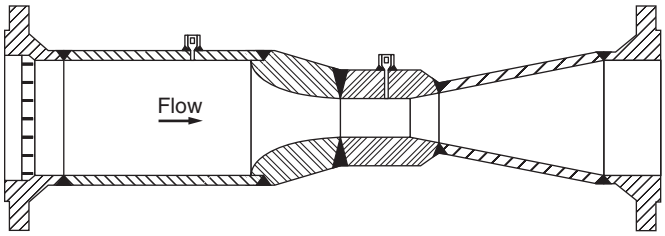

**FIG. 10-18** High Head Recovery FloPak. (*Courtesy of Fluidic Technology.*)

with high-speed recording equipment to provide accurate records of the pressure profiles at the upstream and downstream pressure taps, which can then be analyzed and translated into a mean flow rate.

The rather general practice of producing a steady differential reading by placing restrictions in the manometer leads can result in a reading which, under a fixed set of conditions, may be useful in control of an operation but which has no readily predictable relation to the actual average flow. If calibration is employed to compensate for the presence of pulsations, then complete reproduction of operating conditions, including source of pulsations and waveform, is necessary to ensure reasonable accuracy.

According to Head [*Trans. Am. Soc. Mech. Eng.* **78:** 1471–1479 (1956)], a pulsation intensity limit of $\Gamma = 0.1$ is recommended as a practical pulsation threshold below which the performance of all types of flowmeters will differ negligibly from steady-flow performance (an error of less than 1 percent in flow due to pulsation). The peak-to-trough flow variation $\Gamma$ is expressed as a fraction of the average flow rate. According to the *Report of the ASME Research Committee on Fluid Meters* (pp. 34–35), the fractional metering error $E$ for *liquid flow* through a head meter is given by

$$(1 + E)^2 = 1 + \Gamma^2/8 \tag{10-32}$$

When the pulsation amplitude is such as to result in a greater-than-permissible metering error, consideration should be given to installation of a pulsation damper between the source of pulsations and the flowmeter. References to methods of pulsation damper design are given in the subsection Unsteady-State Behavior.

Pulsations are most likely to be encountered in discharge lines from reciprocating pumps or compressors and in lines supplying steam to reciprocating machinery. For *gas flow,* a combination involving a surge chamber and a constriction in the line can be used to damp out the pulsations to an acceptable level. The surge chamber is generally located as close to the pulsation source as possible, with the constriction between the surge chamber and the metering element. This arrangement can be used for either a suction or a discharge line. For such an arrangement, the metering error has been found to be a function of the *Hodgson number* $N_H$, which is defined as

$$N_H = Qn\,\Delta p_s / q p_s \tag{10-33}$$

where $Q$ = volume of surge chamber and pipe between metering element and pulsation source; $n$ = pulsation frequency; $\Delta p_s$ = permanent pressure drop between metering element and surge chamber; $q$ = average volume flow rate, based on gas density in the surge chamber; and $p_s$ = pressure in surge chamber.

Herning and Schmid [*Z. Ver. Dtsch. Ing.* **82:** 1107–1114 (1938)] presented charts for a simplex double-acting compressor for the prediction of metering error as a function of the Hodgson number and $s$, the ratio of piston discharge time to total time per stroke. Table 10-8*a* gives the minimum Hodgson numbers required to reduce the metering error to 1 percent as given by the charts ( for specific heat ratios between 1.28 and 1.37). Schmid [*Z. Ver. Dtsch. Ing.* **84:** 596–598 (1940)] presented similar charts for a duplex double-acting compressor and a triplex double-acting compressor for a specific heat ratio of 1.37. Table 10-8*b* gives the minimum Hodgson numbers corresponding to a 1 percent metering error for these cases. The value of $Q\,\Delta p_s$ can be calculated from the appropriate Hodgson number, and appropriate values of $Q$ and $\Delta p_s$ selected so as to satisfy this minimum requirement.

## VELOCITY METERS

**Anemometers** An anemometer may be any instrument for the measurement of gas velocity, e.g., a pitot tube, but usually the term refers to one of the following types.

The *vane anemometer* is a delicate revolution counter with jeweled bearings, actuated by a small windmill, usually 75 to 100 mm (about 3 to 4 in) in diameter, constructed of flat or slightly curved radially disposed vanes. Gas velocity is determined by using a stopwatch to find the time interval required to pass a given number of meters ( feet) of gas as indicated by the counter. The velocity so obtained is inversely proportional to gas density. If the original calibration was carried out in a gas of density $\rho_0$ and the density of the gas stream being metered is $\rho_1$, the true gas velocity can be found as follows: From the calibration curve for the instrument, find $V_{t,0}$ corresponding to the quantity $V_m\sqrt{\rho_1/\rho_0}$, where $V_m$ = measured velocity. Then the actual velocity $V_{t,1}$ is equal to $V_{t,0}\sqrt{\rho_0/\rho_1}$. In general, when working with air, the effects of atmospheric density changes can be neglected for all velocities above 1.5 m/s (about 5 ft/s). In all cases, care must be taken to hold the anemometer well away from one's body or from any object not normally present in the stream.

Vane anemometers can be used for gas velocity measurements in the range of 0.3 to 45 m/s (about 1 to 150 ft/s), although a given instrument generally has about a 20-fold velocity range. Bearing friction has to be minimized in instruments designed for accuracy at the low end of the range, while ample rotor and vane rigidity must be provided for measurements at the higher velocities. Vane anemometers are sensitive to shock and cannot be used in corrosive atmospheres. Therefore, accuracy is questionable unless a recent calibration has been done and the history of the instrument subsequent to calibration is known. For additional information, see Ower et al., chap. 8.

**Turbine Flowmeters** They consist of a straight flow tube containing a turbine which is free to rotate on a shaft supported by one or more bearings and located on the centerline of the tube. Means are provided for magnetic detection of the rotational speed, which is proportional to the volumetric flow rate. Its use is generally restricted to clean, noncorrosive fluids. Additional information on construction, operation, range, and accuracy can be obtained from Baker, *Flow Measurement Handbook*, 2000, pp. 215–252; Miller, *Flow Measurement Engineering Handbook*, 1996; and Spitzer, 2005, pp. 303–317.

The *current meter* is generally used for measuring velocities in open channels such as rivers and irrigation channels. There are two types, the cup meter and the propeller meter. The former is more widely used. It consists

of six conical cups mounted on a vertical axis pivoted at the ends and free to rotate between the rigid arms of a U-shaped clevis to which a vaned tailpiece is attached. The wheel rotates because of the difference in drag for the two sides of the cup, and a signal proportional to the revolutions of the wheel is generated. The velocity is determined from the count over a period of time. The current meter is generally useful in the range of 0.15 to 4.5 m/s (about 0.5 to 15 ft/s) with an accuracy of ±2 percent. For additional information see Creager and Justin, *Hydroelectric Handbook,* 2d ed., Wiley, New York, 1950, pp. 42–46.

Other important classes of velocity meters include electromagnetic flowmeters and ultrasonic flowmeters. Both are described in Sec. 8.

## MASS FLOWMETERS

**General Principles** There are two main types of mass flowmeters: (1) the so-called true mass flowmeter, which responds directly to mass flow rate, and (2) the inferential mass flowmeter, which commonly measures volume flow rate and fluid density separately. A variety of types of true mass flowmeters have been developed, including the following: (*a*) the Magnus-effect mass flowmeter, (*b*) the axial-flow, transverse-momentum mass flowmeter, (*c*) the radial-flow, transverse-momentum mass flowmeter, (*d*) the gyroscopic transverse-momentum mass flowmeter, and (*e*) the thermal mass flowmeter. Type *b* is the basis for several commercial mass flowmeters, one version of which is briefly described here.

**Axial-Flow Transverse-Momentum Mass Flowmeter** This type is also referred to as an *angular-momentum* mass flowmeter. One embodiment of its principle involves the use of axial flow through a driven impeller and a turbine in series. The impeller imparts angular momentum to the fluid, which in turn causes a torque to be imparted to the turbine, which is restrained from rotating by a spring. The torque, which can be measured, is proportional to the rotational speed of the impeller and the mass flow rate.

**Inferential Mass Flowmeter** There are several types in this category, including the following:

1. *Head meters with density compensation.* Head meters such as orifices, venturis, or nozzles can be used with one of a variety of densitometers [e.g., based on (*a*) buoyant force on a float, (*b*) hydraulic coupling, (*c*) voltage output from a piezoelectric crystal, or (*d*) radiation absorption]. The signal from the head meter, which is proportional to $\rho V^2$ (where $\rho$ = fluid density and $V$ = fluid velocity), is multiplied by $\rho$ given by the densitometer. The square root of the product is proportional to the mass flow rate.
2. *Head meters with velocity compensation.* The signal from the head meter, which is proportional to $\rho V^2$, is divided by the signal from a velocity meter to give a signal proportional to the mass flow rate.
3. *Velocity meters with density compensation.* The signal from the velocity meter (e.g., turbine meter, electromagnetic meter, or sonic velocity meter) is multiplied by the signal from a densitometer to give a signal proportional to the mass flow rate.

**Coriolis Mass Flowmeter** This type, described in Sec. 8, offers simultaneous direct measurement of both mass flow rate and fluid density. The Coriolis flowmeter is insensitive to upstream and downstream flow disturbances, but its performance is adversely affected by the presence of even a few percent of a gas when measuring a liquid flow.

## VARIABLE-AREA METERS

**General Principles** The underlying principle of an ideal area meter is the same as that of a head meter of the orifice type (see subsection Orifice Meters). The stream to be measured is throttled by a constriction, but instead of observing the variation with flow of the differential head across an orifice of fixed size, the constriction of an area meter is so arranged that its size is varied to accommodate the flow while the differential head is held constant.

A simple example of an area meter is a gate valve of the rising-stem type provided with static-pressure taps before and after the gate and a means for measuring the stem position. In most common types of area meters, the variation of the opening is automatically brought about by the motion of a weighted piston or float supported by the fluid. Two different cylinder- and piston-type area meters are described in the *Report of ASME Research Committee on Fluid Meters*, pp. 82–83.

**Rotameters** The rotameter, an example of which is shown in Fig. 10-19, has become one of the most popular flowmeters in the chemical-process industries. It consists essentially of a plummet, or "float," which is free to move up or down in a vertical, slightly tapered tube having its small end down. The fluid enters the lower end of the tube and causes the float to rise until the annular area between the float and the wall of the tube is such that the pressure drop across this constriction is just sufficient to support the float. Typically, the tapered tube is of glass and carries etched upon it a nearly linear scale on which the position of the float may be visually noted as an indication of the flow.

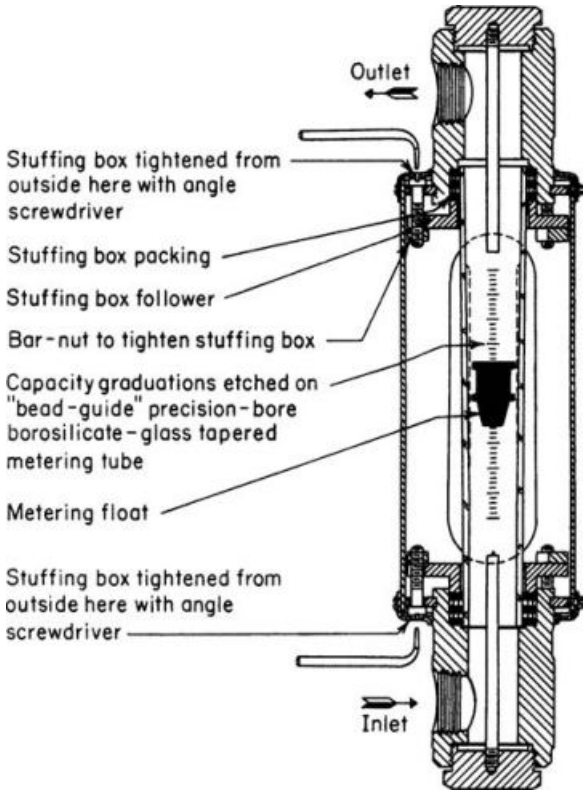

**FIG. 10-19** Rotameter.

Interchangeable precision-bore glass tubes and metal metering tubes are available. Rotameters have proved satisfactory both for gases and for liquids at high and low pressures. A single instrument can readily cover a 10-fold range of flow, and by providing floats of different densities a 200-fold range is practicable. Rotameters are available with pneumatic, electric, and electronic transmitters for actuating remote recorders, integrators, and automatic flow controllers (see Considine, pp. 4-35 to 4-36, and Sec. 8 of this text).

Rotameters require no straight runs of pipe before or after the point of installation. Pressure losses are substantially constant over the whole flow range. In experimental work, for greatest precision, a rotameter should be calibrated with the fluid to be metered. However, most modern rotameters are precision-made so that their performance closely corresponds to a master calibration plot for the type in question. Such a plot is supplied with the meter upon purchase.

According to Head [*Trans. Am. Soc. Mech. Eng.* **76:** 851–862 (1954)], the flow rate through a rotameter can be obtained from

$$\dot{m} = q\rho = KD_f\sqrt{\frac{W_f(\rho_f-\rho)\rho}{\rho_f}} \tag{10-34}$$

and

$$K = \phi\left[\frac{D_t}{D_f}, \frac{\mu}{\sqrt{\frac{W_f(\rho_f-\rho)\rho}{\rho_f}}}\right] \tag{10-35}$$

where $\dot{m}$ = weight flow rate; $q$ = volume flow rate; $\rho$ = fluid density; $K$ = flow parameter, $m^{1/2}/s$ ($ft^{1/2}/s$); $D_f$ = float diameter at constriction; $W_f$ = float weight; $\rho_f$ = float density; $D_t$ = tube diameter at point of constriction; and $\mu$ = fluid viscosity. The appropriate value of $K$ is obtained from a composite correlation of $K$ versus the parameters shown in Eq. (10-35) corresponding to the float shape being used. The relation of $D_t$ to the rotameter reading is also required for the tube taper and size being used.

The ratio of flow rates for two different fluids $A$ and $B$ at the same rotameter reading is given by

$$\frac{\dot{m}_A}{\dot{m}_B} = \frac{K_A}{K_B}\sqrt{\frac{(\rho_f-\rho_A)\rho_A}{(\rho_f-\rho_B)\rho_B}} \tag{10-36}$$

A measure of self-compensation, with respect to weight rate of flow, for fluid density changes can be introduced through the use of a float with a density twice that of the fluid being metered, in which case an increase of 10 percent in ρ will produce a decrease of only 0.5 percent in *w* for the same reading. The extent of immunity to changes in fluid viscosity depends on the shape of the float.

According to Baird and Cheema [*Can. J. Chem. Eng.* **47:** 226–232 (1969)], the presence of square-wave pulsations can cause a rotameter to overread by as much as 100 percent. The higher the pulsation frequency, the less the float oscillation, although the error can still be appreciable even when the frequency is high enough that the float is virtually stationary. Use of a damping chamber between the pulsation source and the rotameter will reduce the error.

Additional information on rotameter theory is presented by Fischer [*Chem. Eng.* **59**(6): 180–184 (1952)], Coleman [*Trans. Inst. Chem. Eng.* **34:** 339–350 (1956)], and McCabe, Smith, and Harriott (*Unit Operations of Chemical Engineering,* 4th ed., McGraw-Hill, New York, 1985, pp. 202–205).

## TWO-PHASE SYSTEMS

It is generally preferable to meter each of the individual components of a two-phase mixture separately prior to mixing, since it is difficult to meter such mixtures accurately. Problems arise because of fluctuations in composition with time and variations in composition over the cross section of the channel. Information on metering of such mixtures can be obtained from the following sources.

**Gas-Solid Mixtures** Carlson, Frazier, and Engdahl [*Trans. Am. Soc. Mech. Eng.* **70:** 65–79 (1948)] describe the use of a *flow nozzle* and a *square-edged orifice* in series for the measurement of both the gas rate and the solids rate in the flow of a finely divided solid-in-gas mixture. The nozzle differential is sensitive to the flow of both phases, whereas the orifice differential is not influenced by the solids flow.

Farbar [*Trans. Am. Soc. Mech. Eng.* **75:** 943–951 (1953)] describes how a *venturi meter* can be used to measure solids flow rate in a gas-solids mixture when the gas rate is held constant. Separate calibration curves (solids flow versus differential) are required for each gas rate of interest.

Cheng, Tung, and Soo [*J. Eng. Power* **92:** 135–149 (1970)] describe the use of an *electrostatic probe* for measurement of solids flow in a gas-solids mixture.

Goldberg and Boothroyd [*Br. Chem. Eng.* **14:** 1705–1708 (1969)] describe several types of solids-in-gas flowmeters and give an extensive bibliography.

**Gas-Liquid Mixtures** An empirical equation was developed by Murdock [*J. Basic Eng.* **84:** 419–433 (1962)] for the measurement of gas-liquid mixtures using *sharp-edged orifice* plates with radius, flange, or pipe taps.

An equation for use with *venturi meters* was given by Chisholm [*Br. Chem. Eng.* **12:** 454–457 (1967)]. A procedure for determining steam quality via pressure drop measurement with upflow through either venturi meters or sharp-edged orifice plates was given by Collins and Gacesa [*J. Basic Eng.* **93:** 11–21 (1971)].

**Liquid-Solid Mixtures** Liptak [*Chem. Eng.* **74**(4): 151–158 (1967)] discusses a variety of techniques that can be used for the measurement of solids-in-liquid suspensions or slurries. These include metering pumps, weigh tanks, magnetic flowmeter, ultrasonic flowmeter, gyroscope flowmeter, etc.

Shirato, Gotoh, Osasa, and Usami [*J. Chem. Eng. Japan* **1:** 164–167 (January 1968)] present a method for determining the mass flow rate of suspended solids in a liquid stream wherein the liquid velocity is measured by an electromagnetic flowmeter and the flow of solids is calculated from the pressure drops across each of two vertical sections of pipe of different diameter through which the suspension flows in series.

## FLOWMETER SELECTION

Web sites for process equipment and instrumentation, such as www.globalspec.com and www.thomasnet.com, are valuable tools when one is selecting a flowmeter. These search engines can scan the flowmeters manufactured by more than 800 companies for specific products that meet the user's specifications. Table 10-4 was based in part on information from these web sites. Note that the accuracies claimed are achieved only under ideal conditions when the flowmeters are clean, properly installed, and calibrated for the application.

**TABLE 10-9 Flowmeter Classes**

| Class I: Flowmeters with wetted moving parts | Class II: Flowmeters with no wetted moving parts |
|---|---|
| Positive displacement<br>Turbine<br>Variable-area | Differential pressure<br>Vortex<br>Target<br>Thermal |
| **Class III: Obstructionless flowmeters** | **Class IV: Flowmeters with sensors mounted external to the pipe** |
| Coriolis mass<br>Electromagnetic<br>Ultrasonic | Clamp-on ultrasonic<br>Correlation |

Adapted from Spitzer, op. cit., 2005.

The purpose of this subsection is to summarize the preferred applications as well as the advantages and disadvantages of some of the common flowmeter technologies.

Table 10-9 divides flowmeters into four classes. Flowmeters in class I depend on wetted moving parts that can wear, plug, or break. The potential for catastrophic failure is a disadvantage. However, in clean fluids, class I flowmeters have often proved reliable and stable when properly installed, calibrated, and maintained.

Class II flowmeters have no wetted moving parts to break and are thus not subject to catastrophic failure. However, the flow surfaces such as orifice plates may wear, eventually biasing flow measurements. Other disadvantages of some flowmeters in this class include high pressure drop and susceptibility to plugging. Very dirty and abrasive fluids should be avoided.

Because class III flowmeters have neither moving parts nor obstructions to flow, they are suitable for dirty and abrasive fluids provided that appropriate materials of construction are available.

Class IV flowmeters have sensors mounted external to the pipe, and would thus seem to be ideal, but problems of accuracy and sensitivity have been encountered in early devices. These comparatively new technologies are under development, and these problems may be overcome in the future.

Section 8 outlines the following criteria for selection of measurement devices: measurement span, performance, reliability, materials of construction, prior use and potential for releasing process materials to the environment, electrical classification, physical access, invasive or non-invasive, and life-cycle cost.

Spitzer, *Industrial Flow Measurement,* 2005, cites four intended end uses of the flowmeter: rate indication, control, totalization, and alarm. Thus high accuracy may be important for rate indication, while control may just need good repeatability. Volumetric flow or mass flow indication is another choice.

Baker, *Flow Measurement Handbook*, 2003, identifies the type of fluid (liquid or gas, slurry, multiphase), special fluid constraints (clean or dirty, hygienic, corrosive, abrasive, high flammability, low lubricity, fluids causing scaling). He lists the following flowmeter constraints: accuracy or measurement uncertainty, diameter range, temperature range, pressure range, viscosity range, flow range, pressure loss caused by the flowmeter, sensitivity to installation, sensitivity to pipework supports, sensitivity to pulsation, whether the flowmeter has a clear bore, availability of a clamp-on version, response time, and ambient conditions. Finally, Baker identifies these environmental considerations: ambient temperature, humidity, exposure to weather, level of electromagnetic radiation, vibration, tamperproof for domestic use, and classification of area requiring explosion proof, intrinsic safety, etc.

Note that the accuracies cited in Table 10-4 can be achieved by those flowmeters only under ideal conditions of application, installation, and calibration. This subsection has given only an introduction to issues to consider in the choice of a flowmeter for a given application. See Baker, 2003; Miller, 1996; and Spitzer, 2005, for further guidance. To further refine choices, obtain application-specific data from flowmeter vendors.

## INTRODUCTION

The following subsections deal with pumps and compressors. A pump or compressor is a physical contrivance that is used to deliver fluids from one location to another through conduits. The term *pump* is used when the fluid is a liquid, while the term *compressor* is used when the fluid is a gas. The basic requirements to define the application are suction and delivery pressures, pressure loss in transmission, and flow rate. Special requirements may exist in food, pharmaceutical, nuclear, and other industries that impose material selection requirements of the pump.

The primary means of transfer of energy to the fluid that causes flow are gravity, displacement, centrifugal force, electromagnetic force, transfer of momentum, mechanical impulse, and a combination of these energy transfer mechanisms. Displacement and centrifugal force are the most common energy transfer mechanisms in use.

Pumps and compressors are designed per technical specifications and standards developed over years of operating and maintenance experience. Table 10-10 lists some of these standards for pumps and compressors and for related equipment such as lubrication systems and gearboxes which, if not properly specified, could lead to many operational and maintenance problems with the pumps and compressors. These standards specify design, construction, maintenance, and testing details such as terminology, material selection, shop inspection and tests, drawings, clearances, construction procedures, and so on.

Three major types of pumps are discussed here: (1) positive-displacement, (2) dynamic (kinetic), and (3) lift. Piston pumps are positive-displacement pumps. The most common centrifugal pumps are of dynamic type; ancient bucket-type pumps are lift pumps. Canned pumps are also becoming popular in the petrochemical industry because of the drive to minimize fugitive emissions. Figure 10-20 shows pump classification.

## TERMINOLOGY

**Displacement** Discharge of a fluid from a vessel by partially or completely displacing its internal volume with a second fluid or by mechanical means is the principle upon which a great many fluid-transport devices operate. Included in this group are reciprocating-piston and diaphragm machines, rotary-vane and gear types, fluid piston compressors, acid eggs, and air lifts.

The large variety of displacement-type fluid-transport devices makes it difficult to list characteristics common to each. However, for most types it is correct to state that (1) they are adaptable to high-pressure operation, (2) the flow rate through the pump is variable (auxiliary damping systems may be employed to reduce the magnitude of pressure pulsation and flow variation), (3) mechanical considerations limit maximum throughputs, and (4) the devices are capable of efficient performance at extremely low-volume throughput rates.

**Centrifugal Force** Centrifugal force is applied by means of the centrifugal pump to a liquid. Though the physical appearance of the many types of centrifugal pumps and compressors varies greatly, the basic function of each is the same, i.e., to produce kinetic energy by the action of centrifugal force and then to convert this energy to pressure by efficiently reducing the velocity of the flowing fluid.

In general, centrifugal fluid-transport devices have these characteristics: (1) discharge is relatively free of pulsation; (2) mechanical design lends itself to high throughputs, and capacity limitations are rarely a problem; (3) the devices are capable of efficient performance over a wide range of pressures and capacities even at constant-speed operation; (4) discharge pressure is a function of fluid density; and (5) these are relatively small high-speed devices and less costly.

A device that combines the use of centrifugal force with mechanical impulse to produce an increase in pressure is the axial-flow compressor or pump. In this device the fluid travels roughly parallel to the shaft through a series of alternately rotating and stationary radial blades having airfoil cross sections. The fluid is accelerated in the axial direction by mechanical impulses from the rotating blades; concurrently, a positive-pressure gradient in the radial direction is established in each stage by centrifugal force. The net pressure rise per stage results from both effects.

**Electromagnetic Force** When the fluid is an electrical conductor, as is the case with molten metals, it is possible to impress an electromagnetic field around the fluid conduit in such a way that a driving force that will cause flow to be created. Such pumps have been developed for the handling of heat-transfer liquids, especially for nuclear reactors.

**Transfer of Momentum** Deceleration of one fluid (motivating fluid) in order to transfer its momentum to a second fluid (pumped fluid) is a principle commonly used in the handling of corrosive materials, in pumping from inaccessible depths, or for evacuation. Jets and eductors are in this category.

Absence of moving parts and simplicity of construction have frequently justified the use of jets and eductors. However, they are relatively inefficient devices. When air or steam is the motivating fluid, operating costs may be several times the cost of alternative types of fluid-transport equipment. In addition, environmental considerations in today's chemical plants often inhibit their use.

**Mechanical Impulse** The principle of mechanical impulse when applied to fluids is usually combined with one of the other means of imparting motion. As mentioned earlier, this is the case in axial-flow compressors and pumps. The turbine or regenerative-type pump is another device that functions partially by mechanical impulse.

**Measurement of Performance** The amount of useful work that any fluid-transport device performs is the product of (1) the mass rate of fluid flow through it and (2) the total pressure differential measured immediately before and after the device, usually expressed in the height of column of fluid equivalent under adiabatic conditions. The first of these quantities is normally referred to as *capacity,* and the second is known as *head.*

**Capacity** This quantity is expressed in the following units. In SI units, capacity is expressed in cubic meters per hour ($m^3/h$) for both liquids and gases. In U.S. Customary System units it is expressed in U.S. gallons per minute (gal/min) for liquids and in cubic feet per minute ($ft^3/min$) for gases. Since all these are volume units, the density or specific gravity must be used for conversion to mass rate of flow. When gases are being handled, capacity must be related to a pressure and a temperature, usually the conditions prevailing at the machine inlet. It is important to note that all heads and other terms in the following equations are expressed in height of column of liquid.

## PUMPS

**Total Dynamic Head** The total dynamic head $H$ of a pump is the total discharge head $h_d$ minus the total suction head $h_s$.

**Total Suction Head** This is the reading $h_{gs}$ of a gauge at the suction flange of a pump (corrected to the pump centerline), plus the barometer reading and the velocity head $h_{vs}$ at the point of gauge attachment:

$$h_s = h_{gs} + \text{atm} + h_{vs} \tag{10-37}$$

If the gauge pressure at the suction flange is less than atmospheric, requiring use of a vacuum gauge, this reading is used for $h_{gs}$ in Eq. (10-38) with a negative sign.

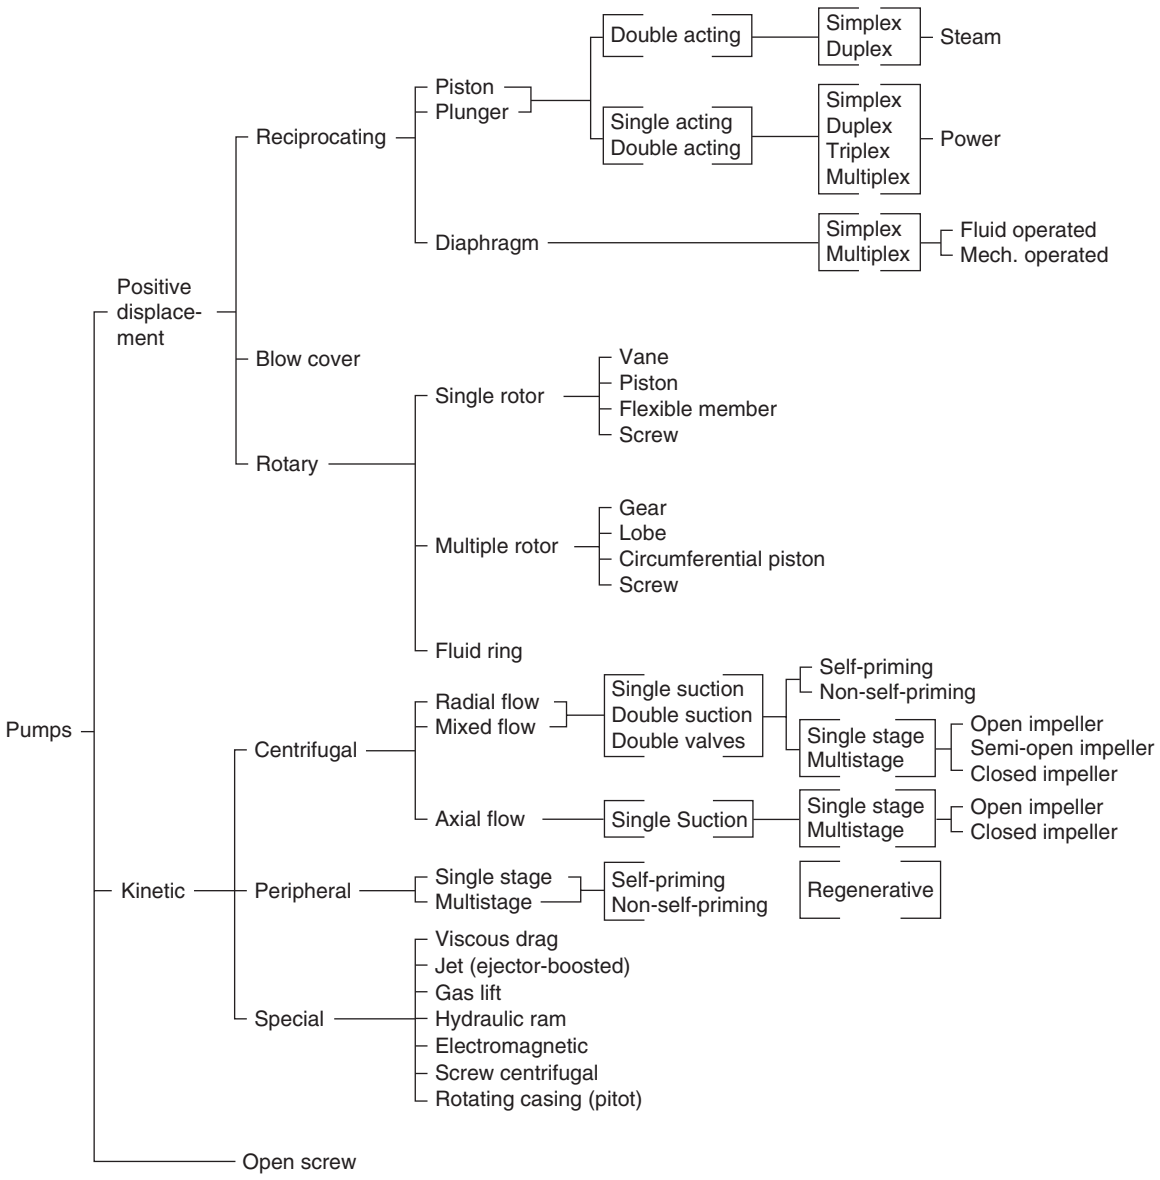

**FIG. 10-20** Classification of pumps. (*Courtesy of Hydraulic Institute.*)

Before installation it is possible to estimate the total suction head as follows:

$$h_s = h_{ss} - h_{fs} \tag{10-38}$$

where $h_{ss}$ = static suction head and $h_{fs}$ = suction friction head.

**Static Suction Head** The static suction head $h_{ss}$ is the vertical distance measured from the free surface of the liquid source to the pump centerline plus the absolute pressure at the liquid surface.

**Total Discharge Head** The total discharge head $h_d$ is the reading $h_{gd}$ of a gauge at the discharge flange of a pump (corrected to the pump centerline*), plus the barometer reading and the velocity head $h_{vd}$ at the point of gauge attachment:

$$h_d = h_{gd} + \text{atm} + h_{vd} \tag{10-39}$$

Again, if the discharge gauge pressure is below atmospheric, the vacuum-gauge reading is used for $h_{gd}$ in Eq. (10-39) with a negative sign.

*On vertical pumps, the correction should be made to the eye of the suction impeller.

Before installation it is possible to estimate the total discharge head from the static discharge head $h_{sd}$ and the discharge friction head $h_{fd}$ as follows:

$$h_d = h_{sd} + h_{fd} \tag{10-40}$$

**Static Discharge Head** The static discharge head $h_{sd}$ is the vertical distance measured from the free surface of the liquid in the receiver to the pump centerline,* plus the absolute pressure at the liquid surface. *Total static head* $h_{ts}$ is the difference between discharge and suction static heads.

**Velocity** Since most liquids are practically incompressible, the relation between the quantity flowing past a given point at a given time and the volume flow rate is expressed as follows:

$$Q = AV_{\text{avg}} \tag{10-41}$$

This relationship in SI units is as follows:

$$V_{\text{avg}}(\text{for circular conduits}) = 3.54Q/d^2 \tag{10-42}$$

where $V_{\text{avg}}$ = average velocity of flow, m/s; $Q$ = quantity of flow, $m^3/h$; and $d$ = inside diameter of conduit, cm.

This same relationship in U.S. Customary System (USCS) units is

$$V_{avg}(\text{for circular conduits}) = 0.409Q/d^2 \quad (10\text{-}43)$$

where $V_{avg}$ = average velocity of flow, ft/s; $Q$ = volume flow rate, gal/min; and $d$ = inside diameter of conduit, in.

**Velocity Head** This is the force generated by the pump and is given in $\text{ft} \cdot \text{lb}_f/\text{lb}_m$, the vertical height that the pump can maintain.

$$H = V^2/2g_c = \text{ft} \cdot \text{lb}_f/\text{lb}_m \quad (10\text{-}44)$$

where $g_c$ = the gravitational constant = $32.2\ \text{ft} \cdot \text{lb}_m/\text{lb}_f \cdot \text{s}^2$

In the SI system the head is in meters.

**Viscosity** (See Sec. 6 for further information.) In flowing liquids, the existence of internal friction or the internal resistance to relative motion of the fluid particles must be considered. This resistance is called *viscosity*. Frictional losses in pipes increase with higher viscosity. Viscosity decreases with the rising temperature of the fluid. The increase in viscosity of fluids will increase the pump power required for the same head and capacity and will reduce the efficiency of the pump.

**Friction Head** This is the pressure required to overcome the resistance to flow in pipe and fittings. It is dealt with in detail in Sec. 6.

**Work Performed in Pumping** To cause liquid to flow, work must be expended. A pump may raise the liquid to a higher elevation, force it into a vessel at higher pressure, provide the head to overcome pipe friction, or perform any combination of these. Regardless of the service required of a pump, all energy imparted to the liquid in performing this service must be accounted for; consistent units for all quantities must be employed in arriving at the work or power performed.

When arriving at the performance of a pump, it is customary to calculate its *power output*, which is the product of (1) the total dynamic head and (2) the mass of liquid pumped in a given time. In SI units power is expressed in kilowatts; horsepower is the conventional unit used in the United States.

In SI units,

$$\text{kW} = HQ\rho/3.670 \times 10^5 \quad (10\text{-}45)$$

where kW is the pump power output, kW; $H$ = total dynamic head, $\text{N} \cdot \text{m/kg}$ (column of liquid); $Q$ = capacity, $\text{m}^3/\text{h}$; and $\rho$ = liquid density, $\text{kg/m}^3$.

When the total dynamic head $H$ is expressed in pascals, then

$$\text{kW} = HQ\rho/3.599 \times 10^6 \quad (10\text{-}46)$$

In USCS units,

$$\text{hp} = HQs/3.960 \times 10^3 \quad (10\text{-}47)$$

where hp is the pump power output, hp; $H$ = total dynamic head, $\text{lbf} \cdot \text{ft/lbm}$ (column of liquid); $Q$ = capacity, U.S. gal/min; and $s$ = liquid specific gravity.

When the total dynamic head hp is expressed in pounds force per square inch, then

$$\text{hp} = HQ/1.714 \times 10^3 \quad (10\text{-}48)$$

The *power input* to a pump is greater than the *power output* because of internal losses resulting from friction, leakage, etc. The efficiency of a pump is therefore defined as

$$\text{Pump efficiency} = (\text{power output})/(\text{power input}) \quad (10\text{-}49)$$

## PUMP SELECTION

When one is selecting pumps for any service, it is necessary to know the liquid to be handled, total dynamic head, suction and discharge heads, and, in most cases, temperature, viscosity, vapor pressure, and specific gravity. In the chemical industry, the task of pump selection is frequently further complicated by the presence of solids in the liquid and liquid corrosion characteristics requiring special materials of construction. Solids may accelerate erosion and corrosion, have a tendency to agglomerate, or require delicate handling to prevent undesirable degradation.

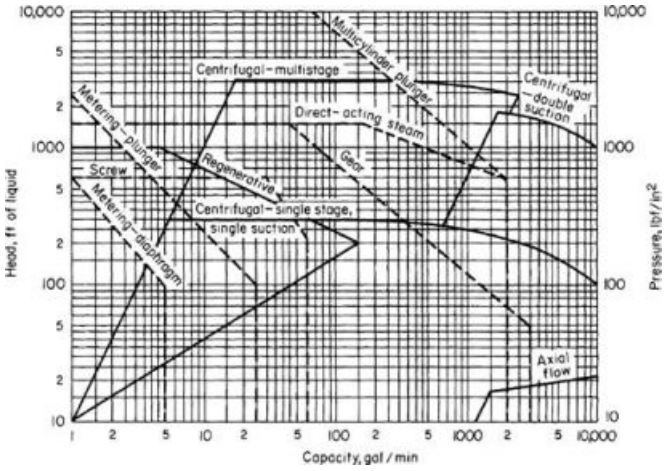

**FIG. 10-21** Pump coverage chart based on normal ranges of operation of commercially available types. Solid lines: use left ordinate, head scale. Broken lines: use right ordinate, pressure scale. To convert gallons per minute to cubic meters per hour, multiply by 0.2271; to convert feet to meters, multiply by 0.3048; and to convert pounds-force per square inch to kilopascals, multiply by 6.895.

**Range of Operation** Because of the wide variety of pump types and the number of factors that determine the selection of any one type for a specific installation, the designer must first eliminate all but those types of reasonable possibility. Since range of operation is always an important consideration, Fig. 10-21 should be of assistance. The boundaries shown for each pump type are at best approximate. In most cases, following Fig. 10-21 will select the pump that is best suited for a given application. Reciprocating pumps and rotary pumps such as gear and roots rotor-type pumps are examples of positive-displacement pumps. Displacement pumps provide high heads at low capacities which are beyond the capability of centrifugal pumps. Displacement pumps achieve high pressure with low velocities and are thus suited for high-viscosity service and slurry.

The centrifugal pump operates over a very wide range of flows and pressures. The axial pump is best suited for low heads but high flows. Both the centrifugal and axial-flow pumps impart energy to the fluid by the rotational speed of the impeller and the velocity it imparts to the fluid.

## NET POSITIVE SUCTION HEAD

*Net positive suction head available* $(\text{NPSH})_A$ is the difference between the total absolute suction pressure at the pump suction nozzle when the pump is running and the vapor pressure at the flowing liquid temperature. All pumps require the system to provide adequate $(\text{NPSH})_A$. In a positive-displacement pump the $(\text{NPSH})_A$ should be large enough to open the suction valve, to overcome the friction losses within the pump liquid end, and to overcome the liquid acceleration head.

**Suction Limitations of a Pump** Whenever the pressure in a liquid drops below the vapor pressure corresponding to its temperature, the liquid will vaporize. When this happens within an operating pump, the vapor bubbles will be carried along to a point of higher pressure, where they suddenly collapse. This phenomenon is known as *cavitation*. Cavitation in a pump should be avoided, as it is accompanied by metal removal, vibration, reduced flow, loss in efficiency, and noise. When the absolute suction pressure is low, cavitation may occur in the pump inlet and damage may result in the pump suction and on the impeller vanes near the inlet edges. To avoid this phenomenon, it is necessary to maintain a *required net positive suction head* $(\text{NPSH})_R$, which is the equivalent total head of liquid at the pump centerline less the vapor pressure $p$. Each pump manufacturer publishes curves relating $(\text{NPSH})_R$ to capacity and speed for each pump.

When a pump installation is being designed, the available net positive suction head $(\text{NPSH})_A$ must be equal to or greater than the $(\text{NPSH})_R$ for the desired capacity. The $(\text{NPSH})_A$ can be calculated as follows:

$$(\text{NPSH})_A = h_{ss} - h_{fs} - p \quad (10\text{-}50)$$

If $(\text{NPSH})_A$ is to be checked on an existing installation, it can be determined as follows:

$$(\text{NPSH})_A = \text{atm} + h_{gs} - p + h_{vs} \quad (10\text{-}51)$$

Practically, the NPSH required for operation without cavitation and vibration in the pump is somewhat greater than the theoretical. The actual $(NPSH)_R$ depends on the characteristics of the liquid, total head, pump speed, capacity, and impeller design. Any suction condition which reduces $(NPSH)_A$ below that required to prevent cavitation at the desired capacity will produce an unsatisfactory installation and can lead to mechanical difficulty.

The following two equations usually provide an adequate design margin between $(NPSH)_A$ and $(NPSH)_R$:

$$(NPSH)_A = (NPSH)_R + 5 \text{ ft} \quad (10\text{-}52)$$

$$(NPSH)_A = 1.35(NPSH)_R \quad (10\text{-}53)$$

Use the larger value of $(NPSH)_A$ calculated with Eqs. (10-52) and (10-53).

**NPSH Requirements for Other Liquids** NPSH values depend on the fluid being pumped. Since water is considered a standard fluid for pumping, various correction methods have been developed to evaluate NPSH when pumping other fluids. The most recent of these corrective methods has been developed by the Hydraulic Institute and is shown in Fig. 10-22.

The chart shown in Fig. 10-22 is for pure liquids. Extrapolation of data beyond the ranges indicated in the graph may not produce accurate results. Figure 10-22 shows the variation of vapor pressure and NPSH reductions for various hydrocarbons and hot water as a function of temperature. Certain rules apply while using this chart. When using the chart for hot water, if the NPSH reduction is greater than one-half of the NPSH required for cold water, deduct one-half of cold water NPSH to obtain the corrected NPSH required. However, if the value read on the chart is less than one-half of cold water NPSH, deduct this chart value from the cold water NPSH to obtain the corrected NPSH.

***Example 10-1 NPSH Calculation*** Suppose a selected pump requires a minimum NPSH of 16 ft (4.9 m) when pumping cold water. What will be the NPSH limitation to pump propane at 55°F (12.8°C) with a vapor pressure of 120 psi ( 8.274 bar)? Using the chart in Fig. 10-22, NPSH reduction for propane gives 9.5 ft (2.9 m). This is greater than one-half of the cold water NPSH of 16 ft (4.9 m). The corrected NPSH is therefore 8 ft (2.4 m) or one-half of the cold water NPSH.

## PUMP SPECIFICATIONS

Pump specifications depend on numerous factors but mostly on application. Typically, the following factors should be considered while preparing a specification:

1. Application, scope, and type
2. Service conditions
3. Operating conditions
4. Construction application-specific details and special considerations
   - *a.* Casing and connections
   - *b.* Impeller details
   - *c.* Shaft
   - *d.* Stuffing box details—lubrications, sealing, etc.
   - *e.* Bearing frame and bearings
   - *f.* Baseplate and couplings
   - *g.* Materials
   - *h.* Special operating conditions and miscellaneous items

Table 10-11 is based on the API and ASME codes and illustrates a typical specification for centrifugal pumps.

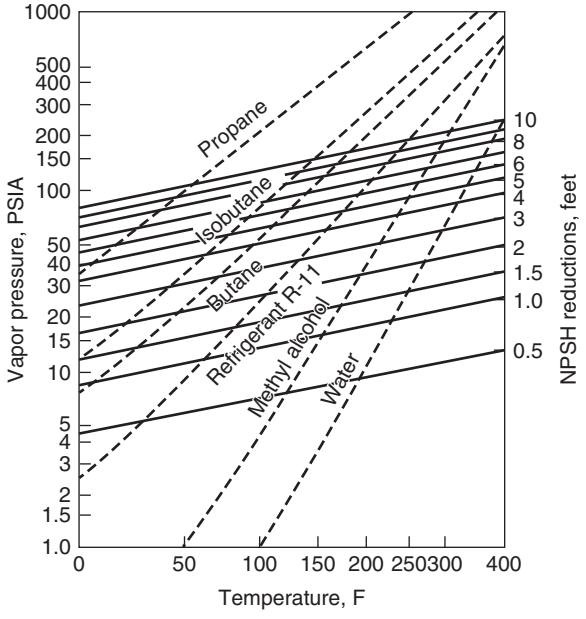

**FIG. 10-22** NPSH reductions for pumps handling hydrocarbon liquids and high-temperature water. This chart has been constructed from test data obtained using the liquids shown. (*Hydraulic Institute Standards.*)

## POSITIVE-DISPLACEMENT PUMPS

Positive-displacement pumps and those that approach positive displacement will ideally produce whatever head is impressed upon them by the system restrictions to flow. The maximum head attainable is determined by the power available in the drive (slippage neglected) and the strength of the pump parts. A pressure relief valve on the discharge side should be set to open at a safe pressure for the casing and the internal components of the pump such as piston rods, cylinders, crankshafts, and other components which would be pressurized. In the case of a rotary pump, the total dynamic head developed is uniquely determined for any given flow by the speed at which it rotates.

In general, overall efficiencies of positive-displacement pumps are higher than those of centrifugal equipment because internal losses are minimized. However, the flexibility of each piece of equipment in handling a wide range of capacities is somewhat limited.

Positive-displacement pumps may be of either the *reciprocating* or the *rotary* type. In all positive-displacement pumps, a cavity or cavities are alternately filled and emptied of the pumped fluid by the action of the pump.

**Reciprocating Pumps** There are three classes of reciprocating pumps: *piston pumps, plunger pumps,* and *diaphragm pumps.* Basically, the action of the liquid-transferring parts of these pumps is the same, with a cylindrical piston, or plunger, or bucket or a round diaphragm being caused to pass or flex back and forth in a chamber. The device is equipped with valves for the inlet and discharge of the liquid being pumped, and the operation of these valves is related in a definite manner to the motions of the piston. In all modern-design reciprocating pumps, the suction and discharge valves are operated by pressure difference. That is, when the pump is on its suction stroke and the pump cavity is increasing in volume, the pressure is lowered within the pump cavity, permitting the higher suction pressure to open the suction valve and allowing liquid to flow into the pump. At the same time, the higher discharge-line pressure holds the discharge valve closed. Likewise, on the discharge stroke, as the pump cavity is decreasing in volume, the higher pressure developed in the pump cavity holds the suction valve closed and opens the discharge valve to expel liquid from the pump into the discharge line.

The *overall efficiency* of these pumps varies from about 50 percent for the small pumps to about 90 percent or more for the larger sizes.

Reciprocating pumps may be of *single-cylinder* or *multicylinder* design. Multicylinder pumps have all cylinders in parallel for increased capacity. Piston-type pumps may be single-acting or double-acting; i.e., pumping may be accomplished from one end or both ends of the piston. Plunger pumps are always single-acting. The tabulation in Table 10-12 provides data on the flow variation of reciprocating pumps of various designs.

**Piston Pumps** There are two ordinary types of piston pumps: simplex double-acting pumps and duplex double-acting pumps.

***Simplex Double-Acting Pumps*** These pumps may be direct-acting (i.e., direct-connected to a steam cylinder) or power-driven (through a crank and flywheel from the crosshead of a steam engine).

***Duplex Double-Acting Pumps*** These pumps differ primarily from those of the simplex type in having two cylinders whose operation is coordinated. They may be direct-acting, steam-driven, or power-driven with crank and flywheel.

**Plunger Pumps** These differ from piston pumps in that they have one or more constant-diameter plungers reciprocating through packing glands and displacing liquid from cylinders in which there is considerable radial clearance. They are always single-acting, in the sense that only one end of the plunger is used in pumping the liquid. Plunger pumps are available with one, two, three, four, five, or even more cylinders. Simplex and duplex units are often built in a horizontal design. Those with three or more cylinders are usually of vertical design.

**Diaphragm Pumps** These pumps perform similarly to piston and plunger pumps, but the reciprocating driving member is a flexible diaphragm fabricated of metal, rubber, or plastic. The chief advantage of this arrangement is the elimination of all packing and seals exposed to the liquid

**TABLE 10-11 Typical Pump Specification**

| Specification | Description |
|---|---|
| 1.0 | Scope: |
| | This specification covers horizontal, end suction, vertically split, single-stage centrifugal pumps with top centerline discharge and "back pullout" feature. |
| 2.0 | Service Conditions: |
| | Pump shall be designed to operate satisfactorily with a reasonable service life when operated either intermittently or continuously in typical process applications. |
| 3.0 | Operating Conditions: |
| | Capacity _____ U.S. gallons per minute _____<br>Head ( __ ft total head) ( __ psig). Speed __ r/min<br>Suction Pressure ( __ ft head) (positive) (lift) ( __ psig)<br>Liquid to be handled _____<br>Specific gravity _____ Viscosity ( _____ )<br>Temperature of liquid at inlet _____ °F<br>Solids content _____% _____ Max. size |
| 4.0 | Pump Construction: |
| | 4.1 *Casing.* Casing shall be vertically split with self-venting top centerline discharge, with an integral foot located directly under the casing for added support. All casings shall be of the "back pullout" design with suction and discharge nozzles cast integrally. Casings shall be provided with bosses in suction and discharge nozzles, and in bottom of casing for gauge taps and drain tap. (Threaded taps with plugs shall be provided for these features.) |
| | 4.2 *Casing Connections.* Connections shall be ANSI flat-faced flanges. [Cast iron (125) (250) psig rated] [Duron metal, steel, alloy steel (150) (300) psig rated] |
| | 4.3 *Casing Joint Gasket.* A confined-type nonasbestos gasket suitable for corrosive service shall be provided at the casing joint. |
| | 4.4 *Impeller.* Fully-open impeller with front edge having contoured vanes curving into the suction for minimum NPSH requirements and maximum efficiency shall be provided. A hex head shall be cast in the eye of the impeller to facilitate removal, and eliminate need for special impeller removing tool. All impellers shall have radial "pump-out" vanes on the back side to reduce stuffing box pressure and aid in eliminating collection of solids at stuffing box throat. Impellers shall be balanced within A.N.S.I. guidelines to ISO tolerances. |
| | 4.4.1 *Impeller Clearance Adjustment.* All pumps shall have provisions for adjustment of axial clearance between the leading edge of the impeller and casing. This adjustment shall be made by a precision microdial adjustment at the outboard bearing housing, which moves the impeller forward toward the suction wall of the casing. |
| | 4.5 *Shafts.* Shafts shall be suitable for hook-type sleeve. Shaft material shall be (SAE 1045 steel on Duron and 316 stainless steel pumps) or (AISI 316 stainless steel on CD-4MCu pumps and #20 stainless steel pumps). Shaft deflection shall not exceed .005 at the vertical center-line of the impeller. |
| | 4.6 *Shaft Sleeve.* Renewable hook-type shaft sleeve that extends through the stuffing box and gland shall be provided. Shaft sleeve shall be (316 stainless steel), (#20 stainless steel) or (XH-800 Ni-chrome-boron coated 316 stainless steel with coated surface hardness of approximately 800 Brinell). |
| | 4.7 *Stuffing Box.* Stuffing box shall be suitable for packing, single (inside or outside) or double-inside mechanical seal without modifications. Stuffing box shall be accurately centered by machined rabbit fits on case and frame adapter. |
| | 4.7.1 *Packed Stuffing Box.* The standard packed stuffing box shall consist of five rings of graphited nonasbestos packing; a stainless steel packing base ring in the bottom of the box to prevent extrusion of the packing past the throat; a Teflon seal cage, and a two-piece 316 stain-less steel packing gland to ensure even pressure on the packing. Ample space shall be provided for repacking the stuffing box. |
| | 4.7.1.1 *Lubrication-Packed Stuffing Box.* A tapped hole shall be provided in the stuffing box directly over the seal cage for lubrication and cooling of the packing. Lubrication liquid shall be supplied ( from an external source) (through a by-pass line from the pump discharge nozzle). |
| | 4.7.2 *Stuffing Box with Mechanical Seal.* Mechanical seal shall be of the (single inside) (single outside) (double inside) (cartridge) type and (balanced) (unbalanced). |
| | Stuffing box is to be (standard) (oversize) (oversize tapered). |
| | Suitable space shall be provided in the standard and oversized stuffing box for supplying a (throttle bushing) (dilution control bushing) with single seals. Throttle bushings and dilution control bushings shall be made of (glass-filled Teflon) (a suitable metal material). |
| | 4.7.2.1 *Lubrication—Stuffing Box with Mechanical Seals.* Suitable tapped connections shall be provided to effectively lubricate, cool, flush, quench, etc., as required by the application or recommendations of the mechanical seal manufacturer. |
| 4.8 | Bearing Frame and Bearings: |
| | 4.8.1 *Bearing Frame.* Frames shall be equipped with axial radiating fins extending the length of the frame to aid in heat dissipation. Frame shall be provided with ductile iron outboard bearing housing. Both ends of the frame shall be provided with lip-type oil seals and labyrinth-type deflectors of metallic reinforced synthetic rubber to prevent the entrance of contaminants. |
| | 4.8.2 *Bearings.* Pump bearings shall be heavy-duty, antifriction ball-type on both ends. The single row inboard bearing, nearest the impeller, shall be free to float within the frame and shall carry only radial load. The double row outboard bearing (F4-G1 and F4-I1) or duplex angular contact bearing (F4-H1), coupling end, shall be locked in place to carry radial and axial thrust loads. Bearings shall be designed for a minimum life of 20,000 hours in any normal pump operating range. |
| 4.9 | *Bearing Lubrication.* Ball bearings shall be oil-mist—lubricated by means of a slinger. The oil slinger shall be mounted on the shaft between the bearings to provide equal lubrication to both bearings. Bulls-eye oil-sight glasses shall be provided on both sides of the frame to provide a positive means of checking the proper oil level from either side of the pump. A tapped and plugged hole shall also be provided in both sides of the frame to mount bottle-type constant-level oilers where desired. A tapped and plugged hole shall be provided on both sides for optional straight-through oil cooling device. |
| 5.0 | Baseplate and Coupling: |
| | 5.1 *Baseplate.* Baseplates shall be rigid and suitable for mounting pump and motor. Baseplates shall be of channel steel construction. |
| | 5.2 *Coupling.* Coupling shall be flexible-spacer type. Coupling shall have at least three–and–one-half–inch spacer length for ease of rotating element removal. Both coupling hubs shall be provided with flats 180° apart to facilitate removal of impeller. Coupling shall not require lubrication.* |
| 6.0 | Mechanical Modifications Required for High Temperature: |
| | 6.1 *Modifications Required, Temperature Range 250–350°F.* Pumps for operation in this range shall be provided with a water-jacketed stuffing box. |
| | 6.2 *Modifications Required, Temperature Range 351–550°F (Maximum).* Pumps for operation in this range shall be provided with a water-jacketed stuffing box and a water-cooled bearing frame. |
| 7.0 | Materials:<br>Pump materials shall be selected to suit the particular service requirements. |
| | 7.1 *Cast Iron—316 SS Fitted.* 15″ only; pump shall have cast iron casing and stuffing box cover. 316 SS metal impeller; shaft shall be 1045 steel with 316 SS sleeve. |
| | 7.2 *All Duron Metal.* All pump materials shall be Duron metal. Shaft shall be 1045 steel, with 316 SS sleeve. 316 SS metal impeller optional. |
| | 7.3 *All AISI 316 Stainless Steel.* All pump materials shall be AISI 316 stainless steel. Shaft should be 1045 steel, with 316 SS sleeve. |
| | 7.4 *All #20 Stainless Steel.* All pump materials shall be #20 SS stainless steel. Shaft shall be 316 SS, with #20 SS sleeve. |
| | 7.5 *All CD-4MCu.* All pump materials shall be CD-4MCu. Shaft shall be 316 SS, with #20 SS sleeve. |
| 8.0 | Miscellaneous: |
| | 8.1 *Nameplates.* All nameplates and other data plates shall be stainless steel, suitably secured to the pump. |
| | 8.2 *Hardware.* All machine bolts, stud nuts, and cap screws shall be of the hex-head type. |
| | 8.3 *Rotation.* Pump shall have clockwise rotation viewed from its driven end. |
| | 8.4 *Parts Numbering.* Parts shall be completely identified with a numerical system (no alphabetical letters) to facilitate parts inventory control and stocking. Each part shall be properly identified by a separate number, and those parts that are identical shall have the same number to effect minimum spare parts inventory. |

*Omit if not applicable.

**TABLE 10-12 Flow Variation of Reciprocating Pumps**

| Number of cylinders | Single- or double-acting | Flow variation per stroke from mean, percent |
|---|---|---|
| Single | Single | +220 to −100 |
| Single | Double | +60 to −100 |
| Duplex | Single | +24.1 to −100 |
| Duplex | Double | +6.1 to −21.5 |
| Triplex | Single and double | +1.8 to −16.9 |
| Quintuplex | Single | +1.8 to −5.2 |

being pumped. This is an important asset for equipment required to handle hazardous or toxic liquids.

Low-capacity diaphragm pumps are designed for metering service and employ a plunger working in oil to actuate a metallic or plastic diaphragm. Built for pressures in excess of 6.895 MPa (1000 lbf/in$^2$) with flow rates up to about 1.135 m$^3$/h (5 gal/min) per cylinder, such pumps possess all the characteristics of plunger-type metering pumps with the added advantage that the pumping head can be mounted in a remote (even a submerged) location entirely separate from the drive.

Figure 10-23 shows a high-capacity 22.7 m$^3$/h (100 gal/min) pump with actuation provided by a mechanical linkage.

**Rotary Pumps** In rotary pumps the liquid is displaced by rotation of one or more members within a stationary housing. Because internal clearances, although minute, are a necessity in all but a few special types, capacity decreases somewhat with increasing pump differential pressure. Therefore, these pumps are not truly positive-displacement pumps. However, for many other reasons they are considered as such.

The selection of materials of construction for rotary pumps is critical. The materials must be corrosion-resistant, compatible when one part is running against another, and capable of some abrasion resistance.

**Gear Pumps** When two or more impellers are used in a rotary-pump casing, the impellers will take the form of toothed-gear wheels as in Fig. 10-24, of helical gears, or of lobed cams. In each case, these impellers rotate with extremely small clearance between them and between the surfaces of the impellers and the casing. In Fig. 10-24, the two toothed impellers rotate as indicated by the arrows; the suction connection is at the bottom. The pumped liquid flows into the spaces between the impeller teeth as these cavities pass the suction opening. The liquid is then carried around the casing to the discharge opening, where it is forced out of the impeller teeth mesh. The arrows indicate this flow of liquid.

Rotary pumps are available in two general classes: interior-bearing and exterior-bearing. The *interior-bearing type* is used for handling liquids of a lubricating nature, and the *exterior-bearing type* is used with nonlubricating liquids. The interior-bearing pump is lubricated by the liquid being pumped, and the exterior-bearing type is oil-lubricated.

The use of spur gears in gear pumps will produce in the discharge pulsations having a frequency equivalent to the number of teeth on both gears multiplied by the speed of rotation. The amplitude of these disturbances is a function of tooth design. The pulsations can be reduced markedly by the use of rotors with helical teeth. This in turn introduces end thrust, which can be eliminated by the use of double-helical or herringbone teeth.

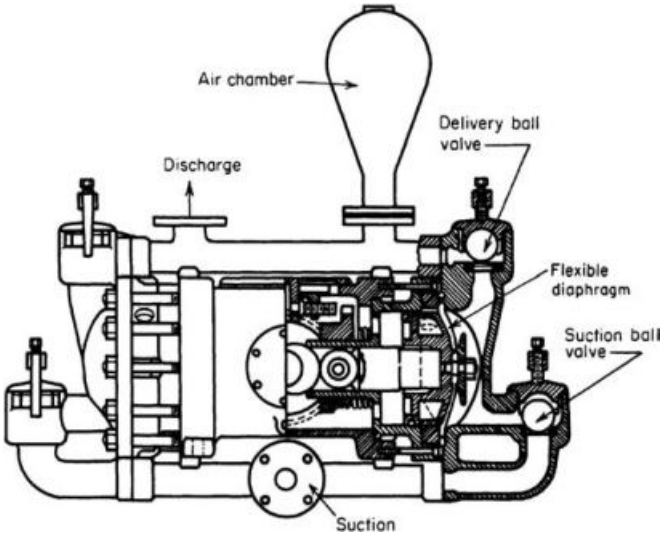

**FIG. 10-23** Mechanically actuated diaphragm pump.

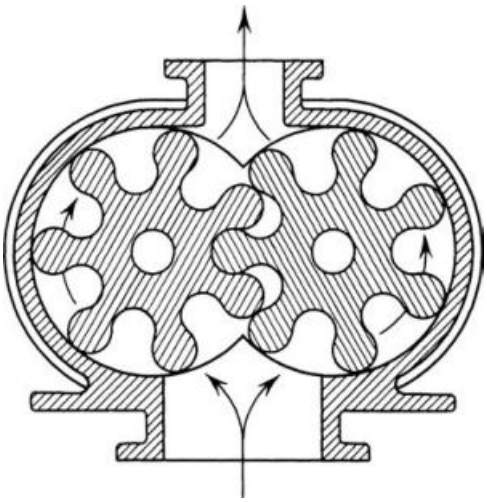

**FIG. 10-24** Positive-displacement gear-type rotary pump.

**Screw Pumps** A modification of the helical gear pump is the screw pump. A screw pump delivers and increases the pressure of slightly lubricating liquids. Both gear and screw pumps are positive-displacement pumps. Figure 10-25 illustrates a two-rotor version in which the liquid is fed to either the center or the ends, depending on the direction of rotation, and progresses axially in the cavities formed by the meshing threads or teeth. In three-rotor versions, the center rotor is the driving member while the other two are driven. Figure 10-26 shows still another arrangement, in which a metal rotor of unique design rotates without clearance in an elastomeric stationary sleeve.

Screw pumps, because of multiple dams that reduce slip, are well adapted for producing higher pressure rises, for example, 6.895 MPa (1000 lbf/in$^2$), especially when handling viscous liquids such as heavy oils. The all-metal pumps are generally subject to the same limitations on handling abrasive solids as conventional gear pumps. In addition, the wide bearing spans usually demand that the liquid have considerable lubricity to prevent metal-to-metal contact.

Among the liquids handled by rotary pumps are mineral oils, vegetable oils, animal oils, greases, glucose, viscose, molasses, paints, varnish, shellac, lacquers, alcohols, catsup, brine, mayonnaise, sizing, soap, tanning liquors, vinegar, and ink. Some screw-type units are specially designed for the gentle handling of large solids suspended in the liquid.

## CENTRIFUGAL PUMPS

The centrifugal pump is the type most widely used in the chemical industry for transferring liquids of all types—raw materials, materials in manufacture, and finished products—as well as for general services of water supply, boiler feed, condenser circulation, condensate return, etc. These pumps are available through a vast range of sizes, in capacities from 0.5 m$^3$/h to $2 \times 10^4$ m$^3$/h (2 gal/min to $10^5$ gal/min), and for discharge heads (pressures) from a few meters to approximately 48 MPa (7000 lbf/in$^2$).

The primary advantages of a centrifugal pump are simplicity, low first cost, uniform (nonpulsating) flow, small floor space, low maintenance expense, quiet operation, and adaptability for use with a motor or a turbine drive.

A centrifugal pump, in its simplest form, consists of an impeller rotating within a casing. The *impeller* consists of a number of blades, either open or shrouded, mounted on a shaft that projects outside the casing. Its axis of rotation may be either horizontal or vertical, to suit the work to be done. *Closed-type,* or *shrouded,* impellers are generally the most efficient. *Open* or *semi-open* impellers are used for viscous liquids or for liquids containing solid materials and on many small pumps for general service. Impellers may be of the *single-suction* or *double-suction* type—single if the liquid enters from one side, double if it enters from both sides.

**Casings** There are three general types of casings, but each consists of a chamber in which the impeller rotates, provided with inlet and exit for the liquid being pumped. The simplest form is the *circular casing,* consisting of an annular chamber around the impeller; no attempt is made to overcome the losses that will arise from eddies and shock when the liquid leaving the impeller at relatively high velocities enters this chamber. Such casings are seldom used.

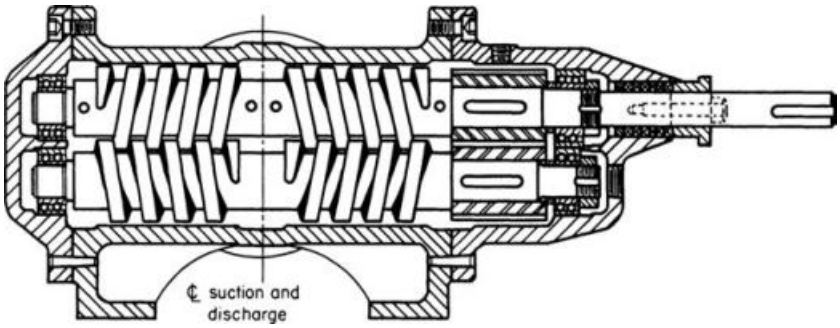

**FIG. 10-25** Two-rotor screw pump. (*Courtesy of Warren Quimby Pump Co.*)

*Volute casings* take the form of a spiral increasing uniformly in cross-sectional area as the outlet is approached. The volute efficiently converts the velocity energy imparted to the liquid by the impeller into pressure energy.

A third type of casing is used in *diffuser-type* or turbine pumps. In this type, *guide vanes* or *diffusers* are interposed between the impeller discharge and the casing chamber. Losses are kept to a minimum in a well-designed pump of this type, and improved efficiency is obtained over a wider range of capacities. This construction is often used in multistage high-head pumps.

**Action of a Centrifugal Pump** Briefly, the action of a centrifugal pump may be shown by Fig. 10-27. Power from an outside source is applied to shaft *A,* rotating the impeller *B* within the stationary casing *C.* The blades of the impeller in revolving produce a reduction in pressure at the entrance or eye of the impeller. This causes liquid to flow into the impeller from the suction pipe *D.* This liquid is forced outward along the blades at increasing tangential velocity. The velocity head it has acquired when it leaves the blade tips is changed to pressure head as the liquid passes into the volute chamber and then out the discharge *E.*

**Centrifugal Pump Characteristics** Figure 10-28 shows a typical characteristic curve of a centrifugal pump. It is important to note that at any fixed speed the pump will operate along this curve and at no other points. For instance, on the curve shown, at 45.5 $m^3$/h (200 gal/min) the pump will generate 26.5-m (87-ft) head. If the head is increased to 30.48 m (100 ft), then 27.25 $m^3$/h (120 gal/min) will be delivered. It is not possible to reduce the capacity to 27.25 $m^3$/h (120 gal/min) at 26.5-m (87-ft) head unless the discharge is throttled so that 30.48 m (100 ft) is actually generated within the pump. On pumps with variable-speed drivers such as steam turbines, it is possible to change the characteristic curve, as shown by Fig. 10-29.

As shown in Eq. (10-44), the head depends on the velocity of the fluid, which in turn depends on the capability of the impeller to transfer energy to the fluid. This is a function of the fluid viscosity and the impeller design. It is important to remember that the head produced will be the same for any liquid of the same viscosity. The pressure rise, however, will vary in proportion to the specific gravity.

For quick pump selection, manufacturers often give the most essential performance details for a whole range of pump sizes. Figure 10-30 shows typical performance data for a range of process pumps based on suction and discharge pipes and impeller diameters. The performance data consist of the pump flow rate and the head. Once a pump meets a required specification, then more-detailed performance data for the particular pump can be easily found based on the curve reference number. Figure 10-31 shows a more detailed pump performance curve that includes, in addition to pump head and flow, the brake horsepower required, NPSH required, number of vanes, and pump efficiency for a range of impeller diameters.

If detailed manufacturer-specified performance curves are not available for a different size of the pump or operating condition, then a best estimate of the off-design performance of pumps can be obtained through similarity relationship or the affinity laws:

1. Capacity $Q$ is proportional to impeller rotational speed $N$.
2. Head $h$ varies as square of the impeller rotational speed.
3. Brake horsepower (BHP) varies as the cube of the impeller rotational speed.

These equations can be expressed mathematically and appear in Table 10-13.

**System Curves** In addition to the pump design, the operational performance of a pump depends on factors such as the downstream load characteristics, pipe friction, and valve performance. Typically, head and flow follow the following relationship:

$$\frac{(Q_2)^2}{(Q_1)^2}=\frac{h_2}{h_1} \tag{10-54}$$

where subscript 1 refers to the design condition and subscript 2 to the actual conditions. The above equation indicates that head will change as the square of the water flow rate.

Figure 10-32 shows the schematic of a pump, moving a fluid from tank A to tank B, both of which are at the same level. The only force that the pump has to overcome in this case is the pipe friction, variation of which with fluid flow rate is also shown in the figure. On the other hand, for the use shown in Fig. 10-33, the pump in addition to pipe friction should overcome head due to the difference in elevation between tanks A and B. In this case, elevation head is constant, whereas the head required to overcome friction depends on the flow rate. Figure 10-34 shows the pump performance requirement of a valve opening and closing.

**Pump Selection** One of the parameters that is extremely useful in selecting a pump for a particular application is specific speed $N_s$. Specific speed of a pump can be evaluated based on its design speed, flow, and head:

$$N_S = \frac{NQ^{1/2}}{H^{3/4}} \tag{10-55}$$

where $N$ = rpm, $Q$ is flow rate in gpm, and $H$ is head in ft · lbf/lbm.

Specific speed is a parameter that defines the speed at which impellers of geometrically similar design have to be run to discharge 1 gal/min against a 1-ft head. In general, pumps with a low specific speed have a low capacity; and high specific speed, high capacity. Specific speeds of different types of pumps are shown in Table 10-14 for comparison.

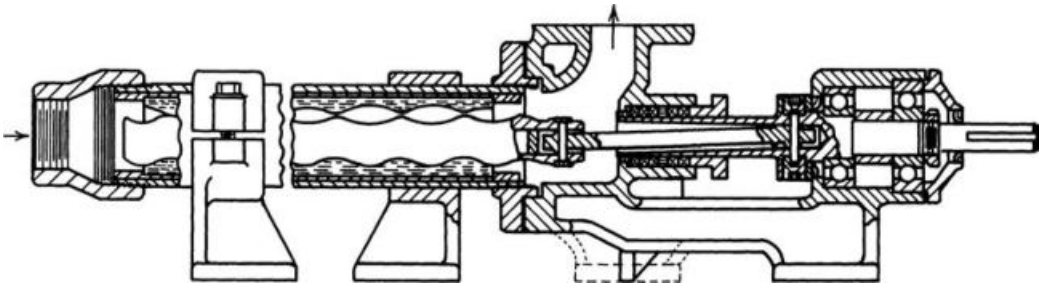

**FIG. 10-26** Single-rotor screw pump with an elastomeric lining. (*Courtesy of Moyno Pump Division, Robbins & Myers, Inc.*)

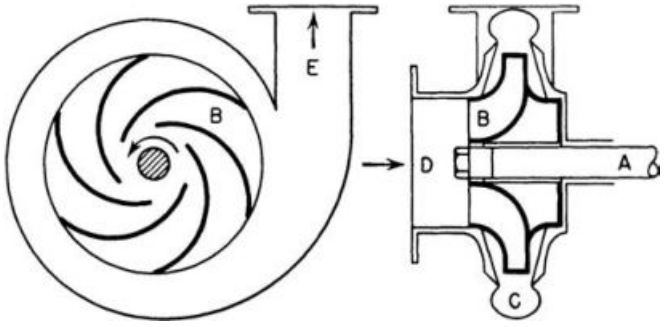

**FIG. 10-27** A simple centrifugal pump.

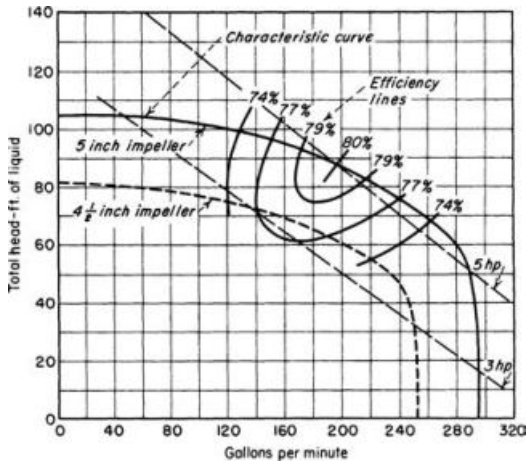

**FIG. 10-28** Characteristic curve of a centrifugal pump operating at a constant speed of 3450 r/min. To convert gallons per minute to cubic meters per hour, multiply by 0.2271; to convert feet to meters, multiply by 0.3048; to convert horsepower to kilowatts, multiply by 0.746; and to convert inches to centimeters, multiply by 2.54.

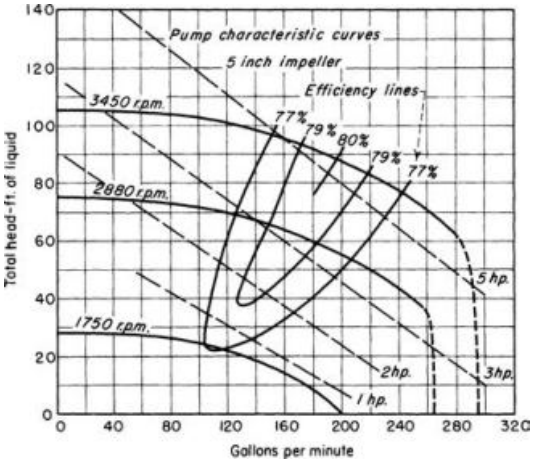

**FIG. 10-29** Characteristic curve of a centrifugal pump at various speeds. To convert gallons per minute to cubic meters per hour, multiply by 0.2271; to convert feet to meters, multiply by 0.3048; to convert horsepower to kilowatts, multiply by 0.746; and to convert inches to centimeters, multiply by 2.54.

Another parameter that helps in evaluating the pump suction limitations, such as cavitation, is the suction-specific speed, $S$:

$$S = \frac{NQ^{1/2}}{(\text{NPSH})^{3/4}} \tag{10-56}$$

Typically, for single-suction pumps, suction-specific speed above 11,000 is considered excellent. Below 7000 is poor and 7000 to 9000 is of an average design. Similarly, for double-suction pumps, suction-specific speed above 14,000 is considered excellent, below 7000 is poor, and 9000 to 11,000 is average.

Figure 10-35 shows the schematic of specific-speed variation for different types of pumps. The figure clearly indicates that as the specific speed increases, the ratio of the impeller outer diameter $D_1$ to inlet or eye diameter $D_2$ decreases, tending to become unity for pumps of axial-flow type.

Typically, axial-flow pumps are of high-flow and low-head type and have a high specific speed. On the other hand, purely radial pumps are of high head and low flow rate capability and have a low specific speed. Obviously, a pump with a moderate flow and head has an average specific speed.

A typical pump selection chart such as shown in Fig. 10-36 calculates the specific speed for given flow, head, and speed requirements. Based on the calculated specific speed, the optimal pump design is indicated.

**Process Pumps** This term is usually applied to single-stage pedestal-mounted units with single-suction overhung impellers and with a single packing box. These pumps are ruggedly designed for ease in dismantling and accessibility, with mechanical seals or packing arrangements, and are built specially to handle corrosive or otherwise difficult-to-handle liquids.

Specifically, but not exclusively for the chemical industry, most pump manufacturers now build to national standards *horizontal and vertical process pumps*. ASME Standards B73.1–2001 and B73.2–2003 apply to the horizontal (Fig. 10-37) and vertical in-line (Fig. 10-38) pumps, respectively.

The horizontal pumps are available for capacities up to 900 $m^3/h$ (4000 gal/min); the vertical in-line pumps, for capacities up to 320 $m^3/h$ (1400 gal/min). Both horizontal and vertical in-line pumps are available for heads up to 120 m (400 ft). The intent of each ANSI specification is that pumps from all vendors for a given nominal capacity and total dynamic head at a given rotative speed shall be dimensionally interchangeable with respect to mounting, size, and location of suction and discharge nozzles, input shaft, baseplate, and foundation bolts.

The vertical in-line pumps, although relatively new additions, are finding considerable use in chemical and petrochemical plants in the United States. An inspection of the two designs will make clear the relative advantages and disadvantages of each.

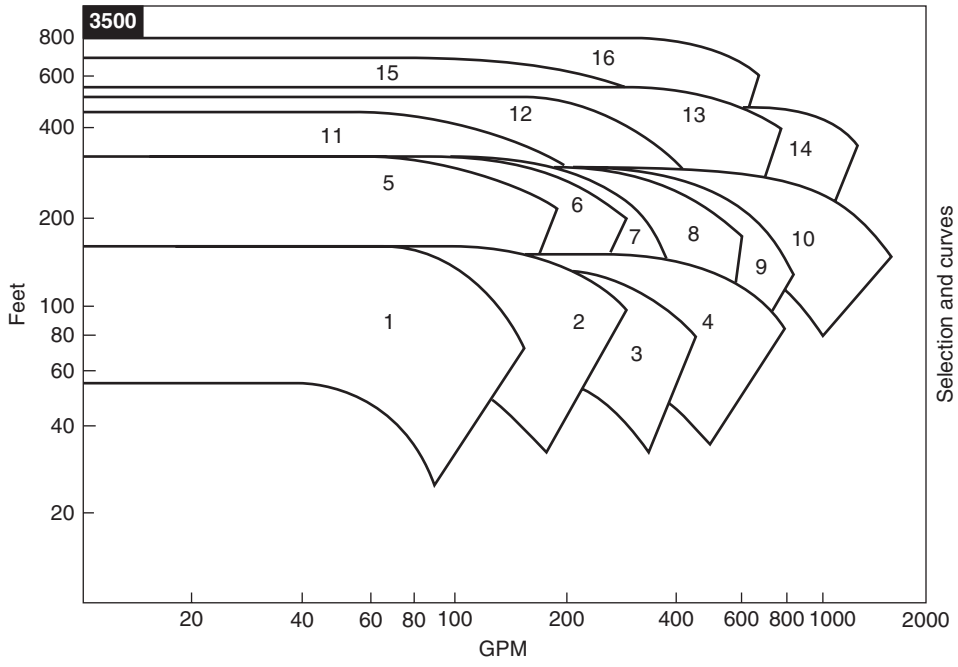
Chemical pumps are available in a variety of materials. Metal pumps are the most widely used. Although they may be obtained in iron, bronze, and iron with bronze fittings, an increasing number of pumps of ductile-iron, steel, and nickel alloys are being used. Pumps are also available in glass, glass-lined iron, carbon, rubber, rubber-lined metal, ceramics, and a variety of plastics, such units usually being employed for special purposes.

**Sealing the Centrifugal Chemical Pump** Engineers who specify an appropriate mechanical sealing system on their pumps can significantly improve the energy efficiency of a manufacturing plant as it is estimated that around 10 percent of electric power is used for pumping equipment. Regulatory bodies and engineers are focused on improving the energy efficiency of pumps and pumping systems. Choosing the right mechanical seal is one of the most effective ways of doing this. The purpose of a mechanical seal is to seal the process fluid—whether it is toxic or expensive, the objective is to keep it within the system and pipework to avoid its seeping out and resulting in a cost for lost process fluid and cleanup. Seals not only prevent process fluid contamination and leakage to the external atmosphere but are an important part of conserving energy within the system.

Mechanical seals on pumps are probably the most delicate components, and using seal flush plans to change the environment that the seals operate in and flourish enables them to provide reliable operation. Flush plans are formalized by the American Petroleum Institute in its Standard API-682, where they are detailed in standardized formats.

Current practice demands that packing boxes be designed to accommodate both packing and mechanical seals. With either type of seal, one consideration is of paramount importance in chemical service: the liquid present at the sealing surfaces must be free of solids. Consequently, it is necessary to provide a secondary compatible liquid to flush the seal or packing whenever the process liquid is not absolutely clean.

The use of *packing seals* requires the continuous escape of liquid past the seal to minimize and to carry away the frictional heat developed. If the effluent is toxic or corrosive, quench glands or catch pans are usually employed. Although packing can be adjusted with the pump operating, leaking mechanical seals require shutting down the pump to correct the leak. Properly applied and maintained *mechanical seals* usually show no visible



| Range No. | Pump | | Curve |

leakage. In general, owing to the more effective performance of mechanical seals, they have gained almost universal acceptance.

**Double-Suction, Single-Stage Pumps** These pumps are used for general water supply and circulating service and for chemical service when liquids that are noncorrosive to iron or bronze are being handled. They are available for capacities from about 5.7 $m^3/h$ (25 gal/min) up to as high as $1.136\times10^4$ $m^3/h$ (50,000 gal/min) and heads up to 304 m (1000 ft). Such units are available in iron, bronze, and iron with bronze fittings. Other materials increase the cost; when they are required, a standard chemical pump is usually more economical.

**Close-Coupled Pumps** Pumps equipped with a built-in electric motor or sometimes steam-turbine-driven (i.e., with pump impeller and driver on the same shaft) are known as *close-coupled pumps* (Fig. 10-39). Such units are extremely compact and are suitable for a variety of services for which standard iron and bronze materials are satisfactory. They are available in capacities up to about 450 $m^3/h$ (2000 gal/min) for heads up to about 73 m (240 ft). Two-stage units in the smaller sizes are available for heads to around 150 m (500 ft).

**Canned-Motor Pumps** These pumps (Fig. 10-40) command considerable attention in the chemical industry. They are close-coupled units in which the cavity housing the motor rotor and the pump casing are interconnected. As a result, the motor bearings run in the process liquid, and all seals are eliminated. Because the process liquid is the bearing lubricant, abrasive solids cannot be tolerated. Standard single-stage canned-motor pumps are available for flows up to 160 $m^3/h$ (700 gal/min) and heads up to 76 m (250 ft). Two-stage units are available for heads up to 183 m (600 ft). Canned-motor pumps are being widely used for handling organic solvents, organic heat-transfer liquids, and light oils as well as many clean toxic or hazardous liquids or for installations in which leakage is an economic problem.

**Vertical Pumps** In the chemical industry, the term *vertical process pump* (Fig. 10-41) generally applies to a pump with a vertical shaft having a length from drive end to impeller of approximately 1 m (3.1 ft) minimum to 20 m (66 ft) or more. Vertical pumps are used as either *wet-pit pumps* (immersed) or *dry-pit pumps* (externally mounted) in conjunction with stationary or mobile tanks containing difficult-to-handle liquids. They have the following advantages: the liquid level is above the impeller, and the pump is thus self-priming; and the shaft seal is above the liquid level and is not wetted by the pumped liquid, which simplifies the sealing task. When no bottom connections are permitted on the tank (a safety consideration for highly corrosive or toxic liquid), the vertical wet-pit pump may be the only logical choice.

These pumps have the following disadvantages: intermediate or line bearings are generally required when the shaft length exceeds about 3 m (10 ft) in order to avoid shaft resonance problems; these bearings must be lubricated whenever the shaft is rotating. Since all wetted parts must be corrosion-resistant, low-cost materials may not be suitable for the shaft, column, etc. Maintenance is costlier since the pumps are larger and more difficult to handle.

**TABLE 10-14 Specific Speeds of Different Types of Pumps**

| Pump type | Specific speed range |
|---|---|
| Below 2000 | Process pumps and feed pumps |
| 2000–5000 | Turbine pumps |
| 4000–10,000 | Mixed-flow pumps |
| 9000–15,000 | Axial-flow pumps |

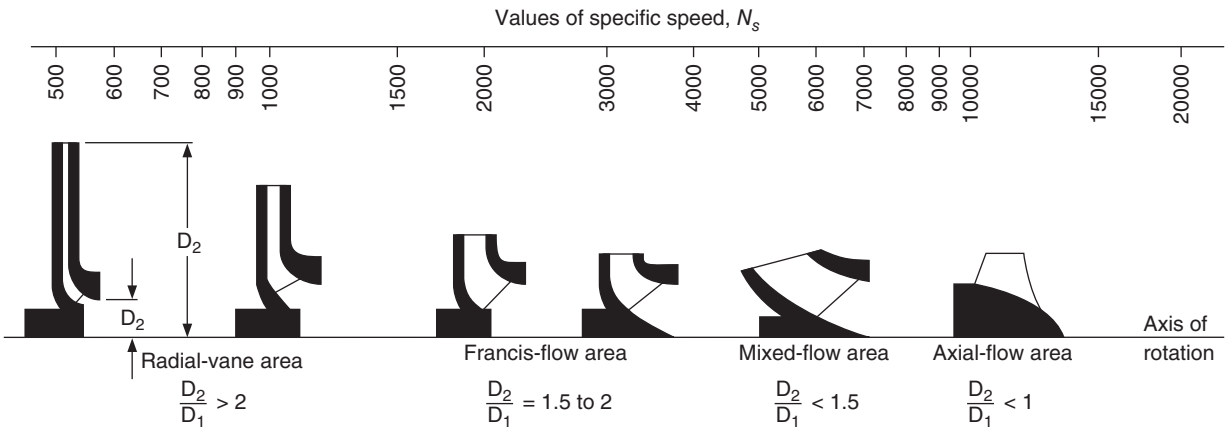

**FIG. 10-35** Specific speed variations of different types of pump.

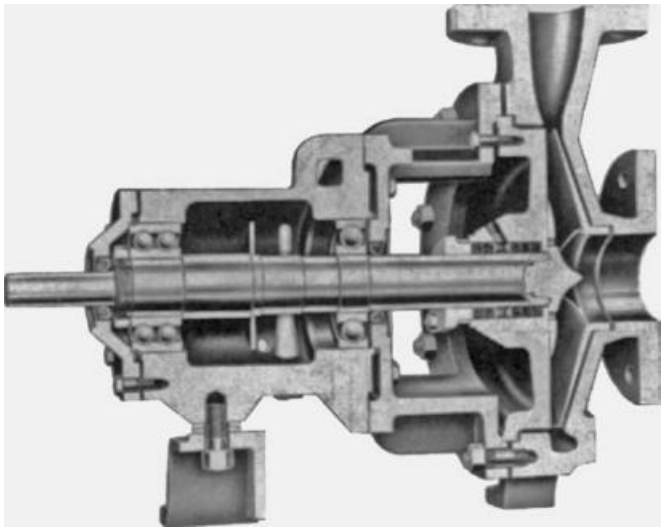

**FIG. 10-37** Horizontal process pump conforming to American Society of Mechanical Engineers Standard B73.1-2001.

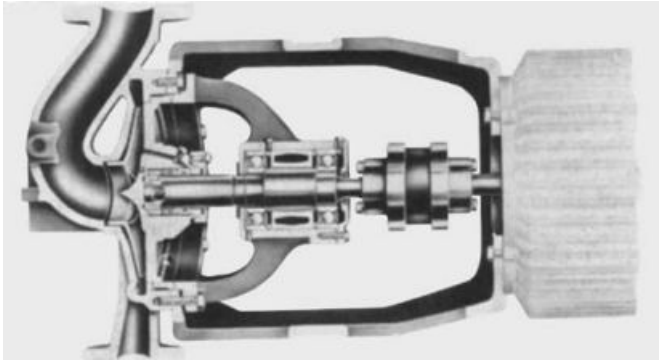

**FIG. 10-38** Vertical in-line process pump conforming to ASME standard B73.2-2003. The pump shown is driven by a motor through flexible coupling. Not shown but also conforming to ASME Standard B73.2-2003 are vertical in-line pumps with rigid couplings and with no coupling (impeller-mounted on an extended motor shaft).

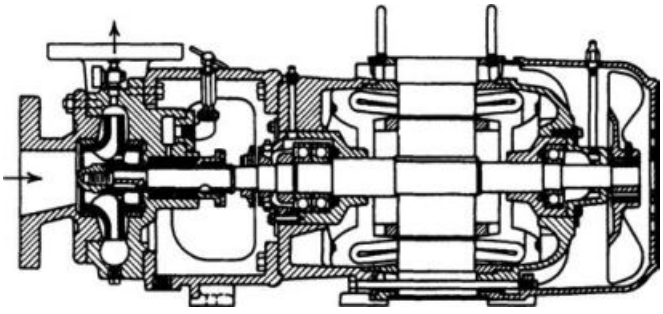

**FIG. 10-39** Close-coupled pump.

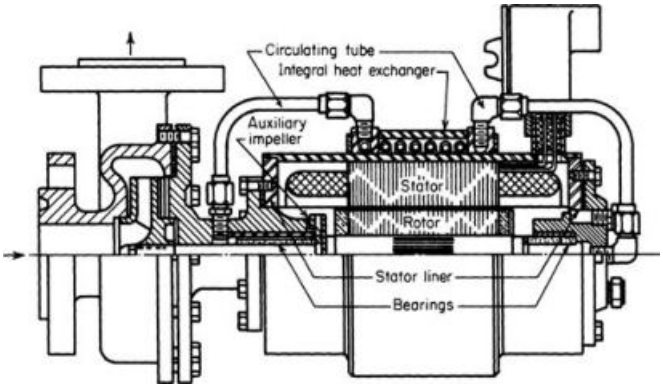

**FIG. 10-40** Canned-motor pump. (*Courtesy of Chempump Division, Crane Co.*)

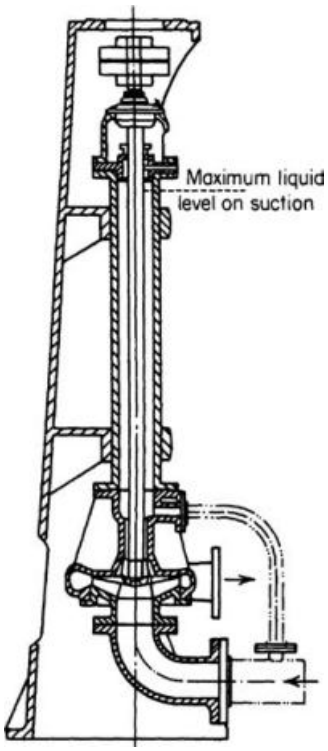

**FIG. 10-41** Vertical process pump for dry-pit mounting. (*Courtesy of Lawrence Pumps, Inc.*)

For abrasive service, vertical cantilever designs requiring no line or foot bearings are available. Generally, these pumps are limited to about a 1-m (3.1-ft) maximum shaft length. Vertical pumps are also used to pump waters to reservoirs. One such application in the Los Angeles water basin has 14 four-stage pumps, each pump requiring 80,000 hp to drive it.

**Sump Pumps** These are small single-stage vertical pumps used to drain shallow pits or sumps. They are of the same general construction as vertical process pumps but are not designed for severe operating conditions.

**Multistage Centrifugal Pumps** These pumps are used for services requiring heads (pressures) higher than can be generated by a single impeller. All impellers are in series, the liquid passing from one impeller to the next and finally to the pump discharge. The total head then is the summation of the heads of the individual impellers. Deep-well pumps, high-pressure water supply pumps, boiler-feed pumps, fire pumps, and charge pumps for refinery processes are examples of multistage pumps required for various services.

Multistage pumps may be of the *volute type* (Fig. 10-42), with single- or double-suction impellers (Fig. 10-43), or of the *diffuser type* (Fig. 10-44). They may have horizontally split casings or, for extremely high pressures, 20 to 40 MPa (3000 to 6000 lbf/in$^2$), vertically split barrel-type exterior casings with inner casings containing diffusers, interstage passages, etc.

## PROPELLER AND TURBINE PUMPS

**Axial-Flow (Propeller) Pumps** These pumps (Fig. 10-45) are essentially very high-capacity, low-head units. Normally they are designed for flows in excess of 450 m$^3$/h (2000 gal/min) against heads of 15 m (50 ft) or less. They are used to great advantage in closed-loop circulation systems in which the pump casing becomes merely an elbow in the line. A common installation is for calandria circulation. A characteristic curve of an axial-flow pump is given in Fig. 10-46.

**Turbine Pumps** The term *turbine pump* is applied to units with mixed-flow (part axial and part centrifugal) impellers. Such units are available in capacities from 20 m$^3$/h (100 gal/min) upward for heads up to about 30 m (100 ft) per stage. Turbine pumps are usually vertical.

A common form of turbine pump is the vertical pump, which has the pump element mounted at the bottom of a column that serves as the discharge pipe (see Fig. 10-47). Such units are immersed in the liquid to be pumped and are commonly used for wells, condenser circulating water, large-volume drainage, etc. Another form of the pump has a shell surrounding the pumping element which is connected to the intake pipe. In this form, the pump is used on condensate service in power plants and for process work in oil refineries.

**Regenerative Pumps** Also referred to as turbine pumps because of the shape of the impeller, regenerative pumps employ a combination of mechanical impulse and centrifugal force to produce heads of several hundred meters (feet) at low volumes, usually less than 20 m$^3$/h (100 gal/min). The impeller, which rotates at high speed with small clearances, has many short radial passages milled on each side at the periphery. Similar channels are milled in the mating surfaces of the casing. Upon entering, the liquid is directed into the impeller passages and proceeds in a spiral pattern around the periphery, passing alternately from the impeller to the casing and receiving successive impulses as it does so. Figure 10-48 illustrates a typical performance characteristic curve.

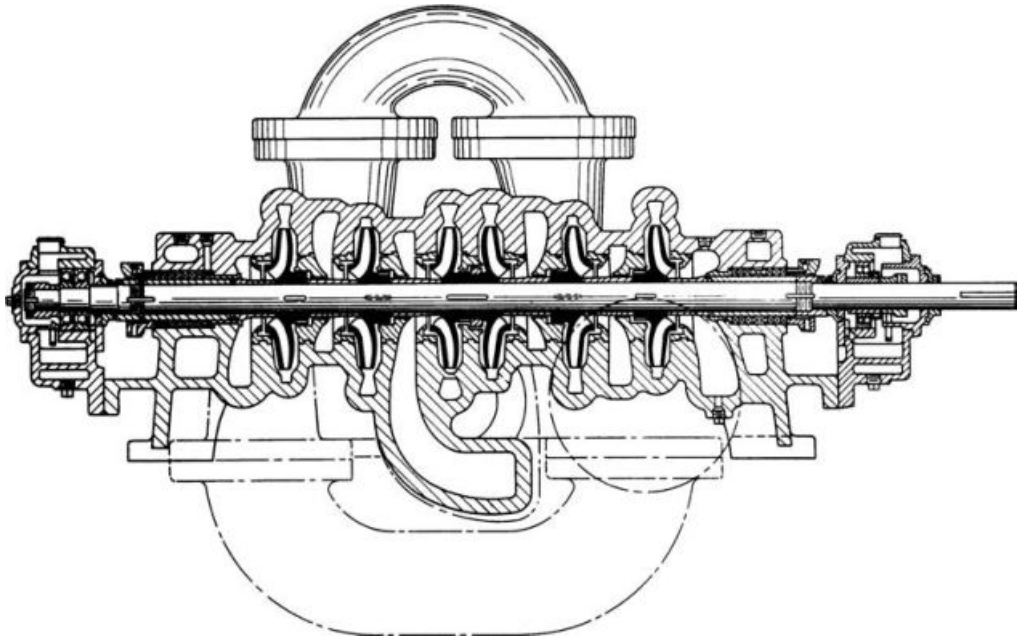

**FIG. 10-42** Six-stage volute-type pump.

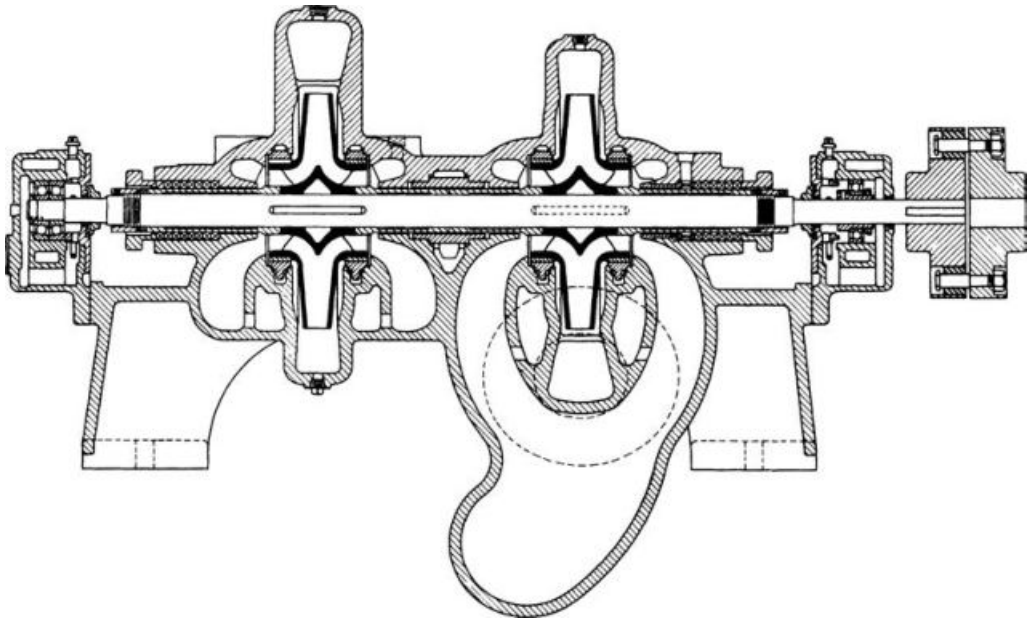

**FIG. 10-43** Two-stage pump having double-suction impellers.

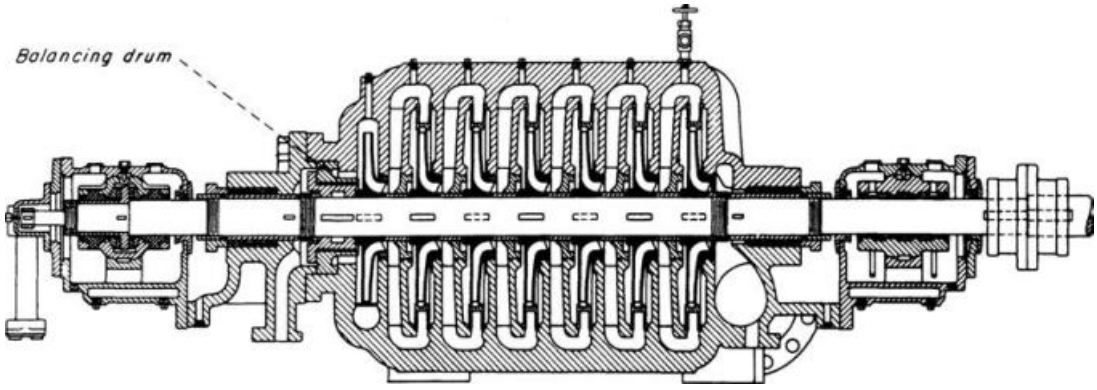

**FIG. 10-44** Seven-stage diffuser-type pump.

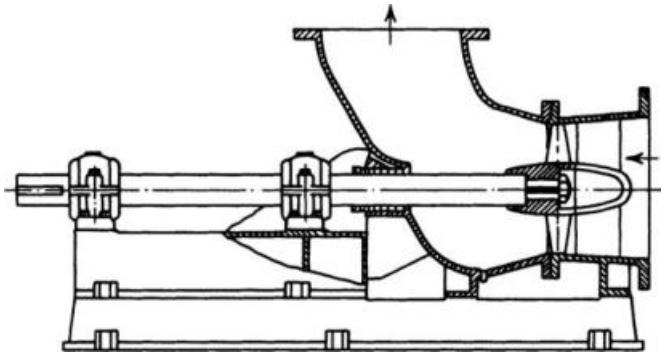

**FIG. 10-45** Axial-flow elbow-type propeller pump. (*Courtesy of Lawrence Pumps, Inc.*)

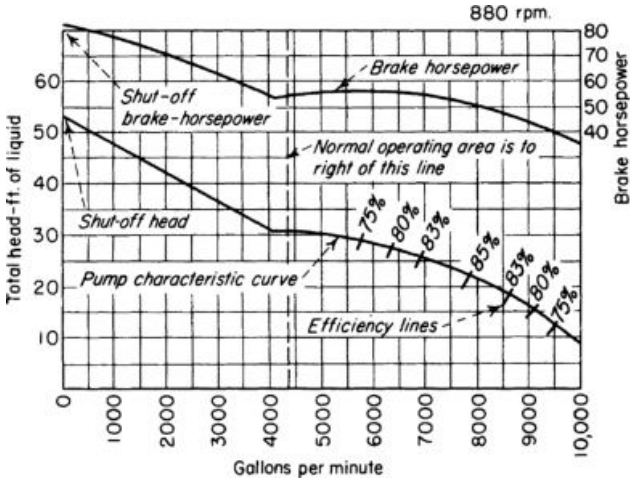

**FIG. 10-46** Characteristic curve of an axial-flow pump. To convert gallons per minute to cubic meters per hour, multiply by 0.2271; to convert feet to meters, multiply by 0.3048; and to convert horsepower to kilowatts, multiply by 0.746.

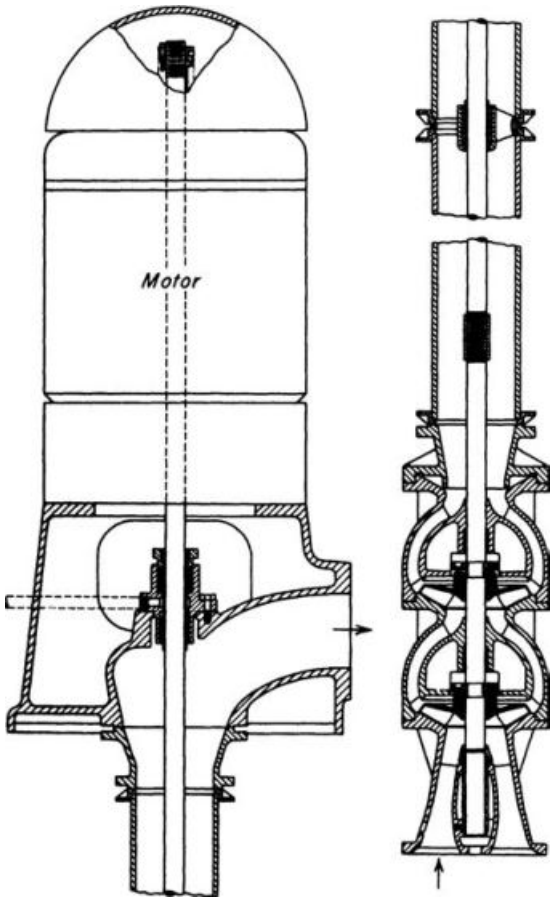

**FIG. 10-47** Vertical multistage turbine, or mixed-flow, pump.

These pumps are particularly useful when low volumes of low-viscosity liquids must be handled at higher pressures than are normally available with centrifugal pumps. Close clearances limit their use to clean liquids. For very high heads, multistage units are available.

## JET PUMPS

Jet pumps are a class of liquid-handling devices that makes use of the momentum of one fluid to move another.

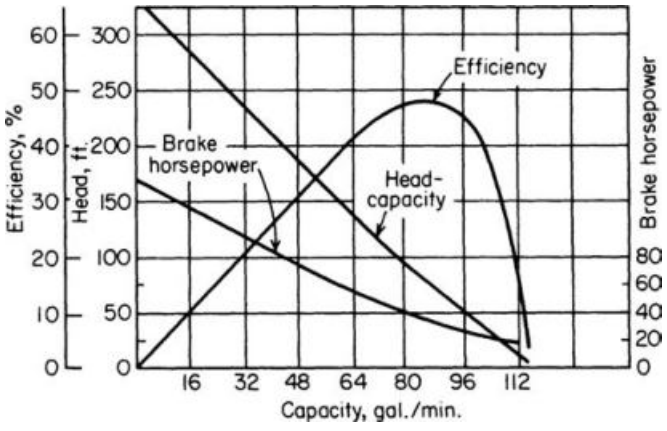

**FIG. 10-48** Characteristic curves of a regenerative pump. To convert gallons per minute to cubic meters per hour, multiply by 0.2271; to convert feet to meters, multiply by 0.3048; and to convert horsepower to kilowatts, multiply by 0.746.

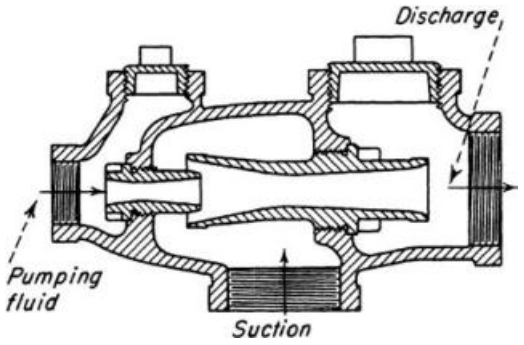

**FIG. 10-49** Simple ejector using a liquid-motivating fluid.

*Ejectors* and *injectors* are the two types of jet pumps of interest to chemical engineers. The ejector, also called the *siphon, exhauster,* or *eductor,* is designed for use in operations in which the head pumped against is low and is less than the head of the fluid used for pumping. The injector is a special type of jet pump, operated by steam and used for boiler feed and similar services, in which the fluid being pumped is discharged into a space under the same pressure as that of the steam being used to operate the injector.

Figure 10-49 shows a simple design for a jet pump of the ejector type. The pumping fluid enters through the nozzle at the left and passes through the venturi nozzle at the center and out of the discharge opening at the right. As it passes into the venturi nozzle, it develops a suction that causes some of the fluid in the suction chamber to be entrained with the stream and delivered through this discharge.

The efficiency of an ejector or jet pump is low, being only a few percent. The head developed by the ejector is also low except in special types. The device has the disadvantage of diluting the fluid pumped by mixing it with the pumping fluid. In steam injectors for boiler feed and similar services in which the heat of the steam is recovered, efficiency is close to 100 percent.

The simple ejector or siphon is widely used, in spite of its low efficiency, for transferring liquids from one tank to another, for lifting acids, alkalies, or solid-containing liquids of an abrasive nature, and for emptying sumps.

## PUMP DIAGNOSTICS

Pump problems vary over a large range depending on the type of pumps and the use of the pumps. They can be classified in the following manner by pump type and service:

1. *Positive-displacement pumps—reciprocating pump* problems can be classified into the following categories:
   - *a.* Compressor valve problems: plate valves, feather valves, concentric disk valves, relief valves
   - *b.* Piston and rod assembly: piston rings, cylinder chatter, cylinder cooling, piston-rod packing
   - *c.* Lubrication system
2. *Positive-displacement pumps—gear-type and roots-type* problems can be classified into the following categories:
   - *a.* Rotor dynamic problems: vibration problems, gear problems or roots rotor problems, bearing and seal problems
   - *b.* Lubrication systems
3. *Continuous flow pumps such as centrifugal pump* problems can be classified into the following categories:
   - *a.* Cavitation
   - *b.* Capacity flow
   - *c.* Motor overload
   - *d.* Impeller
   - *e.* Bearings and seals
   - *f.* Lubrication systems

Table 10-15 classifies different types of centrifugal pump–related problems, their possible causes, and corrective actions that can be taken to solve some of the more common issues. These problems in the table are classified into three major categories: cavitation, flow capacity, and motor overload for these types of pumps. The use of vibration monitoring to diagnose pump and compressor problems is discussed at the end of the subsection on compressor problems.

**TABLE 10-15 Pump Problems**

| Possible causes | Corrective action |
|---|---|
| **Cavitating-Type Problems** | |
| Plugged suction screen. | Check for indications of the presence of screen. Remove and clean screen. |
| Piping gaskets with undersized IDs installed, a very common problem in small pumps. | Install proper-sized gaskets. |
| Column tray parts or ceramic packing lodged in the impeller eye. | Remove suction piping and debris. |
| Deteriorated impeller eye due to corrosion. | Replace impeller and overhaul pump. |
| Flow rate is high enough above design that NPSH for flow rate has increased above NPSH. | Reduce flow rate to that of design. |
| Lined pipe collapsed at gasket area or ID due to buildup of corrosion products between liner and carbon-steel pipe. | Replace deteriorated piping. |
| Poor suction piping layout, too many elbows in too many planes, a tee branch almost directly feeding the suction of the other pump, or not enough straight run before the suction flange of the pump. | Redesign piping layout, using fewer elbows and laterals for tees, and have five or more straight pipe diameters before suction flange. |
| Vertical pumps experience a vortex formation due to loss of submergence required by the pump. Observe the suction surface while the pump is in operation, if possible. | Review causes of vortexing. Consider installation of a vortex breaker such as a bell mouth umbrella or changes to sump design. |
| Spare pump begins to cavitate when attempt is made to switch it with the running pump. The spare is "backed off" by the running pump because its shutoff head is less than the head produced by the running pump. This is a frequent problem when one pump is turbine-driven and one is motor-driven. | Throttle discharge of running pump until spare can get in system. Slow down running pump if it is a turbine or variable-speed motor. |
| Suction piping configuration causes adverse fluid rotation when approaching impeller. | Install sufficient straight run of suction piping, or install vanes in piping to break up pre-rotation. |
| Velocity of the liquid is too high as it approaches the impeller eye. | Install larger suction piping or reduce flow through pump. |
| Pump is operating at a low-flow-producing suction recirculation in the impeller eye. This results in a sound like cavitation. | Install bypass piping back to suction vessel to increase flow through pump. Remember bypass flow may have to be as high as 50 percent of design flow. |
| **Capacity-Type Problems** | |
| Check the discharge block valve opening first. It may be partially closed and thus the problem. | Open block valve completely. |
| Wear-ring clearances are excessive (closed impeller design). | Overhaul pump. Renew wear rings if clearance is about twice design value for energy and performance reasons. |
| Impeller-to-case or head clearances are excessive (open impeller design). | Reposition impeller to obtain correct clearance. |
| Air leaks into the system if the pump suction is below atmospheric pressure. | Take actions as needed to eliminate air leaks. |
| Increase in piping friction to the discharge vessel due to the following:<br>1. Gate has fallen off the discharge valve stem.<br>2. Spring is broken in the spring-type check valve.<br>3. Check valve flapper pin is worn, and flapper will not swing open.<br>4. Lined pipe collapsing.<br>5. Control valve stroke improperly set, causing too much pressure drop. | Take the following actions:<br>1. Repair or replace gate valve.<br>2. Repair valve by replacing spring.<br>3. Overhaul check valve; restore proper clearance to pin and flapper bore.<br>4. Replace damaged pipe.<br>5. Adjust control valve stroke as necessary. |
| Suction and/or discharge vessel levels are not correct, a problem mostly seen in lower-speed pumps. | Calibrate level controllers as necessary. |
| Motor running backward or impeller of double suction design is mounted backward. Discharge pressure developed in both cases is about one-half design value. | Check for proper rotation and mounting of impeller. Reverse motor leads if necessary. |
| Entrained gas from the process lowering NPSH available. | Reduce entrained gas in liquid by process changes as needed. |
| Polymer or scale buildup in discharge nozzle areas. | Shut down pump and remove scale or deposits. |
| Mechanical seal in suction system under vacuum is leaking air into system, causing pump curve to drop. | Change percentage balance of seal faces or increase spring tension. |
| The pump may have formed a vortex at high flow rates or low liquid level. Does the vessel have a vortex breaker? Does the incoming flow cause the surface to swirl or be agitated? | Reduce flow to design rates. Raise liquid level in suction vessel. Install vortex breaker in suction vessel. |
| Variable-speed motor running too slowly. | Adjust motor speed as needed. |
| Bypassing is occurring between volute channels in a double-volute pump casing due to a casting defect or extreme erosion. | Overhaul pump; repair eroded area. |
| The positions of impellers are not centered with diffuser vanes. Several impellers will cause vibration and lower head output. | Overhaul pump; reposition individual impellers as needed. Reposition whole rotor by changing thrust collar locator spacer. |
| When the suction system is under vacuum, the spare pump has difficulty getting into system. | Install a positive-pressure steam ( from running pump) to fill the suction line from the block valve through the check valve. |
| Certain pump designs use an internal bypass orifice port to alter head-flow curve. High liquid velocities often erode the orifice, causing the pump to go farther out on the pump curve. The system head curve increase corrects the flow back up the curve. | Overhaul pump, restore orifice to correct size. |
| Replacement impeller is not correct casting pattern; therefore NPSH required is different. | Overhaul pump; replace casing or repair by welding. Stress-relieve after welding as needed. |
| Volute and cutwater area of casing is severely eroded. | |
| **Overload Problems** | |
| Polymer buildup between wear surfaces (rings or vanes). | Remove buildup to restore clearances. |
| Excessive wear ring (closed impeller) or cover-case clearance (open impeller). | Replace wear rings or adjust axial clearance of open impeller. In severe cases, cover or case must be replaced. |
| Pump circulating excessive liquid back to suction through a breakdown bushing or a diffuser gasket area. | Overhaul pump, replacing parts as needed. |
| Minimum-flow loop left open at normal rates, or bypass around control valve is open. | Close minimum-flow loop or control valve bypass valve. |
| Discharge piping leaking under liquid level in sump-type design. | Inspect piping for leakage. Replace as needed. |
| Electrical switch gear problems cause one phase to have low amperage. | Check out switch gear and repair as necessary. |
| Specific gravity is higher than design specification. | Change process to adjust specific gravity to design value, or throttle pump to reduce horsepower requirements. This will not correct problem with some vertical turbine pumps that have a flat horsepower-required curve. |
| Pump motor not sized for end of curve operation. | Replace motor with one of larger size, or reduce flow rate. |
| Open impeller has slight rub on casing. Most often occurs in operations from 250 to 400°F due to piping strain and differential growth in the pump. | Increase clearance of impeller to casing. |
| A replacement impeller was not trimmed to the correct diameter. | Remove impeller from pump and turn to correct diameter. |

# COMPRESSORS

A compressor is a device that pressurizes a working fluid. One of the basic purposes of using a compressor is to compress the fluid and to deliver it at a pressure higher than its original pressure. Compression is required for a variety of purposes, some of which are listed below:

1. To provide air for combustion
2. To transport process fluid through pipelines
3. To provide compressed air for driving pneumatic tools
4. To circulate process fluid within a process

Different types of compressors are shown in Fig. 10-50. Positive-displacement compressors are used for intermittent flow in which successive volumes of fluid are confined in a closed space to increase their pressures. Rotary compressors provide continuous flow. In rotary compressors, rapidly rotating parts (impellers) accelerate fluid to a high speed; this velocity is then converted to additional pressure by gradual deceleration in the diffuser or volute which surrounds the impeller. Positive-displacement compressors can be further classified as either reciprocating or rotary type, as shown in Fig. 10-50. The reciprocating compressor has a piston having a reciprocating motion within a cylinder. The rotary positive-displacement compressors have rotating elements whose positive action results in compression and displacement. The rotary positive-displacement compressors can be further subdivided into sliding vane, liquid piston, straight lobe, and helical lobe compressors. The continuous flow compressors (Fig. 10-50) can be classified as either dynamic compressors or ejectors. Ejectors entrain the in-flowing fluid by using a high-velocity gas or steam jet and then convert the velocity of the mixture to pressure in a diffuser. The dynamic compressors have rotating elements, which accelerate the in-flowing fluid and convert the velocity head to pressure head, partially in the rotating elements and partially in the stationary diffusers or blade. The dynamic compressors can be further subdivided into centrifugal, axial-flow, and mixed-flow compressors. The main flow of gas in the centrifugal compressor is radial. The flow of gas in an axial compressor is axial, and the mixed-flow compressor combines some characteristics of both centrifugal and axial compressors.

It is not always obvious what type of compressor is needed for an application. Of the many types of compressors used in the process industries, some of the more significant are the centrifugal, axial, rotary, and reciprocating compressors. They fall into three categories, as shown in Fig. 10-51.

For very high flows and low pressure ratios, an axial-flow compressor would be best. Axial-flow compressors usually have a higher efficiency, as seen in Fig. 10-52, but a smaller operating region than does a centrifugal machine. Centrifugal compressors operate most efficiently at medium flow rates and high pressure ratios. Rotary and reciprocating compressors (positive-displacement machines) are best used for low flow rates and high pressure ratios. The positive-displacement compressors and, in particular, reciprocating compressors were the most widely used in the process and pipeline industries up to and through the 1960s.

In turbomachinery the centrifugal flow and axial-flow compressors are the ones used for compressing gases. Positive-displacement compressors such as reciprocating, gear type, or lobe type are widely used in the industry for many other applications such as slurry pumping.

The performance characteristics of a single stage of the three main types of compressors are given in Table 10-16. The pressure ratios of the axial and centrifugal compressors have been classified into three groups: industrial, aerospace, and research.

The industrial pressure ratio is low because the operating range needs to be large. The *operating range* is defined as the range between the surge point and the choke point. The surge point is the point at which the flow is reversed in the compressor. The choke point is the point at which the flow has reached Mach = 1.0, the point where no more flow can get through the unit, a "stone wall." When surge occurs, the flow is reversed, and so are all the forces acting on the compressor, especially the thrust forces. Surge can lead to total destruction of the compressor. Thus surge is a region that must be avoided. Choke conditions cause a large drop in efficiency, but do not lead to destruction of the unit. Note that with the increase in pressure ratio and the number of stages, the operating range is narrowed in axial-flow and centrifugal compressors.

**Compressor Selection** To select the most satisfactory compression equipment, engineers must consider a wide variety of types, each of which offers peculiar advantages for particular applications. Among the major factors to be considered are the flow rate, head or pressure, temperature limitations, method of sealing, method of lubrication, power consumption, serviceability, and cost.

To be able to decide which compressor best fits the job, the engineer must analyze the flow characteristics of the units. The following dimensionless numbers describe the flow characteristics.

The *Reynolds number* is the ratio of the inertia forces to the viscous forces

$$N_{\text{Re}} = \frac{\rho V D}{\mu} \tag{10-57}$$

where $\rho$ is the density of the gas, $V$ is the velocity of the gas, $D$ is the diameter of the impeller, and $\mu$ is the viscosity of the gas.

The *specific speed* compares the adiabatic head and flow rate in geometrically similar machines at various speeds.

$$N_s = \frac{N\sqrt{\dot{Q}}}{H_{\text{ad}}^{3/4}} \tag{10-58}$$

where $N$ is the speed of rotation of the compressor, $\dot{Q}$ is the volume flow rate, and $H$ is the adiabatic head.

The specific diameter compares head and flow rates in geometrically similar machines at various diameters

$$D_S = \frac{DH^{1/4}}{\sqrt{\dot{Q}}} \tag{10-59}$$

The flow coefficient is the capacity of the flow rate of the machine

$$\phi = \frac{\dot{Q}_1}{ND^3} \tag{10-60}$$

The pressure coefficient is the pressure or the pressure rise of the machine

$$\Psi = \frac{H}{N^2 D^2} \tag{10-61}$$

In selecting the machines of choice, the use of specific speed and diameter best describes the flow. Figure 10-53 shows the characteristics of the three types of compressors. Other considerations in chemical plant service such as problems with gases which may be corrosive or have abrasive solids in suspension must be dealt with. Gases at elevated temperatures may create a potential explosion hazard, while air at the same temperatures may be handled quite normally; minute amounts of lubricating oil or water may contaminate the process gas and so may not be permissible, and for continuous-process use, a high degree of equipment reliability is required, since frequent shutdowns for inspection or maintenance cannot be tolerated.

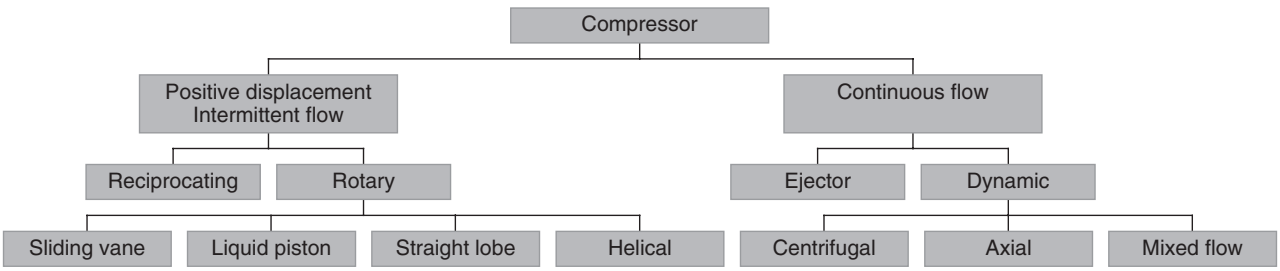

**FIG. 10-50** Principal types of compressors.

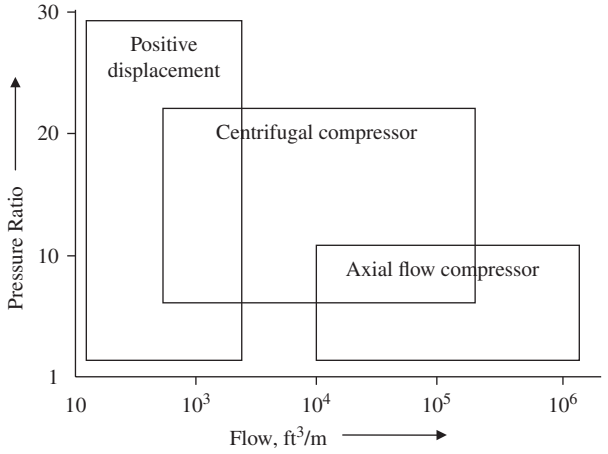

**FIG. 10-51** Performance characteristics of different types of compressors.

## COMPRESSION OF GASES

**Theory of Compression** In any continuous compression process, the relation of absolute pressure $p$ to volume $V$ is expressed by

$$pV^n = C = \text{constant} \tag{10-62}$$

The plot of pressure versus volume for each value of exponent $n$ is known as the *polytropic* curve. Since the work $W$ performed in proceeding from $p_1$ to $p_2$ along any polytropic curve (Fig. 10-54) is

$$W = \int_1^2 p\,dV \tag{10-63}$$

it follows that the amount of work required is dependent on the polytropic curve involved and increases with increasing values of $n$. The path requiring the least amount of input work is $n = 1$, which is equivalent to *isothermal* compression. For *adiabatic* compression (i.e., no heat is being added or taken away during the process), $n = k$ = ratio of specific heat at constant pressure to that at constant volume.

Since most compressors operate along a polytropic path approaching the adiabatic, compressor calculations are generally based on the adiabatic curve.

Some formulas based on the adiabatic equation and useful in compressor work are as follows:

*Pressure, volume,* and *temperature* relations for perfect gases:

$$P_2/P_1 = (V_1/V_2)^k \tag{10-64}$$

$$T_2/T_1 = (V_1/V_2)^{k-1} \tag{10-65}$$

$$P_2/P_1 = (T_2/T_1)^{k/(k-1)} \tag{10-66}$$

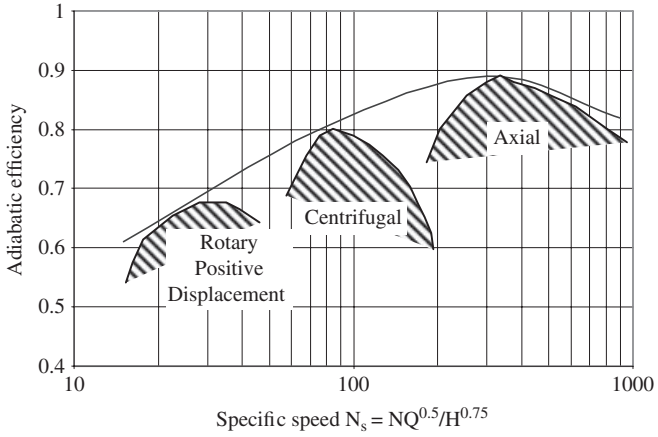

**FIG. 10-52** Variation of adiabatic efficiency with specific speed for the three types of compressors.

**Adiabatic Calculations** Adiabatic head is expressed as follows: In SI units,

$$H_{ad} = \frac{k \times ZRT_1}{k-1}\left[\left(\frac{P_2}{P_1}\right)^{(k-1)/k} - 1\right] \tag{10-67}$$

where $H_{ad}$ = adiabatic head, N·m/kg; $R$ = gas constant = 53.35 ft-lbf/(°R lbm) (BTU system), 287.074 = J/(kg·°K) (metric system); $T_1$ = inlet gas temperature, °R, °K; $P_1$ = absolute inlet pressure, $lb_f/ft^2$, kPa; and $P_2$ = absolute discharge pressure, $lb_f/ft^2$, kPa.

In USCS units,

$$H_{ad} = \frac{k}{k-1} ZRT_1\left[\left(\frac{P_2}{P_1}\right)^{(k-1)/k} - 1\right] \tag{10-68}$$

where $H_{ad}$ = adiabatic head, ft·lbf/lbm; $R$ = gas constant, $(\text{ft}\cdot\text{lb}_f)/(\text{lbm}\cdot°\text{R})$ = 1545/molecular weight; $T_1$ = inlet gas temperature, °R; $P_1$ = absolute inlet pressure, $lb_f/in^2$; and $P_2$ = absolute discharge pressure, $lb_f/in^2$.

The *work* expended on the gas during compression is equal to the product of the adiabatic head and the mass flow of gas handled. Therefore, the adiabatic power is as follows:

In SI units,

$$\text{kW}_{ad} = \frac{\dot{m}H_{ad}}{10^3} = \frac{k \times ZWRT_1}{k-1}\left[\left(\frac{P_2}{P_1}\right)^{(k-1)/k} - 1\right] \tag{10-69}$$

$$\text{kW}_{ad} = 2.78 \times 10^{-4} \frac{k}{k-1} Q_1 P_1\left[\left(\frac{P_2}{P_1}\right)^{(k-1)/k} - 1\right] \tag{10-70}$$

where $\text{kW}_{ad}$ = power, kW; $\dot{m}$ = mass flow, kg/s; and $\dot{Q}_1$ = volume rate of gas flow, $m^3/h$, at compressor inlet conditions.

In USCS units,

$$\text{hp}_{ad} = \frac{\dot{m}H_{ad}}{550} = \frac{k}{k-1}\frac{ZWRT_1}{550}\left[\left(\frac{P_2}{P_1}\right)^{(k-1)/k} - 1\right] \tag{10-71}$$

or

$$\text{hp}_{ad} = \left[\frac{k}{k-1}\right]\frac{\dot{Q}_1 P_1}{3600}\left[\left(\frac{P_2}{P_1}\right)^{(k-1)/k} - 1\right] \tag{10-72}$$

where $\text{hp}_{ad}$ = power, hp; $\dot{m}$ = mass flow, lb/s; and $\dot{Q}_1$ = volume rate of gas flow, $ft^3/min$.

Adiabatic discharge temperature is

$$T_2 = T_1(P_2/P_1)^{(k-1)/k} \tag{10-73}$$

The work in a compressor under ideal conditions as previously shown occurs at constant entropy. The actual process is a polytropic process as shown in Fig. 10-54 and given by the equation of state $PV^n$ = constant.

Adiabatic efficiency is given by the following relationship:

$$\eta_{ad} = \frac{\text{ideal work}}{\text{actual work}} \tag{10-74}$$

In terms of the change in total temperatures, the relationship can be written as

$$\eta_{ad} = \frac{T_2 - T_1}{T_{2a} - T_1} \tag{10-75}$$

where $T_{2a}$ is the total actual discharge temperature of the gas. The adiabatic efficiency can be represented in terms of the total pressure change:

$$\eta_{ad} = \frac{\left(\frac{p_2}{p_1}\right)^{(k-1)/k} - 1}{\left(\frac{p_2}{p_1}\right)^{(n-1)/n} - 1} \tag{10-76}$$

Polytropic head can be expressed by the following relationship:

$$H_{poly} = \frac{n}{n-1} ZRT_1\left[\left(\frac{p_2}{p_1}\right)^{(n-1)/n} - 1\right] \tag{10-77}$$

**TABLE 10-16 Performance Characteristics of Compressors**

| Types of compressors | Pressure ratio per stage | | | Efficiency, % | Operating range surge – choke, % |
|---|---|---|---|---|---|
| | Industrial | Aerospace | Research | | |
| Positive displacement | Up to 30 | — | — | 75–82 | — |
| Centrifugal | 1.2–1.9 | 2.0–7.0 | 13 | 75–87<br>25 | Large |
| Axial | 1.05–1.3 | 1.1–1.45 | 2.1 | 80–91 | Narrow<br>3–10 |

Likewise, for polytropic efficiency, which is often considered as the small stage efficiency, or the hydraulic efficiency

$$\eta_{pc} = \frac{(k-1)/k}{(n-1)/n} \tag{10-78}$$

Polytropic efficiency is the limited value of the isentropic efficiency as the pressure ratio approaches 1.0, and the value of the polytropic efficiency is higher than the corresponding adiabatic efficiency.

A characteristic of polytropic efficiency is that the polytropic efficiency of a multistage unit is equal to the stage efficiency if each stage has the same efficiency.

If the compression cycle approaches the isothermal condition, $pV$ = constant, as is the case when several stages with intercoolers are used, then a simple approximation of the power is obtained from the following formula:

In SI units,

$$\text{kW} = 2.78 \times 10^{-4} \dot{Q}_1 p_1 \ln p_2/p_1 \tag{10-79}$$

In USCS units,

$$\text{hp} = 4.4 \times 10^{-3} \dot{Q}_1 p_1 \ln p_2/p_1 \tag{10-80}$$

**Reciprocating Compressors** Reciprocating compressors are used mainly when high-pressure head is required at a low flow. Reciprocating compressors are furnished in either single-stage or multistage types. The number of stages is determined by the required compressor ratio $p_2/p_1$. The compression ratio per stage is generally limited to 4, although low-capacity units are furnished with compression ratios of 8 and even higher. Generally, the maximum compression ratio is determined by the maximum allowable discharge-gas temperature.

Single-acting air-cooled and water-cooled air compressors are available in sizes up to about 75 kW (100 hp). Such units are available in one, two, three, or four stages for pressure as high as 24 MPa (3500 lbf/in$^2$). These machines are seldom used for gas compression because of the difficulty of preventing gas leakage and contamination of the lubricating oil.

The compressors most commonly used for compressing gases have a crosshead to which the connecting rod and piston rod are connected. This provides a straight-line motion for the piston rod and permits simple packing to be used. Figure 10-55 illustrates a simple single-stage machine of this type having a double-acting piston. Either single-acting (Fig. 10-56) or double-acting pistons (Fig. 10-57) may be used, depending on the size of the machine and the number of stages. In some machines double-acting pistons are used in the first stages and single-acting in the later stages.

On multistage machines, intercoolers are provided between stages. These heat exchangers remove the heat of compression from the gas and reduce its temperature to approximately the temperature existing at the compressor intake. Such cooling reduces the volume of gas going to the high-pressure cylinders, reduces the power required for compression, and keeps the temperature within safe operating limits.

Figure 10-58 illustrates a two-stage compressor end such as might be used on the compressor illustrated in Fig. 10-55.

Compressors with horizontal cylinders such as illustrated in Figs. 10-55 to 10-57 are most commonly used because of their accessibility. However, machines are also built with vertical cylinders and other arrangements such as right-angle (one horizontal and one vertical cylinder) and V-angle.

Compressors up to around 75 kW (100 hp) usually have a single center-throw crank, as illustrated in Fig. 10-55. In larger sizes compressors are commonly of duplex construction with cranks on each end of the shaft (see Fig. 10-59). Some large synchronous motor-driven units are of four-corner construction; i.e., they are of double-duplex construction with two connecting rods from each of the two crank throws (see Fig. 10-60). Steam-driven compressors have one or more steam cylinders connected directly by piston rod or tie rods to the gas-cylinder piston or crosshead.

***Valve Losses*** Above piston speeds of 2.5 m/s (500 ft/min), suction and discharge valve losses begin to exert significant effects on the actual internal compression ratio of most compressors, depending on the valve port area available. The obvious results are high temperature rise and higher power requirements than might be expected. These effects become more pronounced with higher-molecular-weight gases. Valve problems can be a very major contributor to downtime experienced by these machines.

***Control Devices*** In many installations the use of gas is intermittent, and some means of controlling the output of the compressor is therefore necessary. In other cases, constant output is required despite variations in discharge pressure, and the control device must operate to maintain a constant compressor speed. Compressor capacity, speed, or pressure may be varied in accordance with requirements. The nature of the control device will depend on the function to be regulated. Regulation of pressure, volume, temperature, or some other factor determines the type of regulation required and the type of the compressor driver.

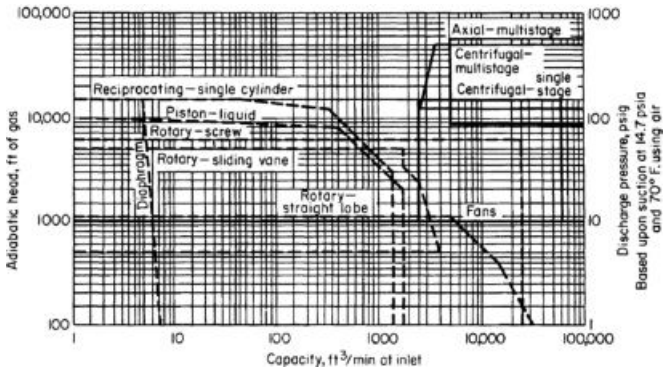

**FIG. 10-53** Compressor coverage chart based on the normal range of operation of commercially available types shown. Solid lines: use left ordinate, head. Broken lines: use right ordinate, pressure. To convert cubic feet per minute to cubic meters per hour, multiply by 1.699; to convert feet to meters, multiply by 0.3048; and to convert pounds-force per square inch to kilopascals, multiply by 6.895; (°F − 32)5/9 = °C.

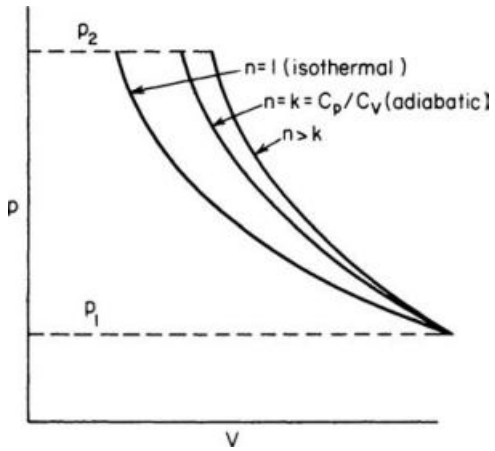

**FIG. 10-54** Polytropic compression curves.

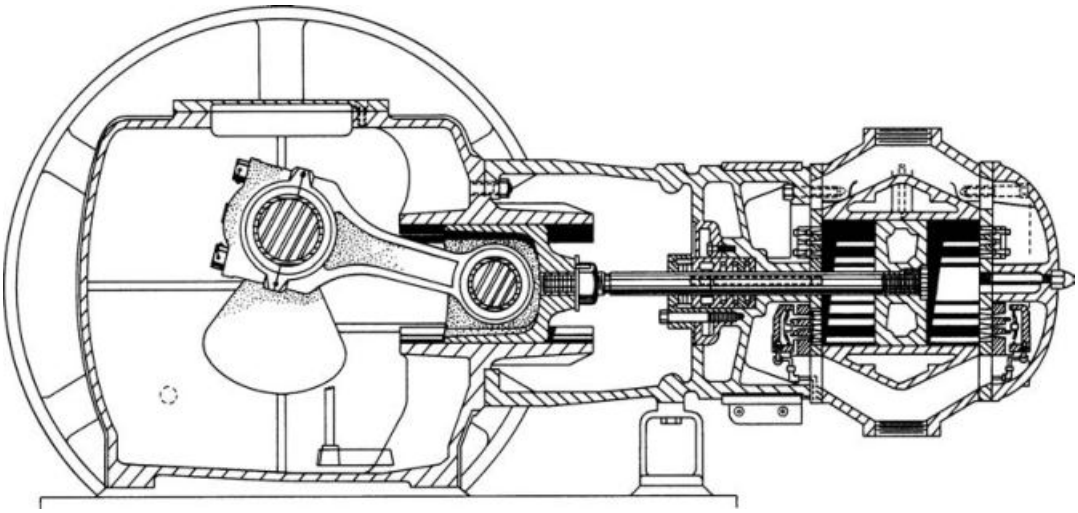

**FIG. 10-55** Typical single-stage, double-acting water-cooled compressor.

The most common control requirement is regulation of capacity. Many capacity controls, or *unloading devices,* as they are usually termed, are actuated by the pressure on the discharge side of the compressor. A falling pressure indicates that gas is being used faster than it is being compressed and that more gas is required. A rising pressure indicates that more gas is being compressed than is being used and that less gas is required.

An obvious method of controlling the capacity of a compressor is to vary the speed. This method is applicable to units driven by variable-speed drivers such as steam pistons, steam turbines, gas engines, diesel engines, etc. In these cases, the regulator actuates the steam-admission or fuel-admission valve on the compressor driver and thus controls the speed.

Motor-driven compressors usually operate at constant speed, and other methods of controlling the capacity are necessary. On reciprocating compressors discharging into receivers, up to about 75 kW (100 hp), two types of control are usually available. These are automatic start-and-stop control and constant-speed control.

Automatic start-and-stop control, as its name implies, stops or starts the compressor by means of a pressure-actuated switch as the gas demand varies. It should be used only when the demand for gas will be intermittent.

Constant-speed control should be used when the gas demand is fairly constant. With this type of control, the compressor runs continuously but compresses only when gas is needed. Three methods of unloading the compressor with this type of control are in common use: (1) *closed suction unloaders,* (2) *open inlet-valve unloaders,* and (3) *clearance unloaders.* The closed suction unloader consists of a pressure-actuated valve which shuts off the compressor intake. Open inlet-valve unloaders (see Fig. 10-61) operate to hold the compressor inlet valves open and thereby prevent compression. Clearance unloaders (see Fig. 10-62) consist of pockets or small reservoirs that are opened when unloading is desired. The gas is compressed into them on the compression stroke and reexpands into the cylinder on the return stroke, thus preventing the compression of additional gas.

It is sometimes desirable to have a compressor equipped with both constant-speed and automatic start-and-stop control. When this is done, a switch allows immediate selection of either type.

Motor-driven reciprocating compressors above about 75 kW (100 hp) in size are usually equipped with a step control. This is in reality a variation of constant-speed control in which unloading is accomplished in a series of steps, varying from full load down to no load. *Three-step control* ( full load, one-half load, and no load) is usually accomplished with inlet-valve unloaders. *Five-step control* ( full load, three-fourths load, one-half load, one-fourth load, and no load) is accomplished by means of clearance pockets (see Fig. 10-63). On some machines, inlet valve and clearance-control unloading are used in combination.

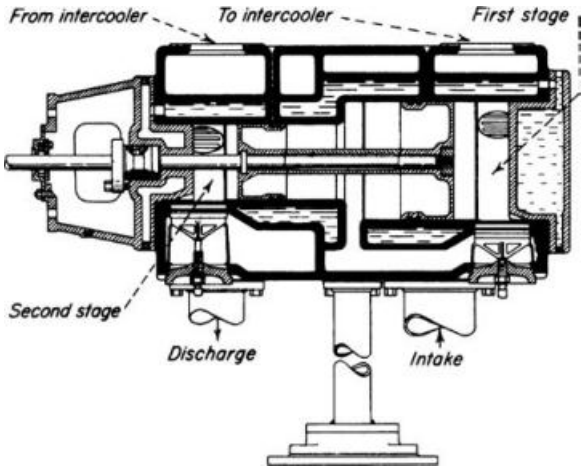

**FIG. 10-56** Two-stage, single-acting opposed piston in a single step-type cylinder.

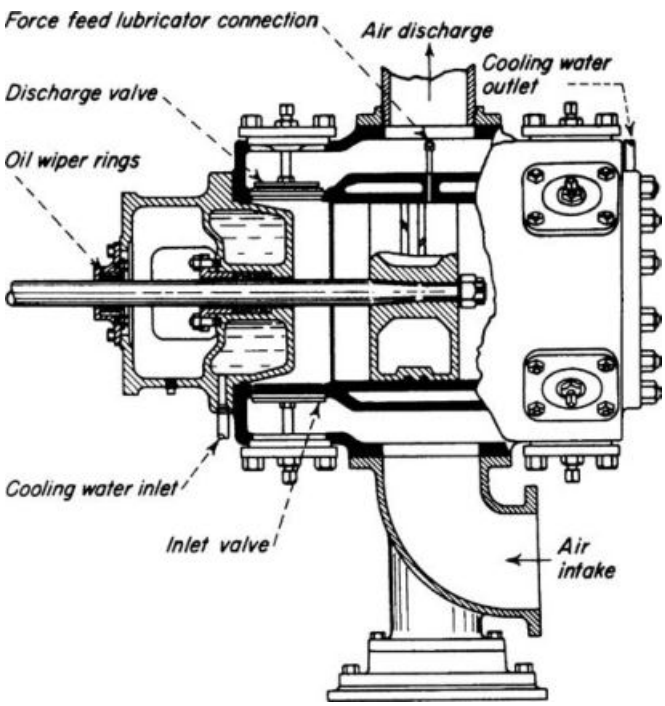

**FIG. 10-57** Typical double-acting compressor piston and cylinder.

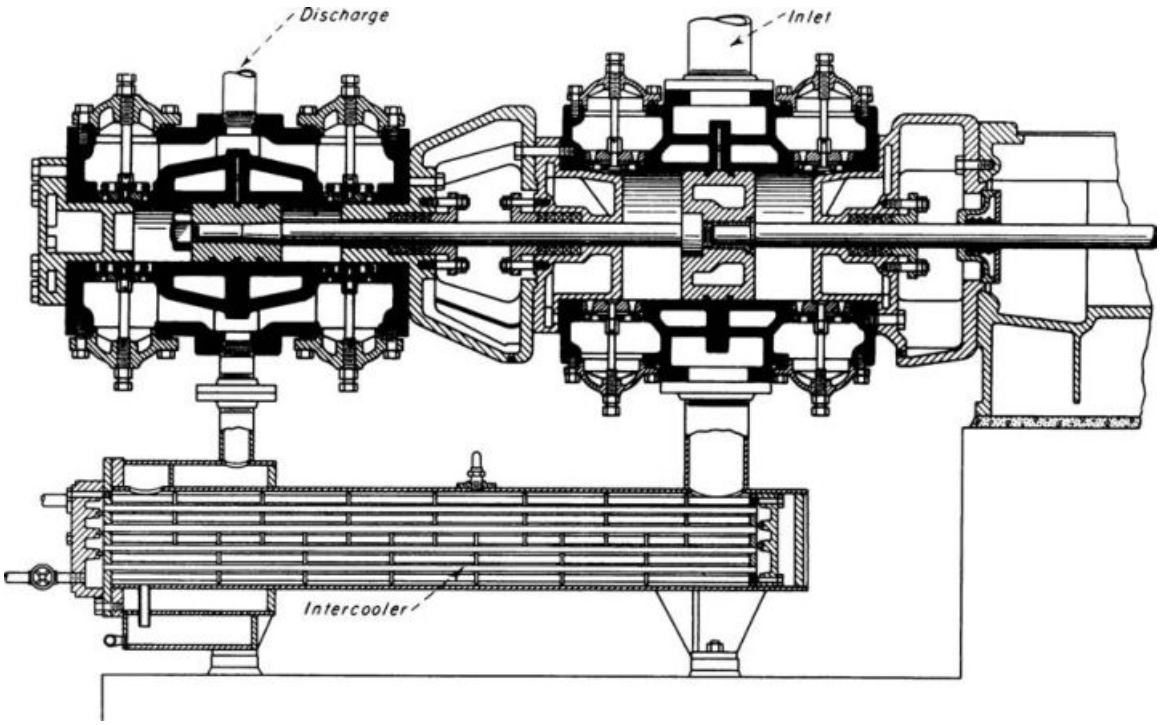

**FIG. 10-58** Two-stage double-acting compressor cylinders with intercooler.

Although such control devices are usually automatically operated, manual operation is satisfactory for some services. When manual operation is provided, it often consists of a valve or valves to open and close clearance pockets. In some cases, a movable cylinder head is provided for variable clearance in the cylinder (see Fig. 10-64).

When no capacity control or unloading device is provided, it is necessary to provide bypasses between the inlet and discharge so that the compressor can be started against no load (see Fig. 10-65).

***Nonlubricated Cylinders*** Most compressors use oil to lubricate the cylinder. In some processes, however, the slightest oil contamination is objectionable. For such cases a number of manufacturers furnish a "nonlubricated" cylinder (see Fig. 10-66). The piston on these cylinders is equipped with piston rings of graphitic carbon or Teflon* as well as pads or rings of the same material to maintain proper clearance between the piston and the cylinder. Plastic packing of a type that requires no lubricant is used on the stuffing box. Although oil-wiper rings are used on the piston rod where it leaves the compressor frame, minute quantities of oil might conceivably enter the cylinder on the rod. If even such small amounts of oil are objectionable, an extended cylinder connecting piece can be furnished. This simply lengthens the piston rod enough that no portion of the rod can alternately enter the frame and the cylinder.

*®Du Pont tetrafluoroethylene fluorocarbon resin.

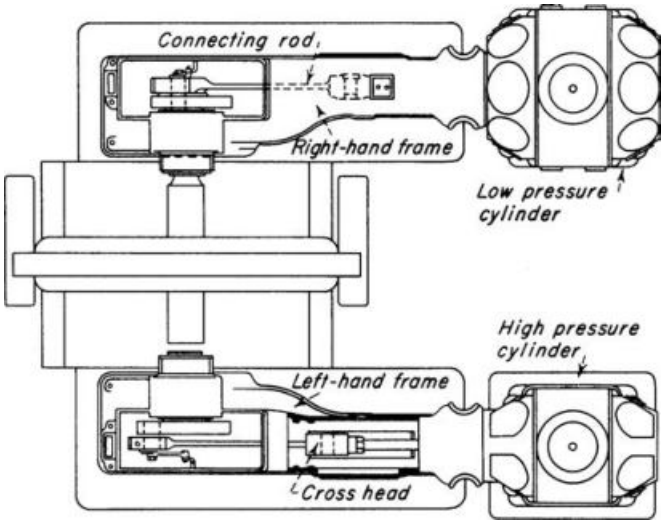

**FIG. 10-59** Duplex two-stage compressor (plan view).

In many cases, a small amount of gas leaking through the packing is objectionable. Special connecting pieces are furnished between the cylinder and the frame, which may be either single-compartment or double-compartment. These may be furnished gastight and vented back to the suction or filled with a sealing gas or fluid and held under a slight pressure.

***High-Pressure Compressors*** There is a definite trend in the chemical industry toward the use of high-pressure compressors with discharge pressures of 34.5 to 172 MPa (5000 to 25,000 lbf/in$^2$) and with capacities from $8.5 \times 10^3$ to $42.5 \times 10^3$ m$^3$/h (5000 to 25,000 ft$^3$/min). These require special design, and a complete knowledge of the characteristics of the gas is necessary. In most cases, these types of applications use the barrel-type centrifugal compressor.

The gas usually deviates considerably from the perfect-gas laws, and in many cases temperature or other limitations necessitate a thorough engineering study of the problem. These compressors usually have five, six, seven, or eight stages, and the cylinders must be properly proportioned to meet the various limitations involved and to balance the load among the various stages. In many cases, scrubbing or other processing is carried on between stages. High-pressure cylinders are steel forgings with single-acting plungers (see Fig. 10-67). The compressors are usually designed so that the pressure load against the plunger is opposed by one or more single-acting pistons of the lower-pressure stages. Piston-rod packing is usually of the segmental-ring metallic type. Accurate fitting and correct lubrication are very important. High-pressure compressor valves are designed for the conditions involved. Extremely high-grade engineering and skill are necessary.

***Piston-Rod Packing*** Proper piston-rod packing is important. Many types are available, and the most suitable is determined by the gas handled and the operating conditions for a particular unit.

There are many types and compositions of soft packing, semimetallic packing, and metallic packing. In many cases, metallic packing is to be recommended. A typical low-pressure packing arrangement is shown in Fig. 10-68. A high-pressure packing arrangement is shown in Fig. 10-69.

When wet, volatile, or hazardous gases are handled or when the service is intermittent, an auxiliary packing gland and soft packing are usually employed (see Fig. 10-70).

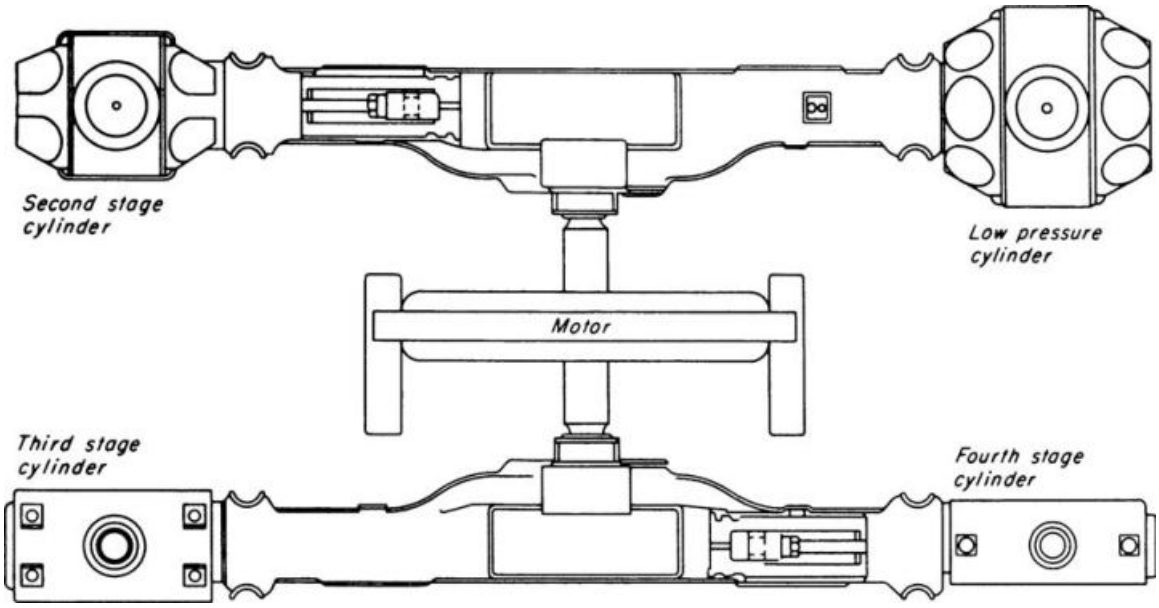

**FIG. 10-60** Four-corner four-stage compressor (plan view).

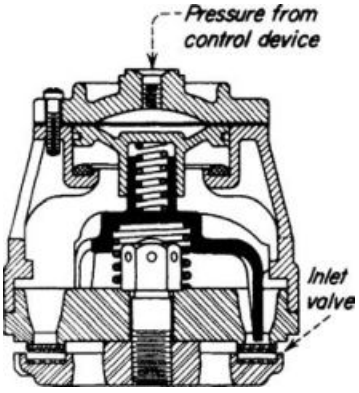

**FIG. 10-61** Inlet-valve unloader.

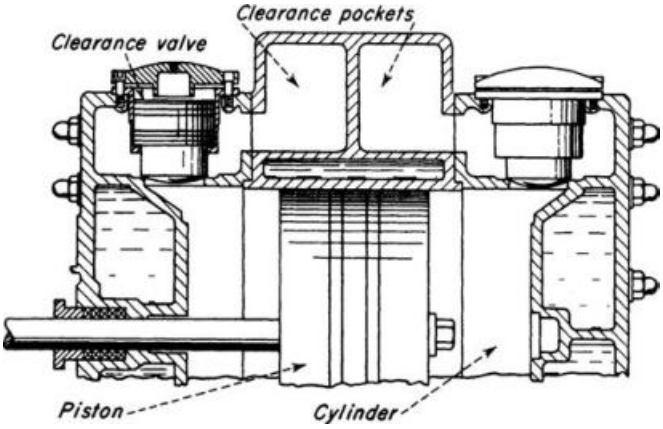

**FIG. 10-62** Clearance-control cylinder. (*Courtesy of Ingersoll-Rand.*)

***Metallic Diaphragm Compressors*** These (Fig. 10-71) are available for small quantities [up to about 17 $m^3/h$ (10 $ft^3/min$)] for compression ratios as high as 10:1 per stage. Temperature rise is not a serious problem, as the large wall area relative to the gas volume permits sufficient heat transfer to approach isothermal compression. These compressors possess the advantage of having no seals for the process gas. The diaphragm is actuated hydraulically by a plunger pump.

## FANS AND BLOWERS

*Fans* are used for low pressures where generally the delivery pressure is less than 3.447 kPa (0.5 $lb/in^2$), and blowers are used for higher pressures.

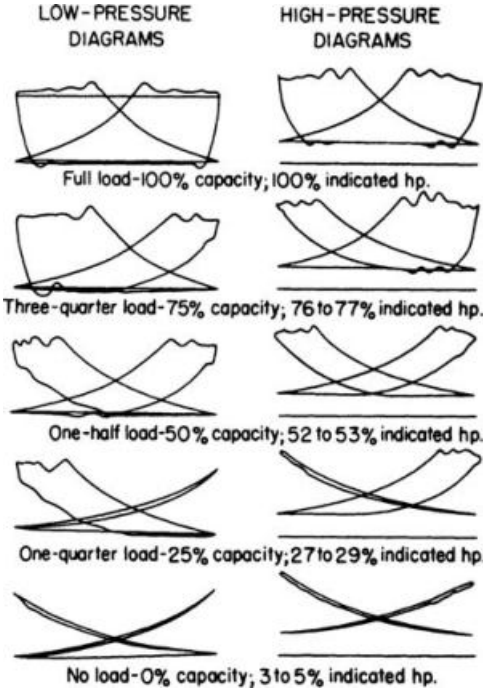

**FIG. 10-63** Actual indicator diagram of a two-stage compressor showing the operation of clearance control at five load points.

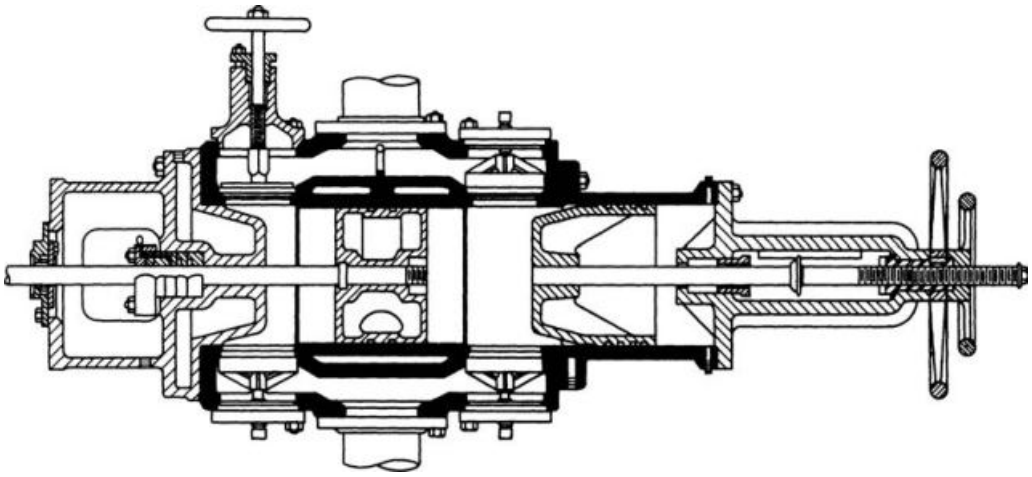

**FIG. 10-64** Sectional view of a cylinder equipped with a hand-operated valve lifter on one end and a variable-volume clearance pocket at other end.

However, they are usually below delivery pressures of 10.32 kPa (1.5 lbf/in$^2$). These units can be either centrifugal or the axial-flow type.

*Fans and blowers* are used for many types of ventilating work such as air-conditioning systems. In large buildings, blowers are often used owing to the high delivery pressures needed to overcome the pressure drop in the ventilation system. Most of these blowers are of the centrifugal type. Blowers are also used to supply draft air to boilers and furnaces. Fans are used to move large volumes of air or gas through ducts, supplying air for drying, conveying material suspended in the gas stream, removing fumes, condensing towers and other high-flow, low-pressure applications.

**Axial-Flow Fans** These are designed to handle very high flow rates and low pressure. The disc-type fans are similar to a household fan. They are usually for general circulation or exhaust work without ducts.

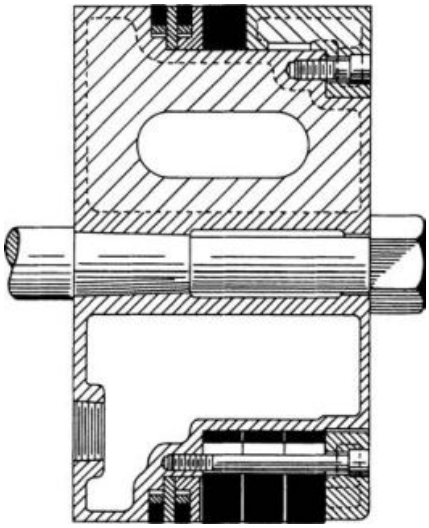

**FIG. 10-66** Piston equipped with carbon piston and wearing rings for a nonlubricated cylinder.

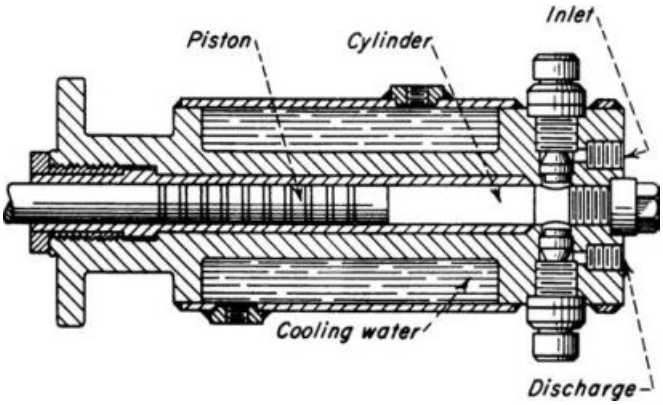

**FIG. 10-67** Forged-steel single-acting high-pressure cylinder.

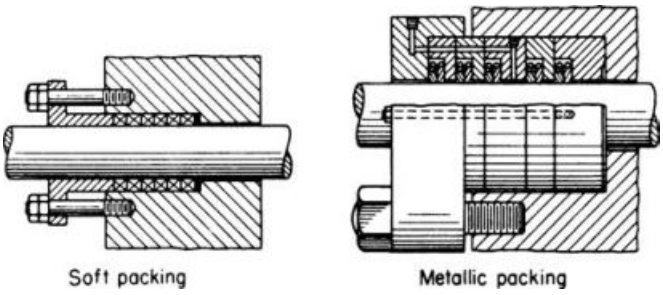

**FIG. 10-68** Typical packing arrangements for low-pressure cylinders.

The so-called propeller-type fans with blades that are aerodynamically designed (as seen in Fig. 10-72) can consist of two or more stages. The air in these fans enters in an axial direction and leaves in an axial direction. The fans usually have inlet guide vanes followed by a rotating blade, followed by a stationary (stator) blade.

**Centrifugal Blowers** These blowers have air or gases entering in the axial direction and being discharged 90° from the entrance. These blowers have three types of blades: radial or straight blades, forward-curved blades, and backward-curved blades (Figs. 10-73 to 10-75).

Radial blade blowers as seen in Fig. 10-73 are usually used in large-diameter or high-temperature applications. The blades being radial in direction have very low stresses compared to the backward- or forward-curved blades. The rotors have anywhere from 4 to 12 blades and usually operate at low speeds. These fans are used in exhaust work especially for gases at high temperature and with suspensions in the flow stream.

**Forward-Curved Blade Blowers** These blowers discharge the gas at a very high velocity. The pressure supplied by this blower is lower than that produced in the other two blade characteristics. The number of blades in such a rotor can be large—up to 50 blades—and the speed is high—usually 3600 to 1800 rpm in 60-cycle countries and 3000 to 1500 rpm in 50-cycle countries.

**Backward-Curved Blade Blowers** These blowers are used when a higher discharge pressure is needed. It is used over a wide range of applications. Both the forward and backward curved blades do have much higher stresses than the radial blade blower.

The centrifugal blower produces energy in the airstream by the centrifugal force and imparts a velocity to the gas by the blades. Forward-curved blades impart the greatest velocity to the gas. The scroll-shaped volute diffuses the air and creates an increase in the static pressure by reducing the gas velocity. The change in total pressure occurs in the impeller—this is usually a small change. The static pressure is increased in both the impeller and

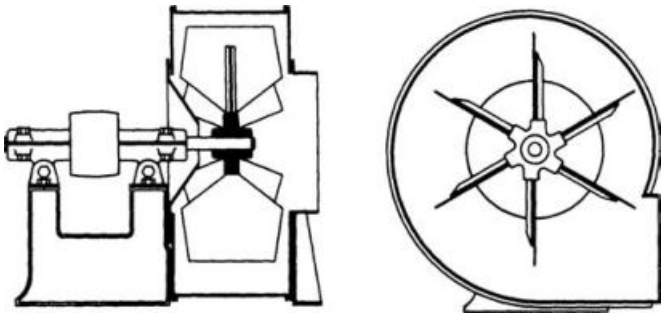

**FIG. 10-73** Straight-blade, or steel-plate, fan.

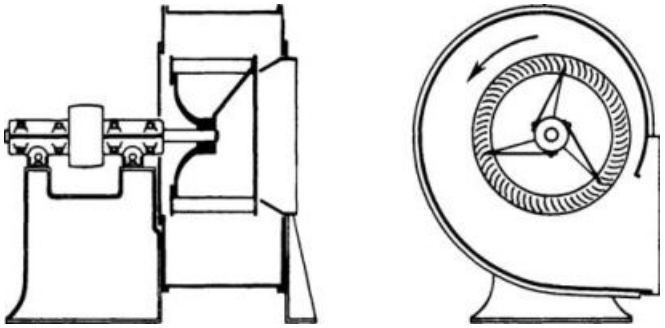

**FIG. 10-74** Forward-curved blade, or "scirocco"-type, fan.

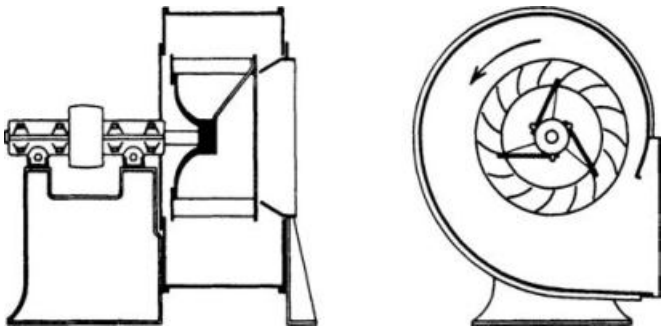

**FIG. 10-75** Backward-curved-blade fan.

the diffuser section. Operating efficiencies of the fan range from 40 to 80 percent. The discharge total pressure is the sum of the static pressure and the velocity head.

The power needed to drive the fan can be computed as follows:

$$\text{Power (kW)} = 2.72 \times 10^{-5} \dot{Q} P \tag{10-81}$$

where $\dot{Q}$ is the fan volume ($m^3/h$) and $P$ is the total discharge pressure in centimeters of water column.

In USCS units,

$$\text{Power (hp)} = 1.57 \times 10^{-4} \dot{Q} P \tag{10-82}$$

where hp is the fan power output, hp; $\dot{Q}$ is the fan volume, $ft^3/min$; and $p$ is the fan operating pressure, inches of water column.

$$\text{Efficiency} = \frac{\text{air power output}}{\text{shaft power input}} \tag{10-83}$$

**Fan Performance** The performance of a centrifugal fan varies with changes in conditions such as temperature, speed, and density of the gas being handled. It is important to keep this in mind in using the catalog data of various fan manufacturers, since such data are usually based on stated

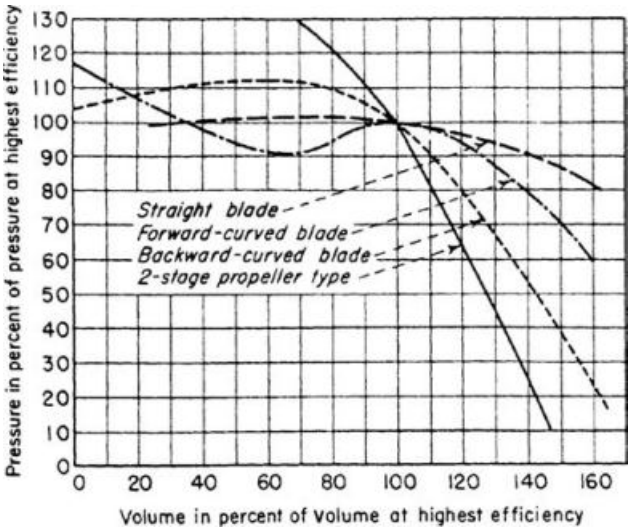

**FIG. 10-76** Approximate characteristic curves of various types of fans.

standard conditions. Corrections must be made for variations from these standards. The usual variations are as follows:

When speed varies, (1) capacity varies directly as the speed ratio, (2) pressure varies as the square of the speed ratio, and (3) horsepower varies as the cube of the speed ratio.

When the temperature of air or gas varies, horsepower and pressure vary inversely as the absolute temperature, with speed and capacity being constant. See Fig. 10-76.

When the density of air or gas varies, horsepower and pressure vary directly as the density, with speed and capacity being constant.

## CONTINUOUS-FLOW COMPRESSORS

Continuous-flow compressors are machines where the flow is continuous, unlike positive-displacement machines where the flow is fluctuating. Continuous-flow compressors are also classified as turbomachines. These types of machines are widely used in the chemical and petroleum industry for many services. They are also used extensively in many other industries such as the iron and steel industry, pipeline boosters, and on offshore platforms for reinjection compressors. Continuous-flow machines are usually much smaller and produce much less vibration than their counterpart, positive-displacement units.

**Centrifugal Compressors** The flow in a centrifugal compressor enters the impeller in an axial direction and exits in a radial direction.

In a typical centrifugal compressor, the fluid is forced through the impeller by rapidly rotating impeller blades. The velocity of the fluid is converted to pressure, partly in the impeller and partly in the stationary diffusers. Most of the velocity leaving the impeller is converted to pressure energy in the diffuser, as shown in Fig. 10-77. It is normal practice to design the compressor so that one-half the pressure rise takes place in the impeller and the other

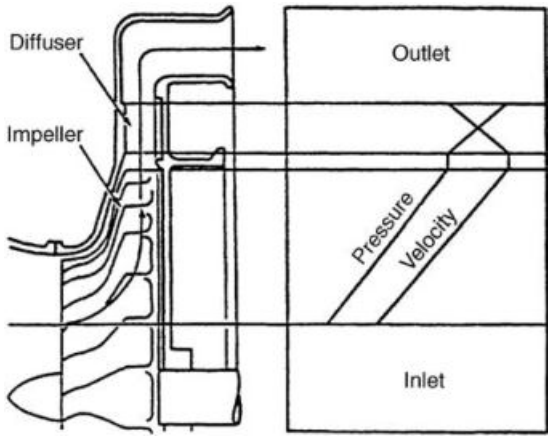

**FIG. 10-77** Pressure and velocity through a centrifugal compressor.

half in the diffuser. The diffuser consists of a vaneless space, a vane that is tangential to the impeller, or a combination of both. These vane passages diverge to convert the velocity head to pressure energy.

Centrifugal compressors in general are used for higher pressure ratios and lower flow rates compared to lower-stage pressure ratios and higher flow rates in axial compressors. The pressure ratio in a single-stage centrifugal compressor varies according to the industry and application. In the petrochemical industry, the single-stage pressure ratio is about 1.2:1. Centrifugal compressors used in the aerospace industry, usually as a compressor of a gas turbine, have pressure ratios from 3:1 to as high as 9:1 per stage.

In the petrochemical industry, the centrifugal compressors consist mainly of casings with multiple stages. In many instances, multiple casings are also used, and to reduce the power required to drive these multiple casings, there are intercoolers between them. Each casing can have up to nine stages. In some cases, intercoolers are also used between single stages of compressor to reduce the power required for compression. These compressors are usually driven by gas turbines, steam turbines, and electric motors. Speed-increasing gears may be used in conjunction with these drivers to obtain the high speeds at which many of these units operate. Rotative speeds as high as 50,000 rpm are not uncommon. Most of the petrochemical units run between 9000 and 15,000 rpm.

The compressor's operating range is between two major regions, as seen in Fig. 10-78, which is a performance map of a centrifugal compressor. These two regions are *surge,* which is the lower flow limit of stable operation, and *choke* or *stonewall,* which is the maximum flow through the compressor at a given operating speed. The centrifugal compressor's operating range between surge and choke is reduced as the pressure ratio per stage is increased or a number of stages are added.

A compressor is said to be in *surge* when the main flow through the compressor reverses its direction. Surge is often symptomized by excessive vibration and a large audible sound. This flow reversal is accompanied with a very violent change in energy, which causes a reversal of the thrust force. The surge process is cyclic, and if it is allowed to cycle for some time, irreparable damage can occur to the compressor. In a centrifugal compressor, surge is usually initiated at the exit of the impeller or at the diffuser entrance for impellers producing a pressure ratio of less than 3:1. For higher pressure ratios, the initiation of surge can occur in the inducer.

A centrifugal compressor impeller can have three types of blades at the exit of the impeller: forward-curved, backward-curved, and radial blades. Forward-curved blades are not often used in a centrifugal compressor's impeller because of the very high-velocity discharge at the compressor that would require conversion of the high velocity to a pressure head in the diffuser, which would be accompanied by high losses. Radial blades are used in impellers of high pressure ratio since the stress levels are minimal. Backward-curved blades give the highest efficiency and the largest operating margin of any of the various types of blades in an impeller. Most centrifugal compressors in the petrochemical industry use backward-curved impellers because of the higher efficiency and larger operating range.

Process compressors have impellers with very low pressure ratio impellers and thus large surge-to-choke margins. The common method of classifying process-type centrifugal compressors is based on the number of impellers and the casing design. Sectionalized casing types have impellers that are usually mounted on the extended motor shaft, and similar sections are bolted together to obtain the desired number of stages. Casing material is either steel or cast iron. These machines require minimum supervision and maintenance and are quite economical in their operating range. The sectionalized casing design is used extensively in supplying air for combustion in ovens and furnaces.

The horizontally split type has casings split horizontally at the midsection and the top. The bottom halves are bolted and doweled together. This design type is preferred for large multistage units. The internal parts such as shaft, impellers, bearings, and seals are readily accessible for inspection and repairs by removing the top half. The casing material is cast iron or cast steel.

Barrel casings are used for high pressures in which the horizontally split joint is inadequate. This type of compressor consists of a barrel into which a compressor bundle of multiple stages is inserted. The bundle is itself a horizontally split casing compressor.

**Compressor Configuration** To properly design a centrifugal compressor, one must know the operating conditions—the type of gas, its pressure, temperature, and molecular weight. One must also know the corrosive properties of the gas so that proper metallurgical selection can be made. Gas fluctuations due to process instabilities must be pinpointed so that the compressor can operate without surging.

Centrifugal compressors for industrial applications have relatively low pressure ratios per stage. This condition is necessary so that the compressors can have a wide operating range while stress levels are kept at a minimum. Because of the low pressure ratios for each stage, a single machine may have a number of stages in one "barrel" to achieve the desired overall pressure ratio. Figure 10-79 shows some of the many configurations. These are some factors to consider when selecting a configuration to meet plant needs:

1. Intercooling between stages can considerably reduce the power consumed.
2. Back-to-back impellers allow for a balanced rotor thrust and minimize overloading of the thrust bearings.
3. Cold inlet or hot discharge at the middle of the case reduces oil-seal and lubrication problems.

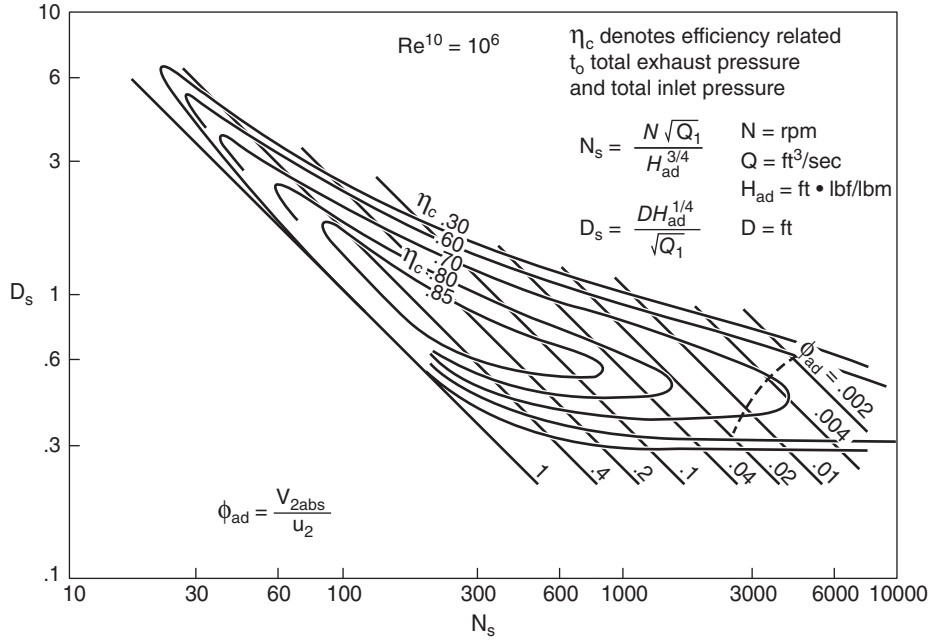

**FIG. 10-78** Centrifugal compressor map. (O. E. Balje, "A Study of Reynolds Number Effects in Turbomachinery," *Journal of Engineering for Power, ASME Trans.,* vol. 86, series A, p. 227.)

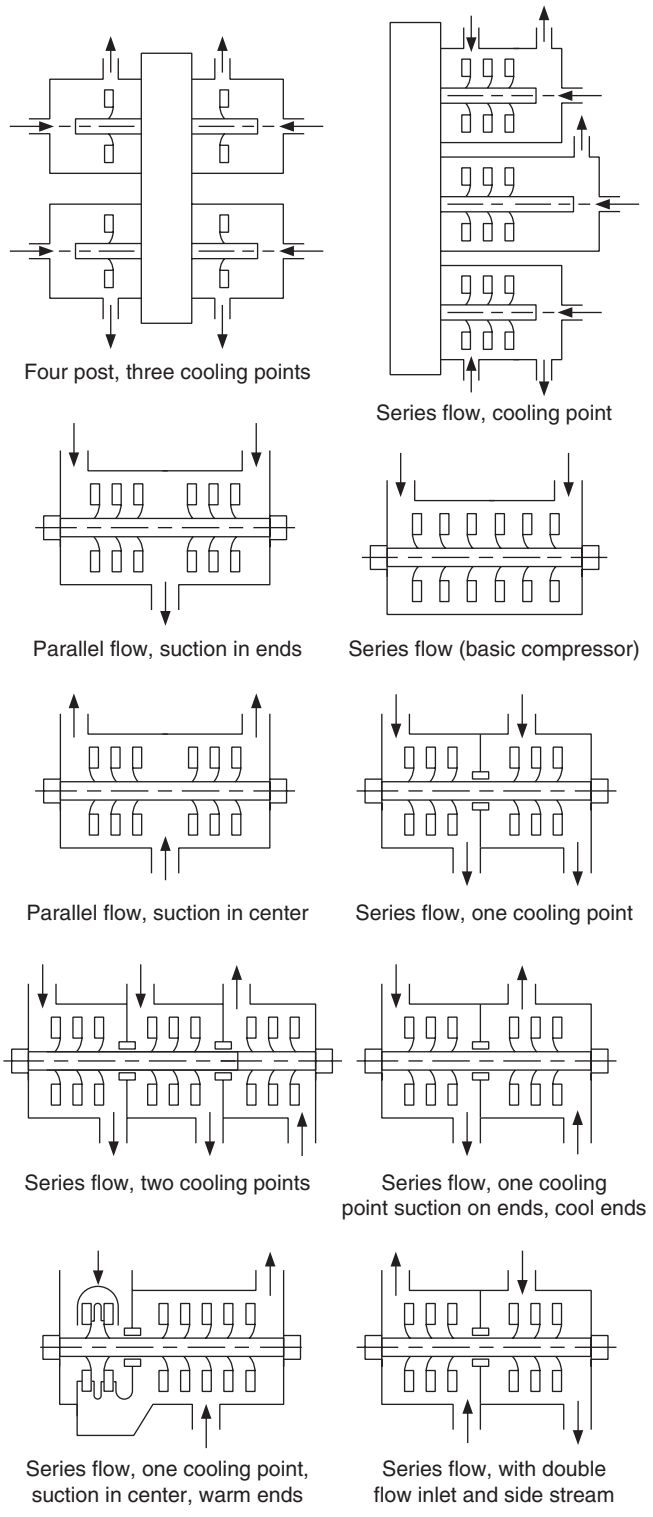

**FIG. 10-79** Various configurations of centrifugal compressors.

4. Single inlet or single discharge reduces external piping problems.
5. Balance planes that are easily accessible in the field can appreciably reduce field-balancing times.
6. Balance piston with no external leakage will greatly reduce wear on the thrust bearings.
7. Hot and cold sections of the case that are adjacent to each other will reduce thermal gradients and thus reduce case distortion.
8. Horizontally split casings are easier to open for inspection than vertically split ones, reducing maintenance time.
9. Overhung rotors present an easier alignment problem because shaft-end alignment is necessary only at the coupling between the compressor and driver.
10. Smaller, high-pressure compressors that do the same job will reduce foundation problems but will have greatly reduced operational range.

**Impeller Fabrication** Centrifugal compressor impellers are either shrouded or unshrouded. Open, shrouded impellers that are mainly used in single-stage applications are made by investment-casting techniques or by three-dimensional milling. Such impellers are used, in most cases, for the high-pressure-ratio stages. The shrouded impeller is commonly used in the process compressor because of its low-pressure-ratio stages. The low tip stresses in this application make it a feasible design. Figure 10-80 shows several fabrication techniques. The most common type of construction is seen in (a) and (b) where the blades are fillet-welded to the hub and shroud. In (b), the welds are full penetration. The disadvantage in this type of construction is the obstruction of the aerodynamic passage. In (c), the blades are partially machined with the covers and then butt-welded down the middle. For backward lean-angled blades, this technique has not been very successful, and there has been difficulty in achieving a smooth contour around the leading edge.

Figure 10-80(d) illustrates a slot-welding technique and is used where blade-passage height is too small (or the backward lean angle too high) to permit conventional fillet welding. In (e), an electron-beam technique is shown. Its major disadvantage is that electron-beam welds should preferably be stressed in tension but, for the configuration of (e), they are in shear. The configurations of (g) through (j) use rivets. Where the rivet heads protrude into the passage, aerodynamic performance is reduced. Riveted impellers were used in the 1960s—they are very rarely used now. Elongation of these rivets occurs at certain critical surge conditions and can lead to major failures.

Materials for fabricating these impellers are usually low-alloy steels, such as AISI 4140 or AISI 4340. AISI 4140 is satisfactory for most applications; AISI 4340 is used for large impellers requiring higher strengths. For corrosive gases, AISI 410 stainless steel (about 12 percent chromium) is used. Monel K-500 is employed in halogen gas atmospheres and oxygen compressors because of its resistance to sparking. Titanium impellers have been applied to chlorine service. Aluminum-alloy impellers have been used in great numbers, especially at lower temperatures (below 300°F). With new developments in aluminum alloys, this range is increasing. Aluminum and titanium are sometimes selected because of their low density. This low density can cause a shift in the critical speed of the rotor, which may be advantageous.

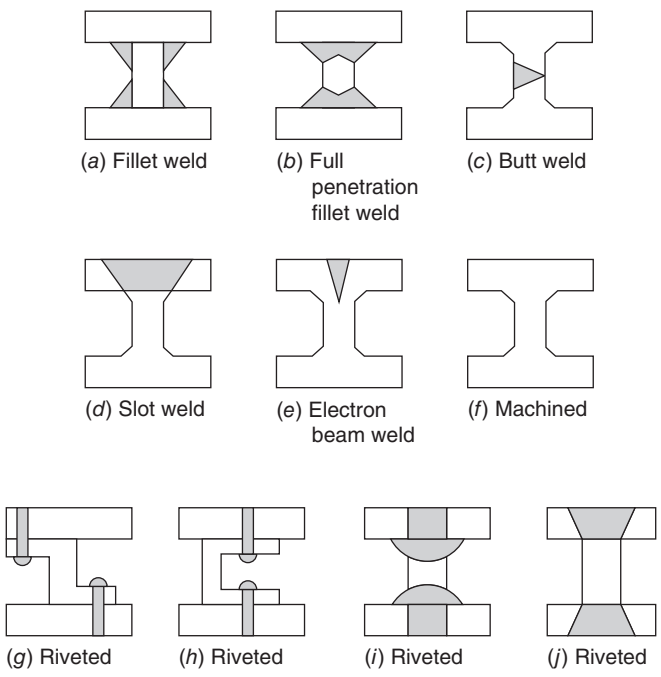

**FIG. 10-80** Several fabrication techniques for centrifugal impellers.

**Axial-Flow Compressors** Axial-flow compressors are used mainly as compressors for gas turbines. They are also used in the steel industry as blast furnace blowers and in the chemical industry for large nitric acid plants. They are mainly used for applications where the head required is low and the flow large.

Figure 10-81 shows a typical axial-flow compressor. The rotating element consists of a single drum to which are attached several rows of decreasing-height blades having airfoil cross sections. Between each rotating blade row is a stationary blade row. All blade angles and areas are designed precisely for a given performance and high efficiency. The use of multiple stages permits overall pressure increases up to 30:1. The efficiency in an axial-flow compressor is higher than that in the centrifugal compressor.

The pressure ratio per casing can be comparable with those of centrifugal equipment, although flow rates are considerably higher for a given casing diameter because of the greater area of the flow path. The pressure ratio per stage is less than that in a centrifugal compressor. The pressure ratio per stage in industrial compressors is between 1:05 and 1:15, and for aero turbines, 1.1 and 1.2.

The axial-flow compressors used in gas turbines vary depending on the type of turbine. The industrial-type gas turbine has an axial-flow compressor of rugged construction. These units have blades that have low aspect ratio ($R$ = blade height/blade chord) with minimum streamline curvation, and the shafts are supported on sleeve-type bearings. The industrial gas turbine compressor has also a lower pressure ratio per stage (stage = rotor + stationary blade), giving a low blade loading. This also gives a larger operating range than its counterpart, the aero axial gas turbine compressor, but considerably less than the centrifugal compressor.

The axial-flow compressors in aero gas turbines are heavily loaded. The aspect ratio of the blades, especially the first few stages, can be as high as 4.0, and the effect of streamline curvature is substantial. The streamline configuration is a function of the annular passage area, the camber and thickness distribution of the blade, and the flow angles at the inlet and outlet of the blades. The shafts on these units are supported on antifriction bearings (roller or ball bearings).

The operation of the axial-flow compressor is a function of the rotational speed of the blades and the turning of the flow in the rotor. The stationary blades (stator) are used to diffuse the flow and convert the velocity increased in the rotor to a pressure increase. One rotor and one stator make up a stage in a compressor. One additional row of fixed blades (inlet guide vanes) is frequently used at the compressor inlet to ensure that air enters the first-stage rotors at the desired angle. In addition to the stators, another diffuser at the exit of the compressor further diffuses the gas and, in the case of gas turbines, controls its velocity entering the combustor. The axial-flow compressor has a much smaller operating range "surge to choke" than its counterpart in the centrifugal compressor. Because of the steep characteristics of the head/flow capacity curve, the surge point is usually within 10 percent of the design point.

The axial-flow compressor has three distinct stall phenomena. Rotating stall and individual blade stall are aerodynamic phenomena. Stall flutter is an aeroelastic phenomenon. Rotating stall (propagating stall) consists of large stall zones covering several blade passages and propagates in the direction of the rotor and at some fraction of rotor speed. The number of stall zones and the propagating rates vary considerably. Rotating stall is the most prevalent type of stall phenomenon. Individual blade stall occurs when all the blades around the compressor annulus stall simultaneously without the occurrence of the stall propagation mechanism. The phenomena of stall flutter are caused by self-excitation of the blade and are aeroelastic. It must be distinguished from classic flutter, since classic flutter is a coupled torsional-flexural vibration that occurs when the freestream velocity over an airfoil section reaches a certain critical velocity. Stall flutter, however, is a phenomenon that occurs due to the stalling of the flow around a blade. Blade stall causes Karman vortices in the airfoil wake. Whenever the frequency of the vortices coincides with the natural frequency of airfoil, flutter will occur. Stall flutter is a major cause of compressor blade failure.

**Positive-Displacement Compressors** Positive-displacement compressors are essentially constant-volume machines with variable discharge pressures. These machines can be divided into two types:

1. Rotary compressors
2. Reciprocating compressors

Many users consider rotary compressors, such as the "Rootes"-type blower, as turbomachines because their behavior in terms of the rotor dynamics is very close to centrifugal and axial-flow machinery. Unlike

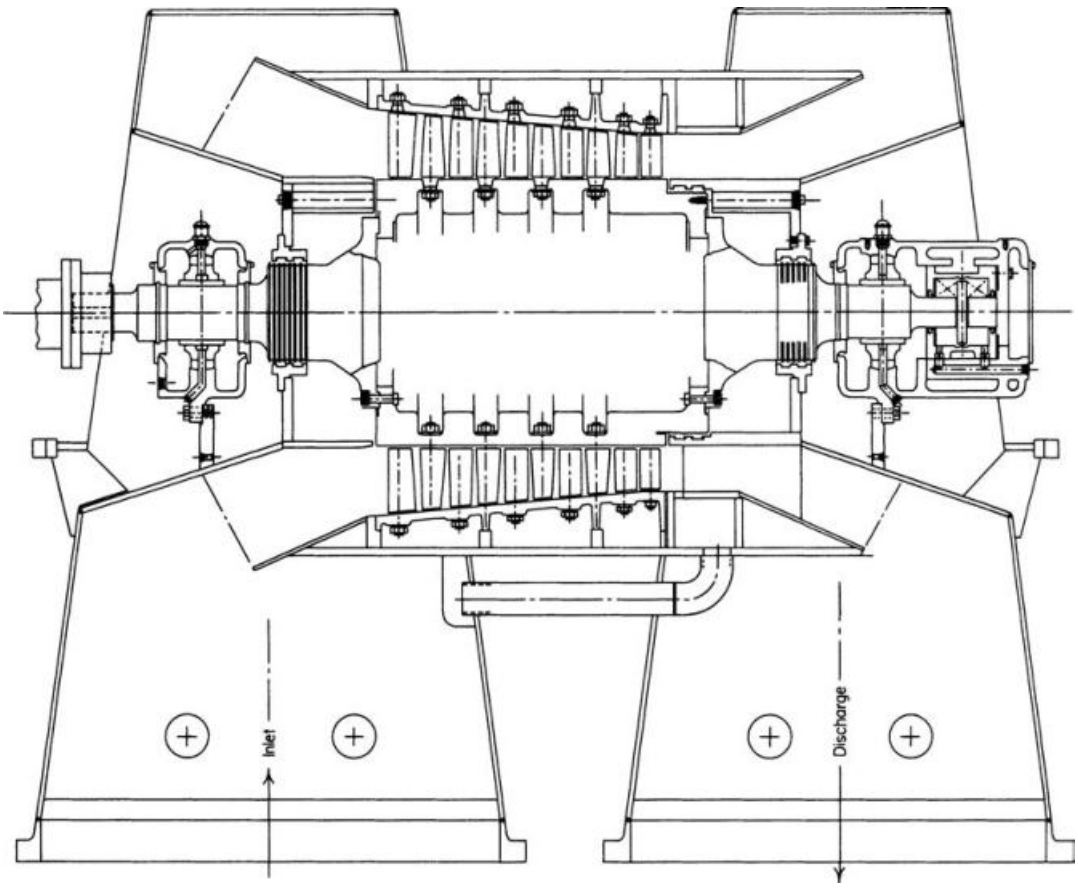

**FIG. 10-81** Axial-flow compressor. (*Courtesy of Allis-Chalmers Corporation.*)

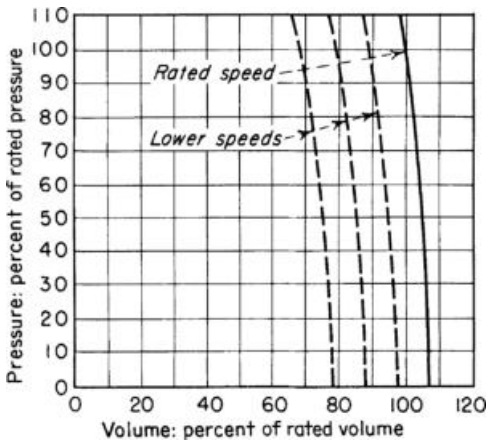

**FIG. 10-82** Approximate performance curves for a rotary positive-displacement compressor. The safety valve in discharge line or bypass must be set to operate at a safe value determined by construction.

the reciprocating machines, the rotary machines do not have a very high vibration problem but, like the reciprocating machines, they are positive-displacement machines.

**Rotary Compressors** Rotary compressors are machines of the positive-displacement type. Such units are essentially constant-volume machines with variable discharge pressure. The volume can be varied only by changing the speed or by bypassing or wasting some of the capacity of the machine. The discharge pressure will vary with the resistance on the discharge side of the system. A characteristic curve typical of the form produced by these rotary units is shown in Fig. 10-82. Rotary compressors are generally classified as of the straight-lobe type, screw type, sliding-vane type, and liquid-piston type.

***Straight-Lobe Type*** This type is illustrated in Fig. 10-83. Such units are available for pressure differentials up to about 83 kPa (12 lbf/in$^2$) and capacities up to $2.549 \times 10^4$ m$^3$/h (15,000 ft$^3$/min). Sometimes multiple units are operated in series to produce higher pressures; individual-stage pressure differentials are limited by the shaft deflection, which must necessarily be kept small to maintain rotor and casing clearance.

***Screw Type*** This type of rotary compressor, as shown in Fig. 10-84, is capable of handling capacities up to about $4.248 \times 10^4$ m$^3$/h (25,000 ft$^3$/min) at pressure ratios of 4:1 and higher. Relatively small-diameter rotors

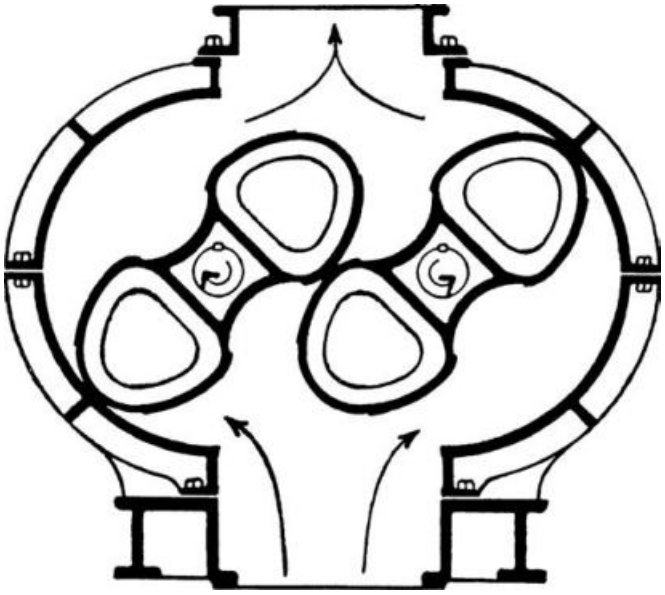

**FIG. 10-83** Two-impeller type of rotary positive-displacement blower.

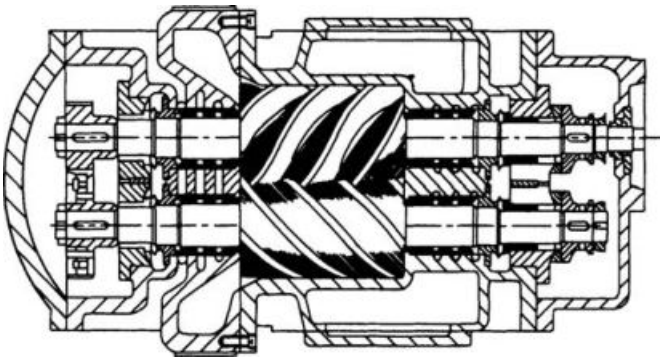

**FIG. 10-84** Screw-type rotary compressor.

allow rotative speeds of several thousand rpm. Unlike the straight-lobe rotary machine, it has male and female rotors whose rotation causes the axial progression of successive sealed cavities. These machines are staged with intercoolers when such an arrangement is advisable. Their high-speed operation usually necessitates the use of suction- and discharge-noise suppressors. The bearings used are sleeve-type bearings. Due to the side pressures experienced, tilting pad bearings are highly recommended.

***Sliding-Vane Type*** This type is illustrated in Fig. 10-85. These units are offered for operating pressures up to 0.86 MPa (125 lbf/in$^2$) and in capacities up to $3.4 \times 10^3$ m$^3$/h (2000 ft$^3$/min). Generally, pressure ratios per stage are limited to 4:1. Lubrication of the vanes is required, and the air or gas stream therefore contains lubricating oil.

***Liquid-Piston Type*** This type is illustrated in Fig. 10-86. These compressors are offered as single-stage units for pressure differentials up to about 0.52 MPa (75 lbf/in$^2$) in the smaller sizes and capacities up to $6.8 \times 10^3$ m$^3$/h (4000 ft$^3$/min) when used with a lower pressure differential. Staging is employed for higher pressure differentials. These units have found wide application as vacuum pumps on wet-vacuum service. Inlet and discharge ports are located in the impeller hub. As the vaned impeller rotates, centrifugal force drives the sealing liquid against the walls of the elliptical housing, causing the air to be successively drawn into the vane cavities and expelled against discharge pressure. The sealing liquid must be externally cooled unless it is used in a once-through system. A separator is usually employed in the discharge line to minimize carryover of entrained liquid. Compressor capacity can be considerably reduced if the gas is highly soluble in the sealing liquid.

The liquid-piston type of compressor has been of particular advantage when hazardous gases are being handled. Because of the gas-liquid contact and because of the much greater liquid specific heat, the gas temperature rise is very small.

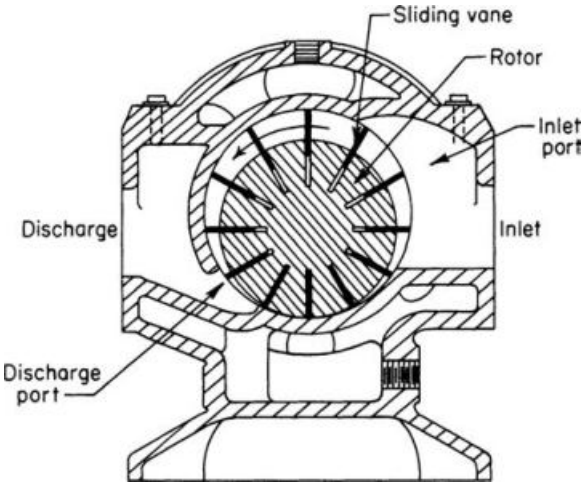

**FIG. 10-85** Sliding-vane type of rotary compressor.

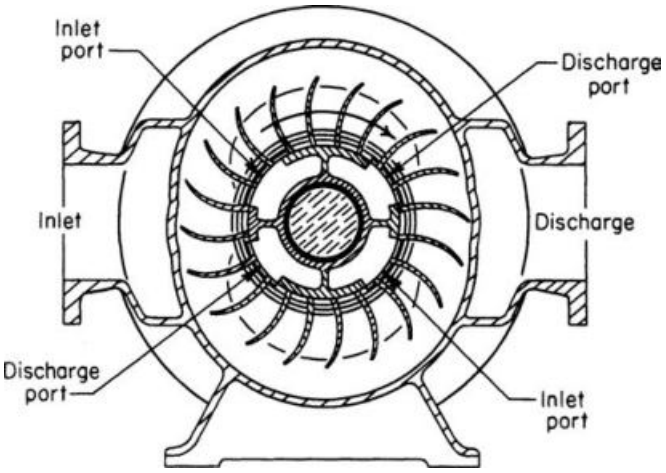

**FIG. 10-86** Liquid-piston type of rotary compressor.

## EJECTORS

An ejector is a simplified type of vacuum pump or compressor that has no pistons, valves, rotors, or other moving parts. Figure 10-87 illustrates a steam-jet ejector. It consists essentially of a nozzle which discharges a high-velocity jet across a suction chamber that is connected to the equipment to be evacuated. The gas is entrained by the steam and carried into a venturi-shaped diffuser which converts the velocity energy to pressure energy. Figure 10-88 shows a large ejector, sometimes called a *booster ejector*, with multiple nozzles. Nozzles are devices in subsonic flow that have a decreasing area and accelerate the flow. They convert pressure energy to velocity energy.

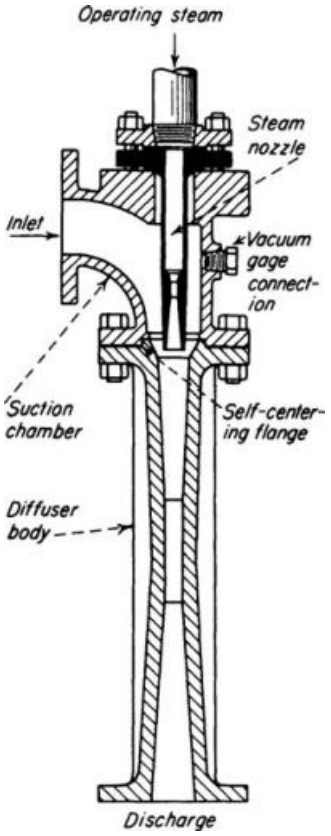

**FIG. 10-87** Typical steam-jet ejector.

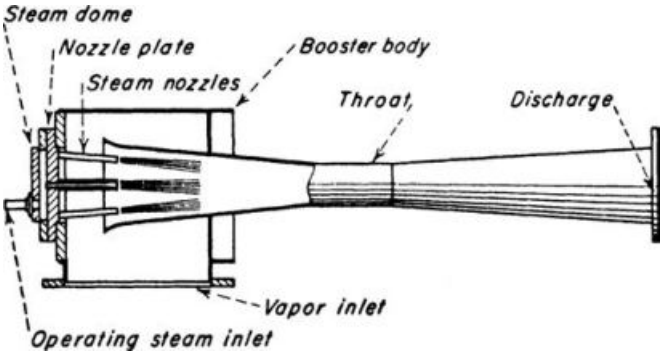

**FIG. 10-88** Booster ejector with multiple steam nozzles.

A minimum area is reached when velocity reaches sonic flow. In supersonic flow, the nozzle is an increasing area device. A diffuser in subsonic flow has an increasing area and converts velocity energy to pressure energy. A diffuser in supersonic flow has a decreasing area.

Two or more ejectors may be connected in series or stages. Also, a number of ejectors may be connected in parallel to handle larger quantities of gas or vapor.

Liquid- or air-cooled condensers are usually used between stages. Liquid-cooled condensers may be of either the direct-contact (barometric) or the surface type. By condensing vapor the load on the following stage is reduced, thus minimizing its size and reducing consumption of motive gas. Likewise, a precondenser installed ahead of an ejector reduces its size and consumption if the suction gas contains vapors that are condensable at the temperature condition available. An *aftercondenser* is frequently used to condense vapors from the final stage, although this does not affect ejector performance.

**Ejector Performance** The performance of any ejector is a function of the area of the motive-gas nozzle and venturi throat, pressure of the motive gas, suction and discharge pressures, and ratios of specific heats, molecular weights, and temperatures. Figure 10-89, based on the assumption of *constant-area mixing,* is useful in evaluating single-stage ejector performance for compression ratios up to 10 and area ratios up to 100 (see Fig. 10-90 for notation).

For example,* assume that it is desired to evacuate air at 2.94 $lb_f/in^2$ with a steam ejector discharging to 14.7 $lb_f/in^2$ with available steam pressure of 100 $lb_f/in^2$. Entering the chart at $p_{03}/p_{0b} = 5.0$, at $p_{0b}/p_{0a} = 2.94/100 = 0.0294$ the optimum area ratio is 12. Proceeding horizontally to the left, $w_b/w_a$ is approximately 0.15 lb of air per 1 lb of steam. This value must be corrected for the temperature and molecular weight differences of the two fluids by Eq. (10-84).

$$w/w_a = w_b/w_a\sqrt{T_{0a}M_b/T_{0b}M_a} \tag{10-84}$$

In addition, there are empirical correction factors which should be applied. Laboratory tests show that for ejectors with constant-area mixing the actual entrainment and compression ratios will be approximately 90 percent of the calculated values and even less at very small values of $p_{0b}/p_{0a}$. This compensates for ignoring wall friction in the mixing section and irreversibilities in the nozzle and diffuser. In theory, each point on a given design curve of Fig. 10-89 is associated with an optimum ejector for prevailing operating conditions. Adjacent points on the same curve represent theoretically different ejectors for the new conditions, the difference being that for each ratio of $p_{0b}/p_{0a}$ there is an optimum area for the exit of the motive-gas nozzle. In practice, however, a segment of a given curve for constant $A_2/A_t$ represents the performance of a single ejector satisfactorily for estimating purposes, provided that the suction pressure lies within 20 to 130 percent of the design suction pressure and the motive pressure within 80 to 120 percent of the design motive pressure. Thus the curves can be used to select an optimum ejector for the design point and to estimate its performance at off-design conditions within the limits noted. Final ejector selection should, of course, be made with the assistance of a manufacturer of such equipment.

**Uses of Ejectors** For the operating range of steam-jet ejectors in vacuum applications, see the subsection Vacuum Systems below.

*All data are given in USCS units since the charts are in these units. Conversion factors to SI units are given on the charts.

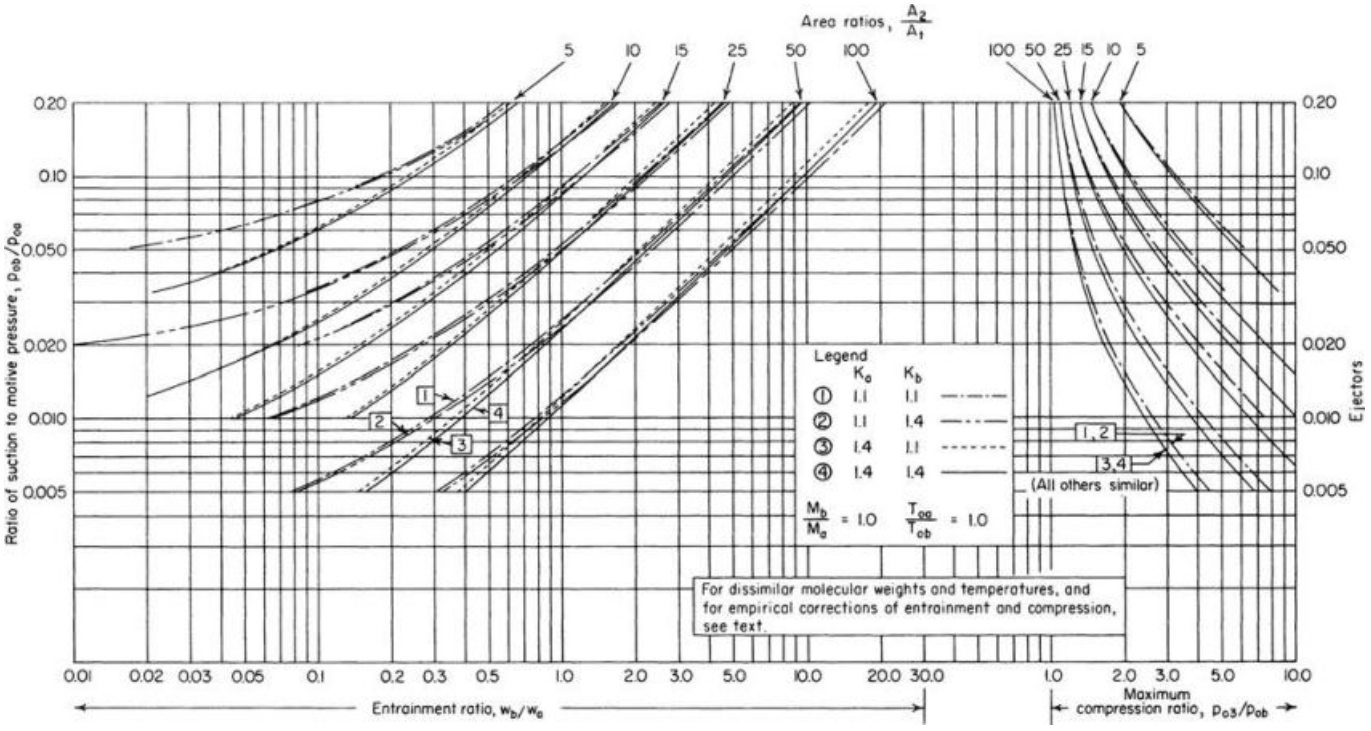

**FIG. 10-89** Design curves for optimum single-stage ejectors. [DeFrate and Hoerl, *Chem. Eng. Prog.* **55,** Symp. Ser. 21, 46 (1959). Reprinted with permission, American Institute of Chemical Engineers. All rights reserved.]

The choice of the most suitable type of ejector for a given application depends upon the following factors:

1. *Steam pressure.* Ejector selection should be based on the minimum pressure in the supply line selected to serve the unit.
2. *Water temperature.* Selection is based on the maximum water temperature.
3. *Suction pressure and temperature.* Overall process requirements should be considered. Selection is usually governed by the minimum suction pressure required (the highest vacuum).
4. *Capacity required.* Again, overall process requirements should be considered, but selection is usually governed by the capacity required at the minimum process pressure.

Ejectors are easy to operate and require little maintenance. Installation costs are low. Since they have no moving parts, they have long life, sustained efficiency, and low maintenance cost. Ejectors are suitable for handling practically any type of gas or vapor. They are also suitable for handling wet or dry mixtures or gases containing sticky or solid matter such as chaff or dust.

Ejectors are available in many materials of construction to suit process requirements. If the gases or vapors are not corrosive, the diffuser is usually constructed of cast iron and the steam nozzle of stainless steel. For more corrosive gases and vapors, many combinations of materials such as bronze, various stainless-steel alloys, and other corrosion-resistant metals, carbon, and glass can be used.

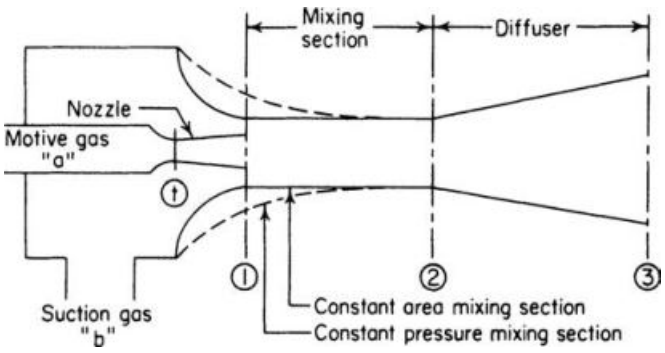

**FIG. 10-90** Notation for Fig. 10-89.

## VACUUM SYSTEMS

Figure 10-91 illustrates the level of vacuum normally required to perform many of the common manufacturing processes. The attainment of various levels is related to available equipment in Fig. 10-92.

**Vacuum Equipment** The equipment shown in Fig. 10-92 has been discussed elsewhere in this section with the exception of the *diffusion pump*. Figure 10-93 depicts a typical design. A liquid of low absolute vapor pressure is boiled in the reservoir. The vapor is ejected at high velocity in a downward direction through multiple jets and is condensed on the walls, which are cooled by the surrounding coils. Molecules of the gas being pumped enter the vapor stream and are driven downward by collisions with the vapor molecules. The gas molecules are removed through the discharge line by a backing pump such as a rotary oil-sealed unit.

Diffusion pumps operate at very low pressures. The ultimate vacuum attainable depends somewhat on the vapor pressure of the pump liquid at the temperature of the condensing surfaces. By providing a cold trap between the diffusion pump and the region being evacuated, pressures as low as $10^{-7}$ mmHg absolute are achieved in this manner. Liquids used for diffusion pumps are mercury and oils of low vapor pressure. Silicone oils have excellent characteristics for this service.

## SEALING OF ROTATING SHAFTS

Seals are very important and often critical components in large rotating machinery especially on high-pressure and high-speed equipment. The principal sealing systems used between the rotor and stationary elements fall into two main categories: (1) noncontacting seals and (2) face seals. These seals are an integral part of the rotating system; they affect the dynamic operating characteristics of the machine. The stiffness and damping factors will be changed by the seal geometry and pressures. In operation the rotating shafts have both radial and axial movement. Therefore, any seal must be flexible and compact to ensure maximum sealing with minimum effect on rotor dynamics.

**Noncontacting Seals** Noncontacting seals are used extensively in gas service in high-speed rotating equipment. These seals have good mechanical reliability and minimum impact on the rotor dynamics of the system. They are not positive sealing. There are two types of noncontacting seals: (1) labyrinth seals and (2) ring seals.

**Labyrinth Seals** The labyrinth is one of the simplest of the many sealing devices. It consists of a series of circumferential strips of metal extending from the shaft or from the bore of the shaft housing to form a cascade

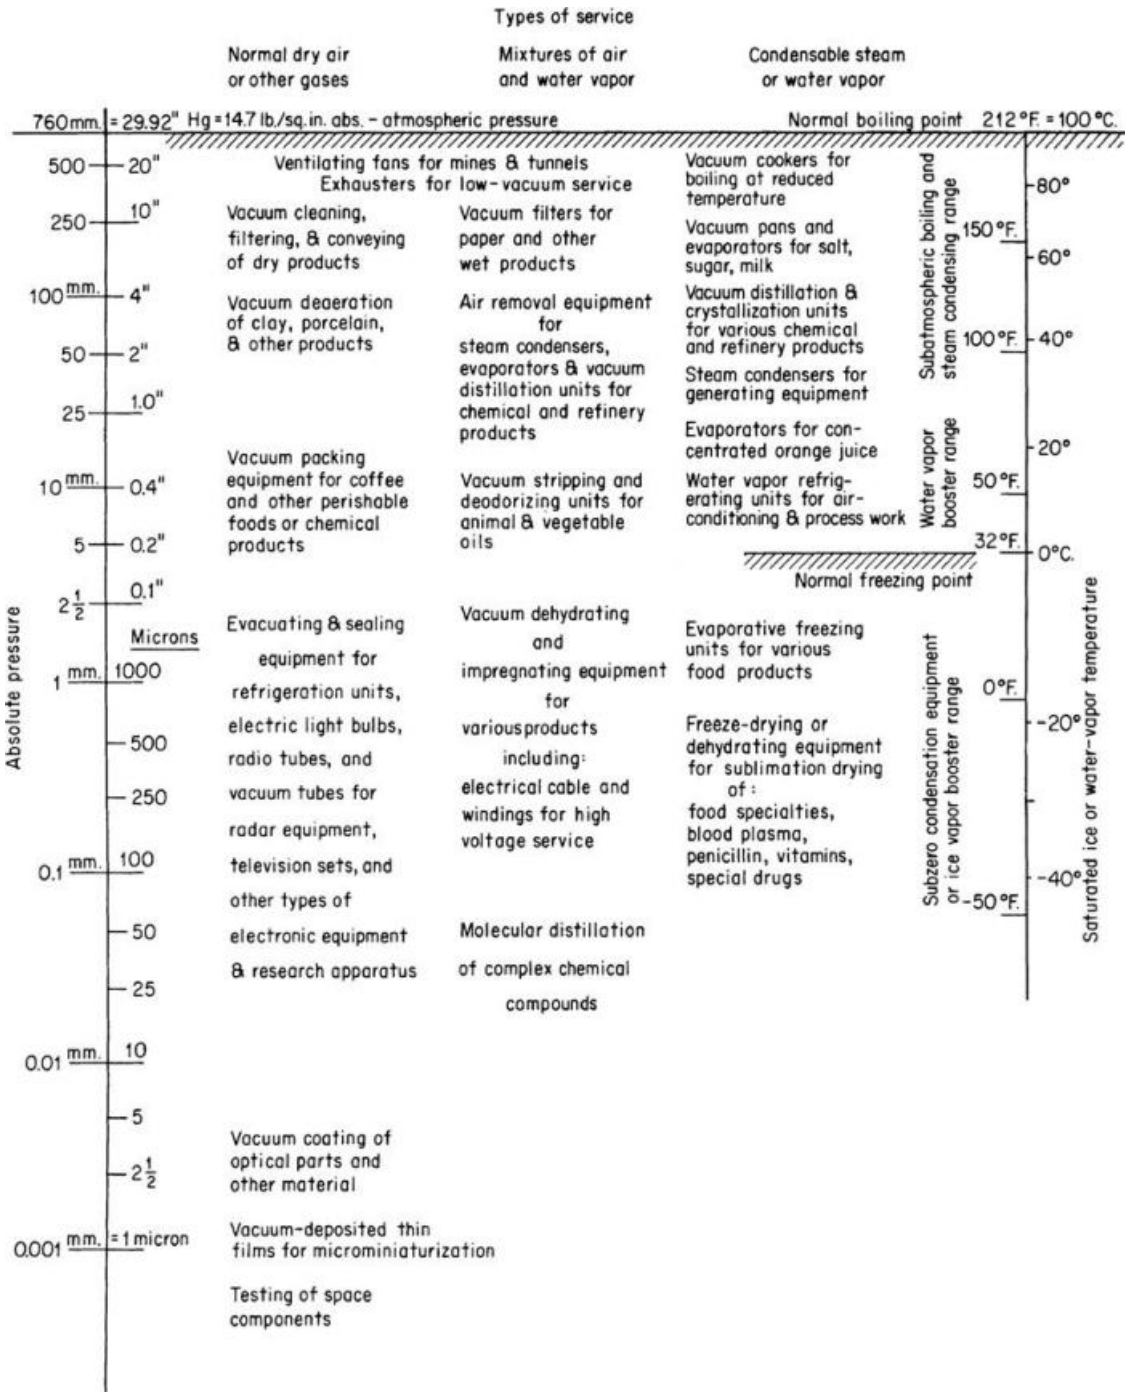

**FIG. 10-91** Vacuum levels normally required to perform common manufacturing processes. (*Courtesy of* Compressed Air *magazine.*)

of annular orifices. Labyrinth seal leakage is greater than that of clearance bushings, contact seals, or film riding seals.

The major advantages of labyrinth seals are their simplicity, reliability, tolerance to dirt, system adaptability, very low shaft power consumption, material selection flexibility, minimal effect on rotor dynamics, back-diffusion reduction, integration of pressure, lack of pressure limitations, and tolerance to gross thermal variations. The major disadvantages are the high leakage; loss of machine efficiency; increased buffering costs; tolerance to ingestion of particulates with resulting damage to other critical items such as bearings; the possibility of the cavity clogging due to low gas velocities or back diffusion; and the inability to provide a simple seal system that meets OSHA or EPA standards. Because of some of the foregoing disadvantages, many machines are being converted to other types of seals.

Labyrinth seals are simple to manufacture and can be made from conventional materials. Early designs of labyrinth seals used knife-edge seals and relatively large chambers or pockets between the knives. These relatively long knives are easily subject to damage. The modern, more functional, and more reliable labyrinth seals consist of sturdy, closely spaced lands. Some labyrinth seals are shown in Fig. 10-94. Figure 10-94*a* is the simplest form of the seal. Figure 10-94*b* shows a grooved seal; it is more difficult to manufacture but produces a tighter seal. Figure 10-94*c* and Fig. 10-94*d* are rotating labyrinth-type seals. Figure 10-94*e* shows a simple labyrinth seal with a buffered gas for which pressure must be maintained above the process gas pressure and the outlet pressure (which can be greater than or less than the atmospheric pressure). The buffered gas produces a fluid barrier to the process gas. The eductor sucks gas from the vent near the atmospheric end.

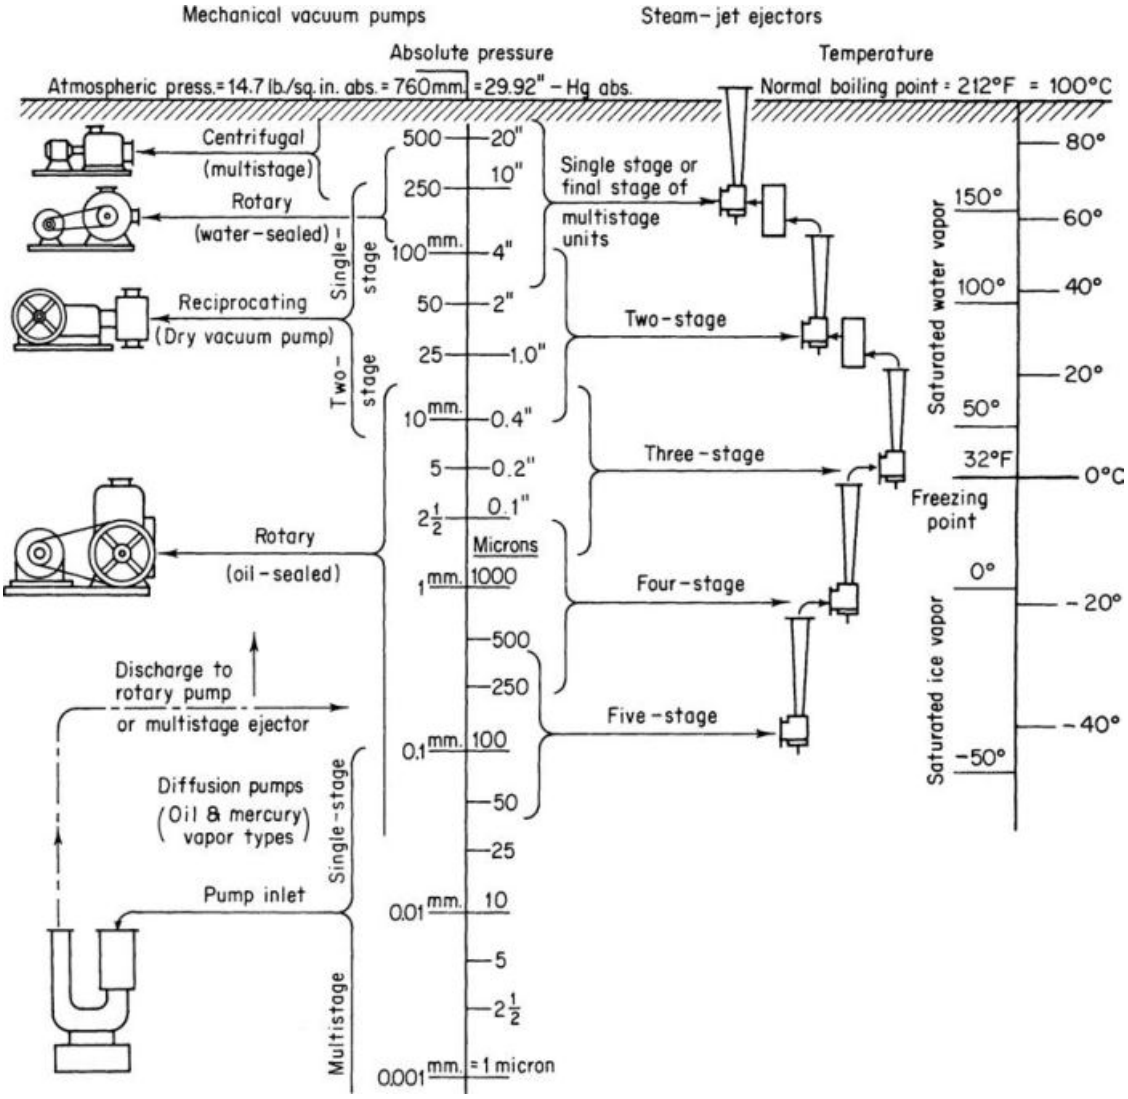

**FIG. 10-92** Vacuum levels attainable with various types of equipment. (*Courtesy of* Compressed Air *magazine.*)

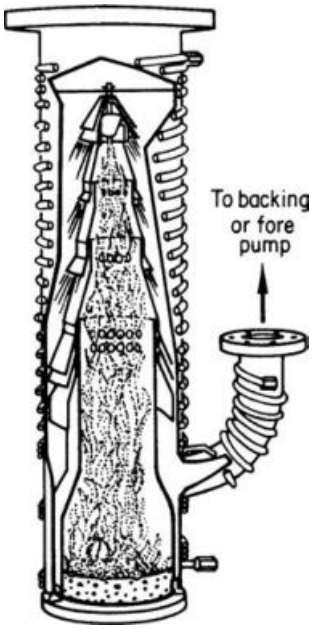

**FIG. 10-93** Typical diffusion pump. (*Courtesy of* Compressed Air *magazine.*)

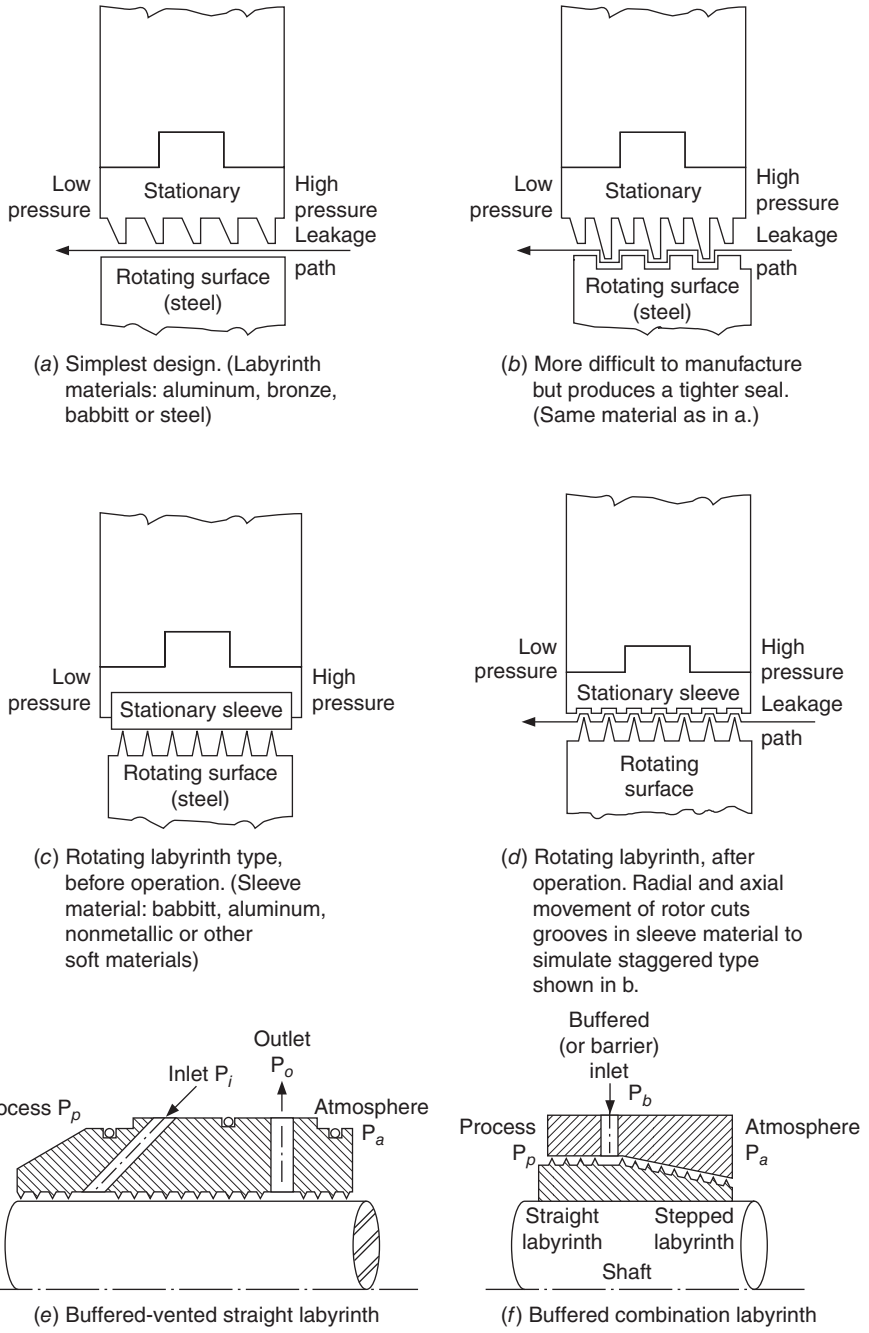
Figure 10-94*f* shows a buffered, stepped labyrinth. The step labyrinth gives a tighter seal. The matching stationary seal is usually manufactured from soft materials such as babbitt or bronze, while the stationary or rotating labyrinth lands are made from steel. This composition enables the seal to be assembled with minimal clearance. The lands can therefore cut into the softer materials to provide the necessary running clearances for adjusting to the dynamic excursions of the rotor. To maintain maximum sealing efficiency, it is essential that the labyrinth lands maintain sharp edges in the direction of the flow.

Leakage past these labyrinths is approximately inversely proportional to the square root of the number of labyrinth lands. This translates to the following relationship if leakage is to be cut in half in a four-labyrinth seal: The number of labyrinths would have to be increased to 16. The Elgi leakage formula can be modified and written as

$$m_\ell = AK\left[\frac{(g/V_o)(P_o - P_n)}{n + \ln(P_n/P_o)}\right]^{1/2} \tag{10-85}$$

where $m_\ell$ = leakage
$A$ = leakage area of single throttling
$K$ = labyrinth constant ($K = 0.9$ for straight labyrinths, $K = 0.75$ for staggered labyrinths)
$P_o$ = absolute pressure before the labyrinth
$P_n$ = absolute pressure after the last labyrinth
$V_o$ = specific volume before the labyrinth
$n$ = number of lands



(*a*) Simplest design. (Labyrinth materials: aluminum, bronze, babbitt or steel)

(*b*) More difficult to manufacture but produces a tighter seal. (Same material as in a.)

(*c*) Rotating labyrinth type, before operation. (Sleeve material: babbitt, aluminum, nonmetallic or other soft materials)

(*d*) Rotating labyrinth, after operation. Radial and axial movement of rotor cuts grooves in sleeve material to simulate staggered type shown in b.

(*e*) Buffered-vented straight labyrinth

(*f*) Buffered combination labyrinth

**FIG. 10-94** Various configurations of labyrinth seals.

The leakage of a labyrinth seal can be kept to a minimum by providing (1) minimum clearance between the seal lands and the seal sleeve, (2) sharp edges on the lands to reduce the flow discharge coefficient, and (3) grooves or steps in the flow path for reducing dynamic head carryover from stage to stage.

The labyrinth sleeve can be flexibly mounted to permit radial motion for self-aligning effects. In practice, a radial clearance under 0.008 is difficult to achieve.

**Ring Seals** The restrictive ring seal is essentially a series of sleeves in which the bores form a small clearance around the shaft. Thus, the leakage is limited by the flow resistance in the restricted area and controlled by the laminar or turbulent friction. There are two types of ring seals: (1) fixed seal rings and (2) floating seal rings. The floating rings permit a much smaller leakage; they can be either the segmented type, as shown in Fig. 10-95*a*, or the rigid type, as shown in Fig. 10-95*b*.

**Fixed Seal Rings** The fixed seal ring consists of a long sleeve affixed to a housing in which the shaft rotates with small clearances. Long assemblies must be used to keep leakage within a reasonable limit. Long seal assemblies aggravate alignment and rubbing problems, thus requiring shafts to operate below their capacity. The fixed bushing seal operates with appreciable eccentricity and, combined with large clearances, produces large leakages, thus making this kind of seal impractical where leakage is undesirable.

**Floating Seal Rings** Clearance seals that are free to move in a radial direction are known as *floating seals*. The floating characteristics permit them to move freely, thus avoiding severe rubs. Due to differential thermal expansion between the shaft and bushing, the bushings should be made of material with a higher coefficient of thermal expansion. This is achieved by shrinking the carbon into a metallic retaining ring with a coefficient of expansion that equals or exceeds that of the shaft material. It is advisable in high-shearing applications to lock the bushings against rotation.

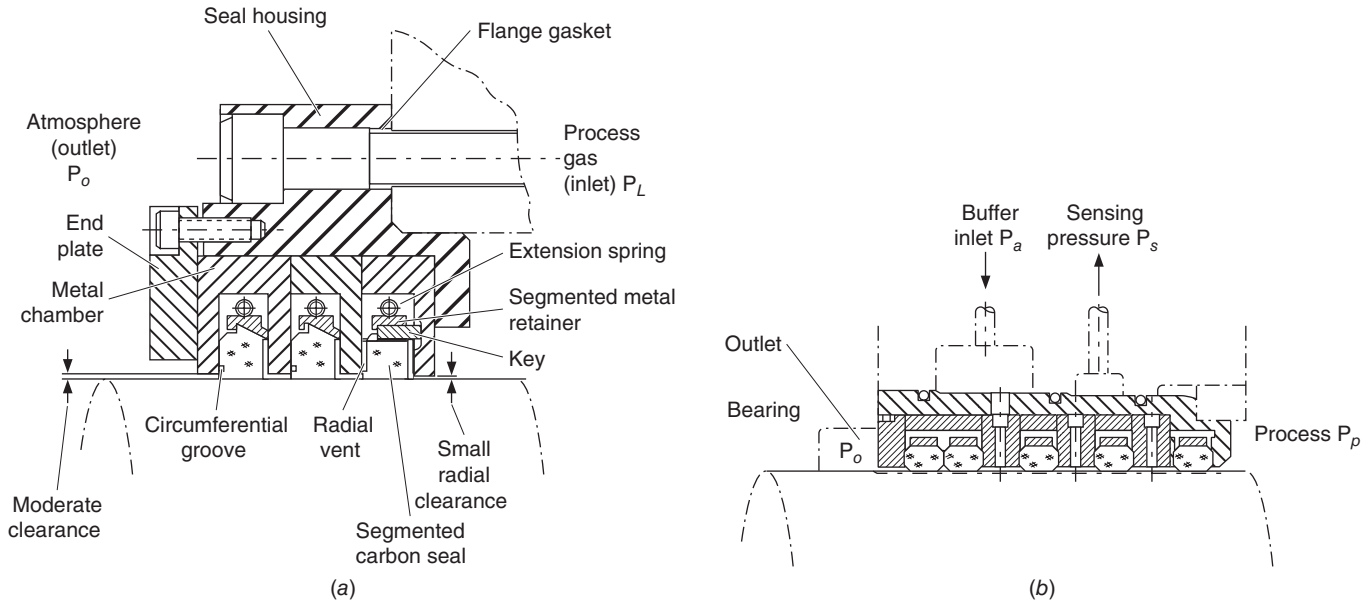


**FIG. 10-95** Floating-type restrictive ring seal.

Buildup of dirt and other foreign material lodged between the seal ring and seat will create an excessive spin and damage on the floating seal ring unit. It is therefore improper to use soft material such as babbitt and silver as seal rings.

**Packing Seal** A common type of rotating shaft seal consists of packing composed of fibers which are first woven, twisted, or braided into strands and then formed into coils, spirals, or rings. To ensure initial lubrication and to facilitate installation, the basic materials are often impregnated. Common materials are braided and twisted rubber and duck, flax, jute, and metallic braids. The so-called plastic packings can be made up with varying amounts of fiber combined with a binder and lubricant for high-speed applications. The maximum temperatures that base materials of packings withstand and still give good service are as follows:

| | °C | °F |
|---|---|---|
| Flax | 38 | 100 |
| Cotton | 93 | 200 |
| Duck and rubber | 149 | 300 |
| Rubber | 177 | 350 |
| Metallic (lead-based) | 218 | 425 |
| Metallic (aluminum-based) | 552 | 1025 |
| Metallic (copper-based) | 829 | 1525 |

Packing may not provide a completely leak-free seal. With shaft surface speeds less than approximately 2.5 m/s (500 ft/min), the packing may be adjusted to seal completely. However, for higher speeds some leakage is required for lubrication, friction reduction, and cooling.

***Application of Packing*** Coils and spirals are cut to form closed or nearly closed rings in the stuffing box. Clearance between ends should be sufficient to allow for fitting and possible expansion due to increased temperature or liquid absorption of the packing while in operation.

The correct form of the ring joint depends on materials and service requirements. Braided and flexible metallic packings usually have butt or square joints (Fig. 10-96*a*). With other packing material, service experience indicates that rings cut with bevel or skive joints (Fig. 10-96*b*) are more satisfactory. A slight advantage of the bevel joint over the butt joint is that the bevel permits a certain amount of sliding action, thus absorbing a portion of ring expansion.

In the manufacture of packings, the proper grade and type of *lubricant* are usually impregnated for each service for which the packing is recommended. However, it may be desirable to replenish the lubricant during the normal life of the packing. Lack of lubrication causes packing to become hard and lose its resiliency, thus increasing friction, shortening packing life, and increasing operating costs.

An effective auxiliary device frequently used with packing and rotary shafts is the *seal cage* (or *lantern ring*), shown in Fig. 10-97. The seal cage provides an annulus around the shaft for the introduction of a lubricant, oil, grease, etc. The seal cage is also used to introduce liquid for cooling, to prevent the entrance of atmospheric air, or to prevent the infiltration of abrasives from the process liquid.

The chief advantage of packing over other types of seals is the ease with which it can be adjusted or replaced. Most equipment is designed so that disassembly of major components is not required to remove or add packing rings. The major disadvantages of a packing-type seal are (1) its short life, (2) the requirement for frequent adjustment, and (3) the need for some leakage to provide lubrication and cooling.

**Mechanical Face Seals** This type of seal forms a running seal between flat precision-finished surfaces. It is an excellent seal against leakages. The sealing surfaces are planes perpendicular to the rotating shaft, and the forces that hold the contact faces are parallel to the shaft axis. For a seal to function properly, there are four sealing points:

1. Stuffing box face
2. Leakage down the shaft
3. Mating ring in the gland plate
4. Dynamic faces

**Mechanical Seal Selection** Many factors govern the selection of seals. These factors apply to any type of seal:

1. Product
2. Seal environment
3. Seal arrangement
4. Equipment
5. Secondary packing
6. Seal face combinations
7. Seal gland plate
8. Main seal body

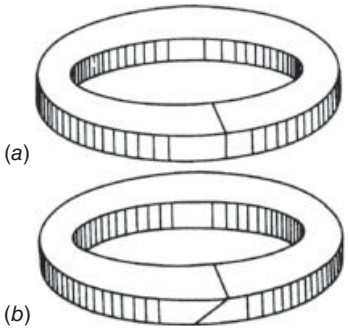

**FIG. 10-96** Butt (*a*) and skive (*b*) joints for compression packing rings.

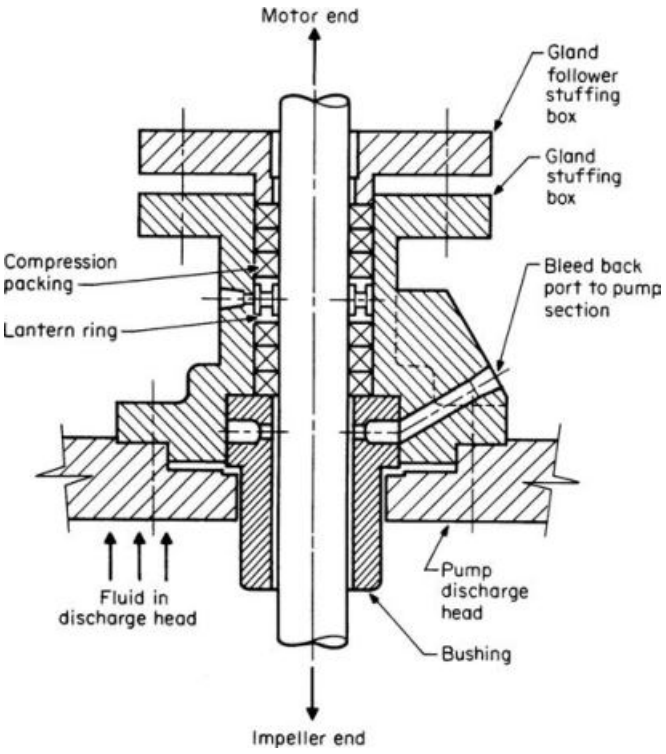

**FIG. 10-97** Seal cage or lantern ring. (*Courtesy of Crane Packing Co.*)

***Product*** Physical and chemical properties of the liquid or gas being sealed place constraints on the type of material, design, and arrangement of the seal.

*Pressure.* Pressure affects the choice of material and whether balanced or unbalanced seal design can be used. Most unbalanced seals are good up to 100 psig stuffing box pressure. Over 100 psig, balanced seals should be used.

*Temperature.* The temperature of the liquid being pumped is important because it affects the seal face material selection as well as the wear life of the seal face.

*Lubricity.* In any mechanical seal design, there is rubbing motion between the dynamic seal faces. This rubbing motion is often lubricated by the fluid being pumped. Most seal manufacturers limit the speed of their seals to 90 ft/s (30 m/s). This is primarily due to centrifugal forces acting on the seal, which tend to restrict the seal's axial flexibility.

*Abrasion.* If there are entrained solids in the liquid, it is desirable to have a flushed single inside type with a face combination of very hard material.

*Corrosion.* This affects the type of seal body: what spring material, what face material, and what type of elastomer or gasket material. The corrosion rate will affect the decision of whether to use a single- or multiple-spring design because the spring can usually tolerate a greater amount of corrosion without weakening appreciably.

***Seal Environment*** The design of the seal environment is based on the product and the four general parameters that regulate it:

1. Pressure control
2. Temperature control
3. Fluid replacement
4. Atmospheric air elimination

***Seal Arrangement*** There are four types of seal arrangements:

1. Double seals are standard with toxic and lethal products, but maintenance problems and seal design contribute to poor reliability. The double face-to-face seal may be a better solution.
2. Do not use a double seal in dirty service—the inside seal will hang up.
3. API standards for balanced and unbalanced seals are good guidelines; too low a pressure for a balanced seal may encourage face liftoff.
4. Arrangement of the seal will determine its success more than the vendor. Over 100 arrangements are available.

***Equipment*** The geometry of the pump or compressor is very important in seal effectiveness. Different pumps with the same shaft diameter and total differential head can present different sealing problems.

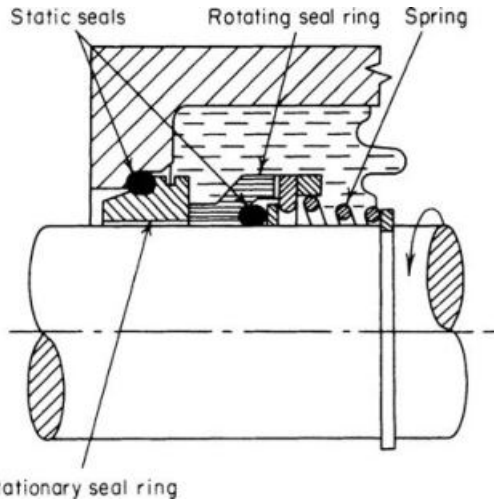

**FIG. 10-98** Mechanical-seal components.

***Secondary Packing*** Much greater emphasis should be placed on secondary packing, especially if Teflon is used. A wide variation in performance is seen between various seal vendors, and depending on the seal arrangement there can be differences in mating ring packing.

***Seal Face Combinations*** The dynamics of seal faces are better understood today. Seal face combinations have come a long way in the past 8 to 10 years. Stellite is being phased out of the petroleum and petrochemical applications. Better grades of ceramic are available, the cost of tungsten has come down, and relapping of tungsten is available near most industrial areas. Silicon carbide is being used in abrasive service.

***Seal Gland Plate*** The seal gland plate is caught in between the pump vendor and the seal vendor. Special glands should be furnished by seal vendors, especially if they require heating, quenching, and drain with a floating-throat bushing. Gland designs are complex and may have to be revisited, especially if seals are changed.

***Main Seal Body*** The term *seal body* makes reference to all rotating parts on a pusher seal, excluding the shaft packing and seal ring. In many cases it is the chief reason to avoid a particular design for a particular service.

Basically, most mechanical seals have the following components, as seen in Fig. 10-98.

1. Rotating seal ring
2. Stationary seal ring
3. Spring devices to provide pressure
4. Static seals

A loading device such as a spring is needed to ensure that the sealing surfaces are kept closed in the event of loss of hydraulic pressure. The amount of the load on the sealing area is determined by the degree of "seal balance." Figure 10-99 shows what seal balance means. A completely balanced seal

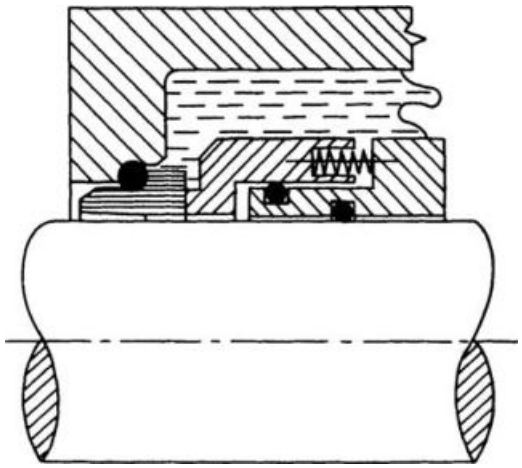

**FIG. 10-99** Balanced internal mechanical seal.

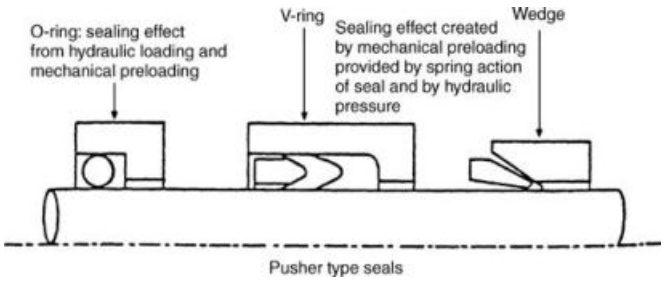

**FIG. 10-100** Various types of shaft-sealing elements.

exists when the only force exerted on the sealing surfaces is the spring force; i.e., hydraulic pressure does not act on the sealing surface. The type of spring depends on the space available, loading characteristics, and seal environment. Based on these considerations, either a single spring or multiple springs can be used. In small axial space, Belleville springs, finger washers, or curved washers can be used.

Shaft-sealing elements can be split up into two groups. The first type may be called *pusher-type* seals and includes the O-ring, V-ring, U-cup, and wedge configurations. Figure 10-100 shows some typical pusher-type seals. The second type is the bellow-type seals, which differ from the pusher-type seals in that they form a static seal between themselves and the shaft.

**Internal and External Seals** Mechanical seals are classified broadly as internal or external. *Internal seals* (Fig. 10-101) are installed with all seal components exposed to the fluid sealed. The advantages of this arrangement are (1) the ability to seal against high pressure, since the hydrostatic force is normally in the same direction as the spring force; (2) protection of seal parts from external mechanical damage; and (3) reduction in the shaft length required.

For high-pressure installations, it is possible to balance partially or fully the hydrostatic force on the rotating member of an internal seal by using a stepped shaft or shaft sleeve (Fig. 10-99). This method of relieving face pressure is an effective way of decreasing power consumption and extending seal life.

When abrasive solids are present and it is not permissible to introduce appreciable quantities of a secondary flushing fluid into the process, double internal seals are sometimes used (Fig. 10-102). Both sealing faces are protected by the flushing fluid injected between them even though the inward flow is negligible.

*External seals* (Fig. 10-103) are installed with all seal components protected from the process fluid. The advantages of this arrangement are that (1) fewer critical materials of construction are required, (2) the installation and setting are somewhat simpler because of the exposed position of the parts, and (3) stuffing-box size is not a limiting factor. Hydraulic balancing is accomplished by proper proportioning of the seal face and secondary seal diameters.

**Throttle Bushings** These bushings (Fig. 10-104) are commonly used with single internal or external seals when solids are present in the fluid and the inflow of a flushing fluid is not objectionable. These close-clearance

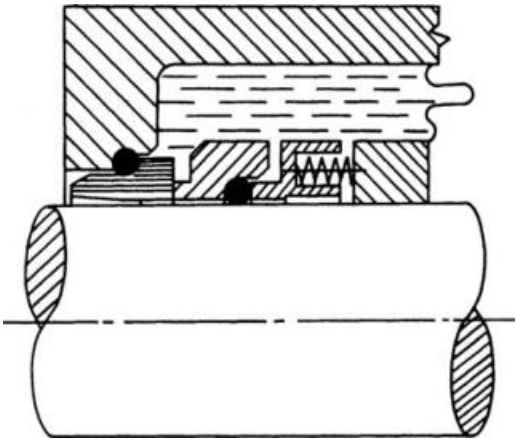

**FIG. 10-101** Internal mechanical seal.

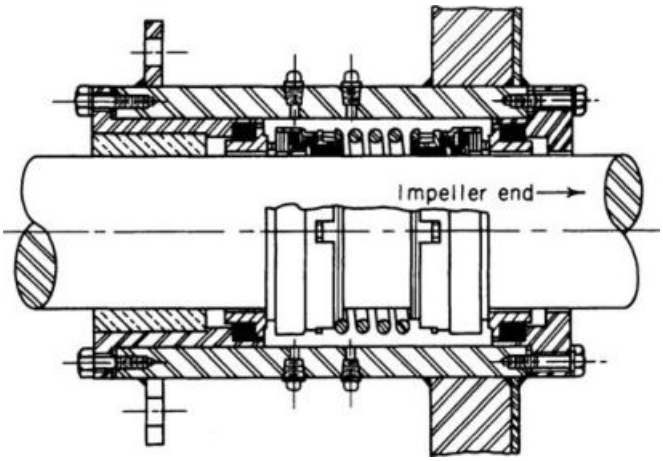

**FIG. 10-102** Internal bellows-type double mechanical seal.

bushings are intended to serve as flow restrictions through which the maintenance of a small inward flow of flushing fluid prevents the entrance of a process fluid into the stuffing box.

A typical complex seal utilizes both the noncontact and mechanical aspects of sealing. Figure 10-105 shows such a seal with its two major elements. This type of seal will normally have buffering via a labyrinth seal and a positive shutdown device. For shutdown, the carbon ring is tightly sandwiched between the rotating seal ring and the stationary sleeve, with gas pressure to prevent gas from leaking out when no oil pressure is available.

In operation the seal oil pressure is about 30 to 50 psi over the process gas pressure. The high-pressure oil enters the top and completely fills the seal cavity. A small percentage is forced across the carbon ring seal faces. The rotative speed of the carbon ring can be anywhere between zero and full rotational speed. Oil crossing the seal faces contacts the process gas and therefore is "contaminated oil." The contaminated oil leaves through the contaminated oil drain to a degassifier for purification. The majority of the oil flows through the uncontaminated seal oil drain.

**Materials** Springs and other metallic components are available in a wide variety of alloys and are usually selected on the basis of temperature and corrosion conditions. The use of a particular mechanical seal is frequently restricted by the temperature limitations of the organic materials used in the static seals. Most elastomers are limited to about 121°C (250°F). Teflon will withstand temperatures of 260°C (500°F) but softens appreciably above 204°C (400°F). Glass-filled Teflon is dimensionally stable up to 232 to 260°C (450 to 500°F).

One of the most common elements used for seal faces is carbon. Although compatible with most process media, carbon is affected by strong oxidizing agents, including fuming nitric acid, hydrogen chloride, and high-temperature air [above 316°C (600°F)]. Normal mating-face materials for carbon are tungsten or chromium carbide, hard steel, stainless steel, or one of the cast irons.

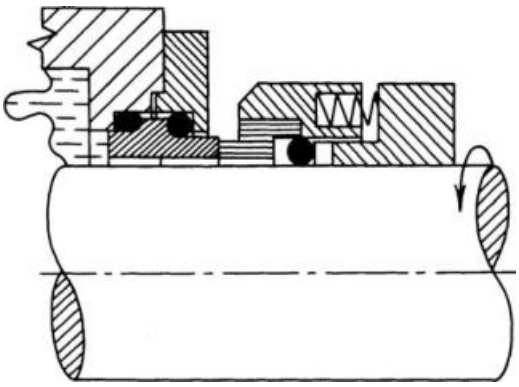

**FIG. 10-103** External mechanical seal.

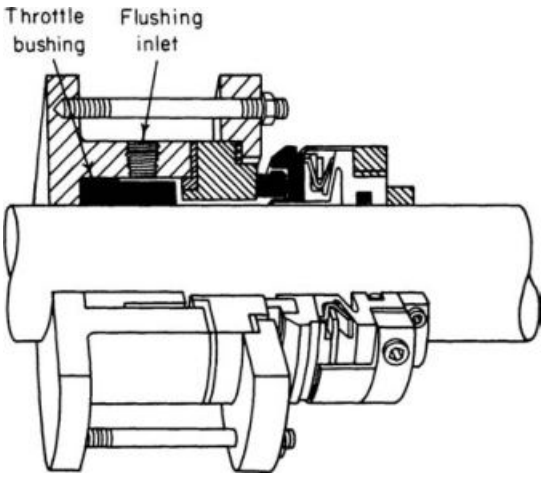

**FIG. 10-104** External mechanical seal and throttle bushing.

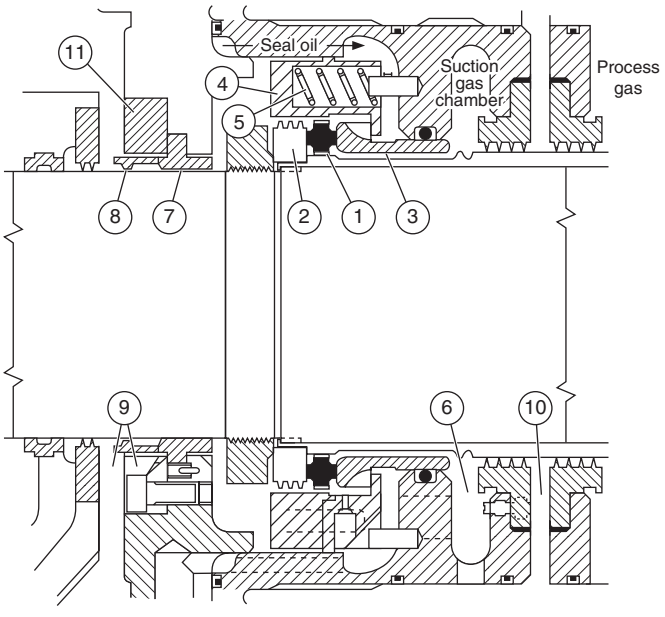
Other sealing-face combinations that have been satisfactory in corrosive service are carbide against carbide, ceramic against ceramic, ceramic against carbon, and carbon against glass. The ceramics have also been mated with the various hard-facing alloys. When one is selecting seal materials, the possibility of galvanic corrosion must also be considered.

## BEARINGS

Many factors enter into the selection of the proper design for bearings. These are some of the factors:

1. Shaft speed range
2. Maximum shaft misalignment that can be tolerated
3. Critical speed analysis and the influence of bearing stiffness on this analysis
4. Loading of the compressor impellers



1. Rotating carbon ring
2. Rotating seal ring
3. Stationary sleeve
4. Spring retainer
5. Spring
6. Gas and contaminated oil drain
7. Floating babbitt-faced steel ring
8. Seal wiper ring
9. Seal oil drain line
10. Buffer gas injection port
11. Bypass orifice

**FIG. 10-105** Mechanical contact shaft seal.

5. Oil temperatures and viscosity
6. Foundation stiffness
7. Axial movement that can be tolerated
8. Type of lubrication system and its contamination
9. Maximum vibration levels that can be tolerated

**Types of Bearings** Figure 10-106 shows a number of different types of journal bearings. A description of a few of the pertinent types of journal bearings is given here.

1. *Plain journal.* The bearing is bored with equal amounts of clearance (on the order of 0.0015 to 0.002 in per inch of journal diameter) between the journal and bearing.

2. *Circumferential grooved bearing.* Normally the oil groove is one-half the bearing length. This configuration provides better cooling but reduces load capacity by dividing the bearing into two parts.

3. *Cylindrical bore bearings.* This is another common bearing type used in turbines. It has a split construction with two axial oil-feed grooves at the split.

4. *Pressure or pressure dam.* Used in many places where bearing stability is required, this bearing is a plain journal bearing with a pressure pocket cut in the unloaded half. This pocket is approximately $\frac{1}{32}$ in deep with a width 50 percent of the bearing length. This groove or channel covers an arc of 135° and terminates abruptly in a sharp edge at the dam edge. The direction or rotation is such that the oil is pumped down the channel toward the sharp edge. Pressure dam bearings are for one direction of rotation. They can be used in conjunction with cylindrical bore bearings as shown in Fig. 10-106.

5. *Lemon bore or elliptical.* This bearing is bored with shims split line, which are removed before installation. The resulting shape approximates an ellipse with the major axis clearance approximately twice the minor axis clearance. Elliptical bearings are for both directions of rotation.

6. *Three-lobe bearing.* The three-lobe bearing is not commonly used in turbomachines. It has a moderate load-carrying capacity and can be operated in both directions.

7. *Offset halves.* In principle, this bearing acts very similar to a pressure dam bearing. Its load-carrying capacity is good. It is restricted to one direction of rotation.

8. *Tilt-pad bearings.* This bearing is the most common bearing type in today's machines. It consists of several bearing pads posed around the circumference of the shaft. Each pad is able to tilt to assume the most effective working position. This bearing also offers the greatest increase in fatigue life because of the following advantages:

- Thermal conductive backing material dissipates heat developed in the oil film.
- A thin babbitt layer can be centrifugally cast with a uniform thickness of about 0.005 in. Thick babbitts greatly reduce bearing life. Babbitt thickness in the neighborhood of 0.01 in reduces the bearing life by more than one-half.
- Oil film thickness is critical in bearing stiffness calculations. In a tilt-pad bearing, one can change this thickness in a number of ways: change the number of pads; direct the load on or in between the pads; change the axial length of the pad.

The previous list contains some of the most common types of journal bearings. They are listed in order of growing stability. All the bearings designed for increased stability are obtained at higher manufacturing costs and reduced efficiency. The antiwhirl bearings all impose a parasitic load on the journal, which causes higher-power losses to the bearings and in turn requires higher oil flow to cool the bearing.

**Thrust Bearings** The most important function of a thrust bearing is to resist the unbalanced force in a machine's working fluid and to maintain the rotor in its position (within prescribed limits). A complete analysis of the thrust load must be conducted. As mentioned earlier, compressors with back-to-back rotors reduce this load greatly on thrust bearings. Figure 10-107 shows a number of thrust bearing types. Plain, grooved thrust washers are rarely used with any continuous load, and their use tends to be confined to cases where the thrust load is of very short duration or possibly occurs at standstill or low speed only. Occasionally, this type of bearing is used for light loads (less than 50 lb/in$^2$), and in these circumstances the operation is probably hydrodynamic due to small distortions present in the nominally flat bearing surface.

When significant continuous loads have to be taken on a thrust washer, it is necessary to machine into the bearing surface a profile to generate a fluid film. This profile can be either a tapered wedge or occasionally a small step.

The tapered-land thrust bearing, when properly designed, can take and support a load equal to that of a tilt-pad thrust bearing. With perfect alignment, it can match the load of even a self-equalizing tilt-pad thrust bearing that pivots on the back of the pad along a radial line. For variable-speed operation, tilt-pad thrust bearings, as shown in Fig. 10-108, are advantageous when compared to conventional taper-land bearings. The pads are free to pivot to form a proper angle for lubrication over a wide speed range. The self-leveling feature equalizes individual pad loadings and reduces the sensitivity to shaft misalignments that may occur during service. The major

| Bearing type | Load capacity | Suitable direction of rotation | Resistance to half-speed whirl | Stiffness and damping |
|---|---|---|---|---|
| Cylindrical bore  | Good |  | Worst | Moderate |
| Cylindrical bore with dammed groove | Good | | | Moderate |
| Lemon bore  | Good |  | Increasing | Moderate |
| Three lobe | Moderate |  | | Good |
| Offset halves  | Good | | | Excellent |
| Tilting pad  | Moderate |  | Best | Good |

**FIG. 10-106** Comparison of general bearing types.

drawback of this bearing type is that standard designs require more axial space than a nonequalizing thrust bearing.

The thrust-carrying capacity can be greatly improved by maintaining pad flatness and removing heat from the loaded zone. By the use of high-thermal-conductivity backing materials with proper thickness and proper support, the maximum continuous thrust limit can be increased to 1000 psi or more. This new limit can be used to increase the factor of safety and improve the surge capacity of a given size bearing or reduce the thrust bearing size and consequently the losses generated for a given load.

Since the higher-thermal-conductivity material (copper or bronze) is a much better bearing material than the conventional steel backing, it is possible to reduce the babbitt thickness to 0.010 to 0.030 in. Embedded thermocouples and RTDs will signal distress in the bearing if properly positioned. Temperature-monitoring systems have been found to be more accurate than axial-position indicators, which tend to have linearity problems at high temperatures.

In a change from steel backing to copper backing, a different set of temperature limiting criteria should be used. Figure 10-109 shows a typical set of curves for the two backing materials. This chart also shows that drain oil temperature is a poor indicator of bearing operating conditions because there is very little change in drain oil temperature from low load to failure load.

**Thrust Bearing Power Loss** The power consumed by various thrust bearing types is an important consideration in any system. Power losses must be accurately predicted so that turbine efficiency can be computed and the oil supply system properly designed.

Figure 10-110 shows a typical power consumption in thrust bearings as a function of unit speed. The total power loss is usually about 0.8 to 10 percent of the total rate power of the unit. New vector lube bearings reduce the horsepower loss by as much as 30 percent. In large vertical pumps, thrust bearings take not only the load caused by the fluid but also the load caused by the weight of the entire assembly (shaft and impellers). In some large pumps these could be about 60 ft (20 m) high and weigh 16 US tons. The thrust bearing for such a pump is over 5 ft. (1.7 m) in diameter with each thrust pad weighing more than 110 lb. (50 kg). In such cases, the entire pump assembly is first floated before the unit is started.

## CENTRIFUGAL COMPRESSOR PROBLEMS

Compressors in process gas applications suffer from many problems. The following are some of the major categories in which these problems fall (see Meherwan P. Boyce, *Centrifugal Compressors: A Basic Guide,* PennWell, Nashua, N.H., 2003):

1. Compressor fouling
2. Compressor failures
3. Impeller problems

| Bearing type | Load capacity | Suitable direction of rotation | Tolerance of changing load/speed | Tolerance of misalignment | Space requirement |
|---|---|---|---|---|---|
| Plain washer  | Poor | | Good | Moderate | Compact |
| Taper land  Bidirectional | Moderate | | Poor | Poor | Compact |
| Unidirectional | Good | | Poor | Poor | Compact |
| Tilting pad Bidirectional | Good | | Good | Good | Greater |
| Unidirectional | Good | | Good | Good | Greater |

**FIG. 10-107** Comparison of thrust bearing types.

4. Rotor thrust problems
5. Seal and bearing problems
6. Bearing maintenance

**Compressor Fouling** Centrifugal compressors, especially in the process gas applications, suffer greatly from fouling. Fouling is the deposit and nonuniform accumulation of debris in the gas on internal compressor surfaces. Fouling is due to the carryover of liquids and other debris from the suction knockout drums. Debris can roughen compressor surfaces. Polymerization can occur also due to changes in process conditions. In wet gas compressors, ethylene plant cracked gas compressors, and polyethylene recycle compressors, the temperature of the gas must be kept below the threshold temperature that would initiate polymerization. The buildup will usually occur on the hub and the shroud with a larger buildup on the shroud at the elbow of the impeller on closed-face impellers. There is also a buildup on the blades, with the buildup usually more on the pressure side than on the suction side. Often the buildup is the heaviest on the pressure side at the blade exit where there is also flow separation.

***Techniques to Prevent Fouling in Process Gas Compressors***

1. *Condition monitoring of compressor aerodynamic and mechanical parameters.* Vibration monitoring could also alert the operator to fouling problems.

2. *Process control.* Accurate control of process conditions can prevent fouling in applications where polymers can form. Control of temperature is usually the most important. The following are examples of applications that can be affected by excessive process temperature:
   *a.* Ethylene cracked gas
   *b.* Linear low-density polyethylene
   *c.* High-density propylene
   *d.* Fluid catalytic cracker off-gas (wet gas)
   *e.* Thermal cracker off-gas (wet gas)
   *f.* Coker gas

The temperature below which fouling can be prevented varies with each process, compressor, and application. Monitoring of process conditions is

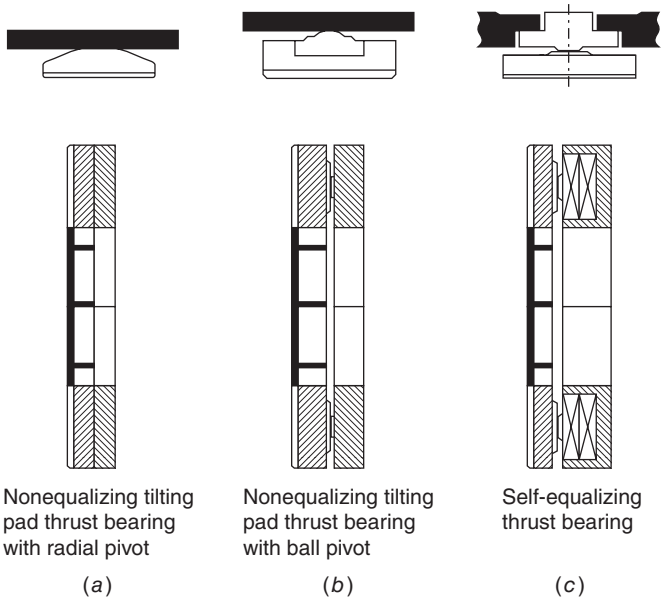


**FIG. 10-108** Various types of thrust bearings.

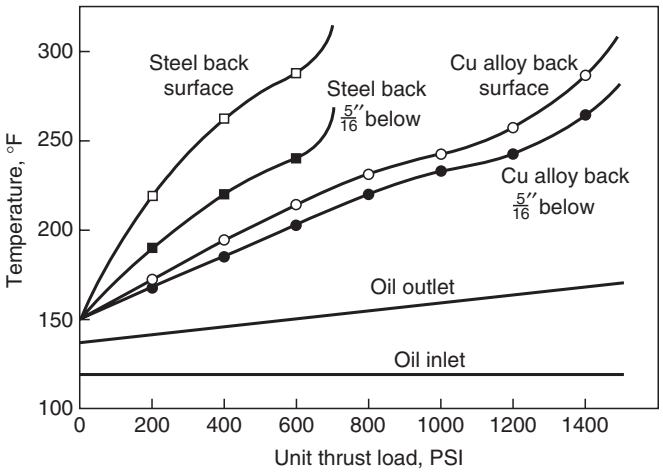

**FIG. 10-109** Thrust bearing temperature characteristics.

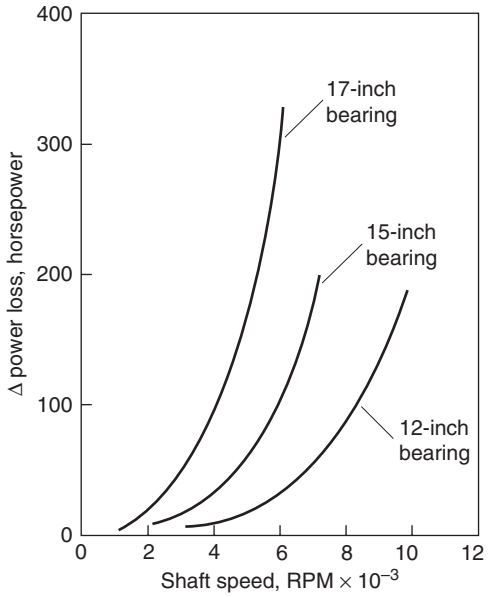

**FIG. 10-110** Difference in total-power-loss data test minus catalog frictional losses versus shaft speed for 6 × 6 pad double-element thrust bearings.

necessary to establish a threshold temperature in each case. In some cases, fouling cannot be prevented with an existing compressor. It may be necessary to modify the aerodynamic design and/or add cooling.

3. *On-line solvent injection.* On-line solvent injection is very successful in various processes. The objective of this measure is to *continuously* inject a small amount of solvent to reduce the friction coefficient of the blade and impeller surface and thus prevent fouling of the surface. The injection should be done from the start; otherwise, the foulant could be dislodged and moved downstream, creating a major problem. The downstream areas are much smaller so foulant lodging there could create a blockage.

***Air Compressors Inlet Filter*** In air compressors filter selection is an important factor in preventing fouling. Most high-efficiency air filters have a triple-stage filtration system. Also these filters often have rain shades to prevent water from entering the filters. Site conditions play a very important part in the selection of the filters.

***Compressor Blade Coating*** Coatings protect blades against oxidation, corrosion, and cracking problems. Coatings guard the base metal of the compressor from attack. Other benefits include reduced thermal fatigue from cyclic operation, increased surface smoothness, reduced erosion, and reduced heat flux loading when one is considering thermal barriers. Coatings increase resistance to spalling from light impacts. Coatings also extend compressor life, better endure operational conditions, and serve as a sacrificial layer by allowing the coating to be restripped and recoated on the same base metal.

**Compressor Failures** In the process industry there are three types of compressors that have very different maintenance problems:

1. Barrel-type compressor
2. Horizontal split-casing centrifugal compressor with closed-face impellers
3. Air integral gear-type compressor with open-face impellers

***Barrel-Type Compressors*** Barrel-type compressors are being utilized in the process industry to an increased extent because the barrel design confines gases more effectively than horizontally split cases. This becomes a critical consideration in two areas: high-pressure and low-molecular-weight gas compression. API-617, *Centrifugal Compressors for General Refinery Services,* requires a barrel design based on the molecular percentage of hydrogen contained in the process gas and the discharge pressure. API-617 defines high-pressure compressors as units in which the partial pressure of the hydrogen exceeds 200 psig, and it specifies that these units must be vertically (radially) split. Hydrogen partial pressure is given by the following relationship (in absolute pressures):

$$P_{H_2} = P(\%H_2/100) \tag{10-86}$$

Maximum casing working pressure for axially split compressors (psig) is

$$P_{casing} = \frac{200}{\%H_2/100} \tag{10-87}$$

The casings should include a minimum of a ⅛-in corrosion allowance. Casing strength and rigidity should limit change of alignment to 0.002 in if it is caused by the worst combination of pressure, torque, or allowable piping stress.

The barrel design is essentially a compressor placed inside a pressure vessel. For higher pressures some manufacturers have merely "beefed up" lower-pressure barrel designs, while others have perfected unique designs such as the "shear ring" head design. All these designs make extensive use of elastomer O-rings as sealing devices. There are several inherent maintenance problems with barrel-type compressors:

*Handling:* Barrel-type machines must be removed from their foundations for total maintenance. Because barrel machines weigh up to 30 tons, the handling problems can be formidable.

*Inner casing alignment:* Since this type of compressor consists of a bundle contained within the pressure walls of the barrel, alignment and positive positioning are often very poor, and the bundle is free to move to a certain extent. Bundle length is critical. Interstage leakage may occur if the bundle length is not correct. Assembly errors can be particularly detrimental in the case of a stacked diaphragm design, and care must be exercised to maintain proper impeller-diaphragm positioning. Since the bundle is subjected to discharge pressure on one end and suction pressure on the other, a force builds up that is transmitted from diaphragm to diaphragm, causing high loading on the inlet wall.

*Internal leakage:* The discharge and suction compartments of the inner bundle on a straight-through flow design are normally separated by a single O-ring. Compressors with side nozzles can have several bundles of O-rings. Excessive bundle-to-barrel clearance may cause leakage past the O-rings. O-rings are frequently pinched and cut across the suction nozzle opening in the barrel, a condition that is hard to prevent and doubly hard to detect if it occurs. Pressure differentials in excess of 400 to 500 psi, even using good design practice, can cause extrusion and failure of the O-rings. In many cases backup rings to the O-rings have been added to prevent failures. Grooves with O-ring ribbons have been added to the horizontal joints of the bundles of almost all the machines to prevent interstage leakage.

*Bearing bracket alignment:* In contrast to horizontally split compressors where the bearing brackets are normally an integral part of the lower casing half, in barrel machines bearing brackets are bolted to the barrel heads. Both the bearing brackets *and* the head are removed during the disassembly operation, thus requiring *all* internal alignment to be reestablished each time maintenance work is performed.

*Material problems:* To limit the physical size of the case or pressure vessel, to limit the rotor bearing span, and to maximize the number of stages within the heavy barrel, the gas path of a barrel is "squeezed" to a greater extent than in a horizontally split machine. This means the diaphragms and inlet guide vanes are intricate shapes with very small openings. Plain gray cast iron is normally used for these shapes because of casting ease and for other economic reasons. The gray iron is not strong enough in many instances to withstand the pressure differentials imposed on it, resulting in failures. Inlet guide vanes have been especially troublesome. On several occasions inlet guide vanes have been fabricated from wrought stainless and carbon steel materials. Replacement diaphragms and inlet guide vanes cast of nodular iron have also been used to alleviate some of these material problems.

**Impeller Problems** The high-speed rotation of the impeller of a centrifugal compressor imparts the vital aerodynamic velocity to the flow within the gas path. The buffeting effects of the gas flow can cause fatigue failures in the conventional fabricated shrouded impeller due to vibration-induced alternating stresses. These may be of the following types:

1. Resultant vibration in a principal mode
2. Forced-undamped vibration, associated with aerodynamic buffeting or high acoustic energy levels

The vibratory mode most frequently encountered is of the plate type and involves either the shroud or the disc. Fatigue failure generally originates at the impeller outside diameter, adjacent to a vane often due to the vibratory motion of the shroud or disc. The fatigue crack propagates inward along the nodal line, and finally a section of the shroud or disc tears out.

To eliminate failures of the covered impellers when operating at high density levels, the impellers are frequently scalloped between vanes at the outside diameter. The consequent reduction in disc friction also causes a small increase in impeller efficiency. However, there may be a slight reduction in overall efficiency due to higher losses in the diffuser. The advantages of scalloped impellers from a mechanical point of view are large. Several rotors have been salvaged by scalloping the wheels after a partial failure has occurred.

**Rotor Thrust Problems** Thrust loads in compressors due to aerodynamic forces are affected by impeller geometry, by pressure rise through the compressor, and by internal leakage due to labyrinth clearances. The impeller thrust is calculated by using correction factors to account for internal leakage, and a balance piston size is selected to

compensate for the impeller thrust load. These common assumptions are made in the calculation:

1. The radial pressure distribution along the outside of the disc cover is essentially balanced.
2. Only the "eye" area is effective in producing thrust.
3. The pressure differential applied to the eye area is equal to the difference between the static pressure at the impeller tip, corrected for the pumping action of the disc, and the total pressure at inlet.

These "common assumptions" are grossly erroneous and can be disastrous when applied to high-pressure, barrel-type compressors where a large part of the impeller-generated thrust is compensated by a balance piston. The actual thrust is about 50 percent more than the calculations indicate. The error is less when the thrust is compensated by opposed impellers, because the mistaken assumptions offset one another.

The magnitude of the thrust is considerably affected by leakage at the impeller labyrinth seals. Increased leakage here produces increased thrust independent of balancing piston labyrinth seal clearance or leakage.

The thrust errors are further compounded in the design of the balancing piston, labyrinths, and bleed line. API-617, *Centrifugal Compressors*, specifies that a separate pressure tap connection must be provided to indicate the pressure in the balance chamber. It also specifies that (1) the balance line should be sized to handle balance piston labyrinth gas leakage at twice the initial clearance without exceeding the load ratings of the thrust bearing and (2) thrust bearings for compressors should be selected at no more than 50 percent of the bearing manufacturer's rating. The leaks and the consequential pressure change across the balance piston destabilize the entire rotor system.

**Journal Bearing Failures** With high-speed machines, simple bearing failures are rare unless they are caused by faulty alignment, distortion, wrong clearance, or dirt. More common are failures caused by vibrations and rotor whirls. Some of these originate in the bearings; others can be amplified or attenuated by the bearings, the bearing cases, and the bearing support structure.

During inspection, all journal bearings should be closely inspected. If the machine has not suffered from excessive vibration or lubrication problems, the bearings can be reinstalled and utilized.

Four places should be checked for wear during inspection periods:

1. Babbitted shoe surface
2. Pivoting shoe surface and seat in retaining ring
3. Seal ring bore or end plates
4. The shoe thickness at the pivot point or across ball *and* socket (all shoes should be within 0.0005 percent of the same thickness)

**Thrust Bearing Failures** The tilting-pad-type thrust bearings are used in most major pieces of rotating equipment under the general term *Kingsbury type*. A thrust bearing failure is one of the worst things that can happen to a machine, since it often wrecks the machine. To evaluate the reliability of a thrust bearing arrangement, one must first consider how a failure is initiated and evaluate the merits of the various designs.

Failures caused by bearing overload during normal operation (design error) are rare today, but still far more thrust failures occur than one would expect, considering all the precautions taken by the bearing designer. The causes in the following list are roughly in sequence of importance:

1. *Fluid slugging.* Passing a slug of fluid through a turbine or compressor can increase the thrust to many times its normal level.
2. *Buildup of solids in rotor and/or stator passages* (*"plugging" of turbine blades*). This problem should be noticed from performance or pressure distribution in the machine (first-stage pressure) long before the failure occurs.
3. *Off-design operation.* This arises especially from backpressure (vacuum), inlet pressure, extraction pressure, or moisture. Many failures are caused by overload, off-design speed, and flow fluctuations.
4. *Compressor surging.* This problem occurs especially in double-flow machines.
5. *Gear coupling thrust.* This is a frequent cause of failure, especially of upstream thrust bearings. The thrust is caused by friction in the loaded teeth that opposes thermal expansion. Therefore, thrust can get very high, since it has no relation to the normal thrust caused by pressure distribution inside the machine. The coupling thrust may act either way, adding to or subtracting from normal thrust. Much depends on tooth geometry and coupling quality.
6. *Dirt in oil.* This is a common cause of failures, especially when combined with other factors. The oil film at the end of the oil wedge is only a small fraction of 0.001 in thick. If dirt goes through, it can cause the film to rupture, and the bearing may burn out. Therefore, very fine filtering of the oil is required.
7. *Momentary loss of oil pressure.* This type of failure is usually encountered while switching filters or coolers, or in some instances when the dc pump does not come on-line when the main pumps fail.

The thrust bearings must be closely maintained. This type of bearing consists of pivoted segments or pads (usually six) against which the thrust collar revolves, forming a wedge-shaped oil film. This film plus minute misalignment of the thrust collar and the bearing pads causes movement and wear of the various bearing parts. The erroneous thrust calculations discussed earlier cause the bearing to be loaded more heavily than desired. This accelerates the wear problem. There are seven wear points in the bearing. All these points must be checked for wear:

1. The soft babbitted shoe face
2. The hardened steel shoe insert face
3. The face of the hardened steel upper leveling plate
4. The outer edge of the upper leveling plate
5. The upper edge of lower leveling plate
6. The pivot point of the lower leveling plate
7. The inner face of the base ring

To protect thrust bearings, accurate and reliable instrumentation is now available to monitor thrust bearings well enough to ensure safe continuous operation and to prevent catastrophic failure in the event of an upset to the system.

Temperature sensors, such as resistance temperature detectors (RTDs), thermocouples, and thermistors, can be installed directly in the thrust bearing to measure metal temperature.

Axial proximity probes are another means of monitoring rotor position and the integrity of the thrust bearing. This method detects thrust collar runout and rotor movement. In most cases this ideal positioning of the probes is not possible. Many times the probes are indexed to the rotor or other convenient locations and thus do not truly show the movement of the rotor with respect to the thrust bearing.

A critical installation should have the metal temperature sensors in the thrust pad. Axial proximity probes may be used as a backup system. If metal temperatures are high and the rate of change of those temperatures begins to alter rapidly, thrust bearing failure should be anticipated.

**Compressor Seal Problems** The extent of the leakage past the seals where the shaft comes through the casing frequently limits the running time of the compressor; yet the seals and the seal systems are not given adequate treatment in the maintenance manuals or in the operating instructions furnished by the compressor manufacturer.

Shaft seals are divided into the following categories by API Standard 617:

- Labyrinth
- Restrictive carbon rings
- Mechanical (contact) type
- Liquid-film or floating bushing type
- Liquid-film type with pump bushings

The first two seal categories are usually operated dry, and the last three categories require seal oil consoles either separately or as part of the lube system. Each of these seal designs has its own characteristics and maintenance difficulties.

Oil flows and critical clearances are not spelled out well in either the operating instructions or the maintenance manuals. Because of this, several maintenance technique improvements are needed:

1. *Radial clearances.* Radial clearance between the bushing and the shaft as well as the length of the bushing must be selected to obtain minimum leakage without exceeding fluid temperature limitations.
2. *Quality control.* The flatness, parallelism, and surface finish of the mating sleeve faces must be carefully controlled to obtain maximum seal effectiveness.
3. *Axial clearances.* Axial clearance between the bushing or sleeve and the housing is critical. There should be 12 to 15 mils of clearance per bushing between the bushing or sleeve and the housing; where the sleeves are mounted back to back, there will be 25 to 30 mils of clearance total for the seal.
4. *Seal design.* In higher-pressure seals, more than one outboard (i.e., high differential) sleeve may be used. Generally, it is desirable to use a single sleeve because the inboard sleeve operates with up to 80 percent of the total pressure drop across it. The outer sleeve with the lower differential causes lubrication and cooling problems that can shorten the life of one or both sleeves.
5. *Guidelines.* These should be explicit in indicating oil flow rates and the interaction of various components.
6. *Rules of thumb.* There are a few rules of thumb that help in understanding seal operation and maintenance.

   *a.* The oil flow rate will vary (1) *directly* with the differential pressure and the wetted perimeter of the sleeve; (2) with the *cube* of the radial clearance; (3) with the *square* of the eccentricity of the sleeve and shaft; (4) *inversely* with oil viscosity, temperature, and length of the sleeve.

   *b.* Shear work done on the sealing fluid during its passage through the sleeve raises its temperature to a much higher level than may be expected.

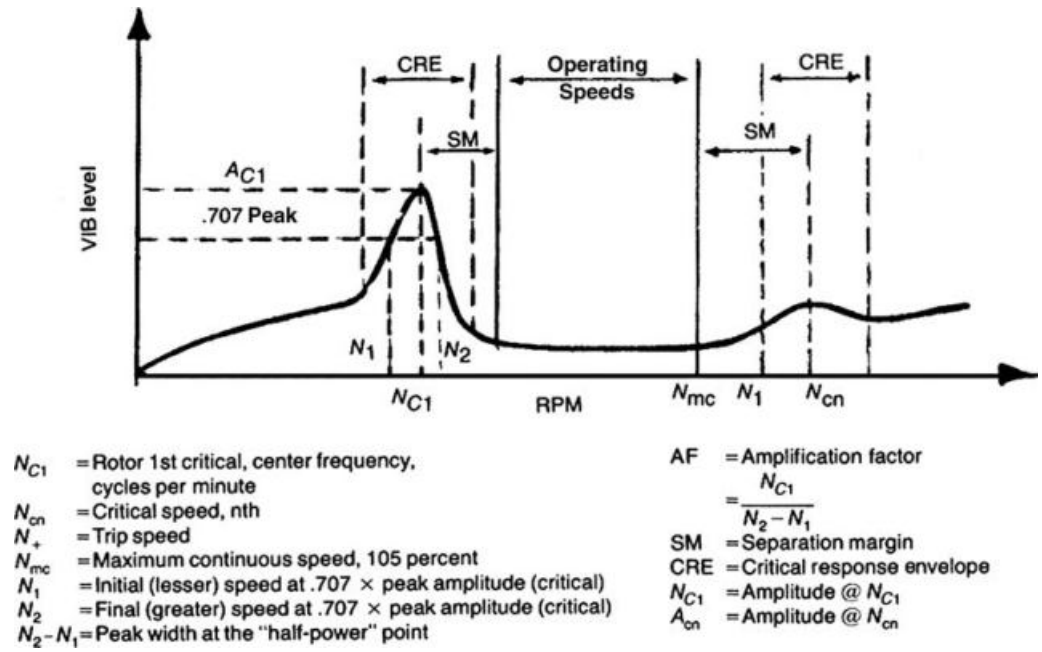

**FIG. 10-111** Rotor response plot. This plot is Figure 7 in API Standard 617, *Centrifugal Compressors for General Refinery Services*, 4th ed., 1979. (*Courtesy American Petroleum Institute.*)

## ROTOR DYNAMICS

The rotating elements consist of the impeller and the shaft. The shaft should be made of one-piece, heat-treated forged steel, with the shaft ends tapered for coupling fits. Interstage sleeves should be renewable and made of material which is corrosion-resistant in the specified service. The rotor shaft sensing area observed by the noncontact probes should be concentric with the bearing journals and free of any scratches, marks, or other surface discontinuity. The surface finish should be 16 to 32 μin root mean square, and the area should be demagnetized and treated. Electromechanical runout should not exceed 25 percent of the maximum allowed peak-to-peak vibration amplitude or 0.25 mil, whichever is greater. Although not mentioned in the standard, chrome plating of the shaft in the sensing area is unacceptable. Maximum vibration should not exceed 2.0 mils as given by

$$\text{Vib}_{\max} = \sqrt{\frac{12{,}000}{\text{rpm}}} + 0.25\sqrt{\frac{12{,}000}{\text{rpm}}} \qquad (10\text{-}88)$$

(Vibration) (runout)

At the trip speed of the driver (105 percent for a gas turbine), the vibration should not exceed this level by more than 0.5 mil.

The impellers can be an open-faced (stationary shroud) or closed-face (rotating shroud) design. As long as the tip velocities are below 1000 ft/s, closed-face impellers can be used. The standards allow the impellers to be welded, riveted, milled, or cast. Riveted impellers are unacceptable, especially if the impeller loading is high. Impellers are to be assembled on the shaft with a shrink fit with or without key. Shrink fits should be carefully done because excessive shrink fits can cause a problem known as *hysteresis whirl*. In compressors where the impellers require their thrust to be balanced, a balance drum is acceptable and preferred.

The high-speed pumps or compressors must operate in a region away from any critical speed. The *amplification factor* AF used to indicate the severity of the critical speed is given by the relationship

$$\text{AF} = \frac{\text{critical speed}}{\text{differential between RMS (0.707) of the final and initial speed}} \qquad (10\text{-}89)$$

$$\text{AF} = \frac{N_{C1}}{N_2 - N_1} \qquad (10\text{-}90)$$

where $N_2 - N_1$ is the rpm corresponding to the 0.707 (root mean square) of the peak critical amplitude between the final and the initial critical speed.

The amplification factor should be below 8 and preferably above 5. A rotor response plot is shown in Fig. 10-111. The operational speed for units operating below their first critical speed should be at least 20 percent below the critical speed. For units operating above their first critical speed, the operational speed must be at least 15 percent above the critical speed and/or 20 percent below any critical speed. The preferred bearings for the various types of installation are tilting-shoe radial bearings and the self-equalizing tilting-pad thrust bearings. Radial and thrust bearings should be equipped with embedded temperature sensors to detect pad surface temperatures.

## VIBRATION MONITORING

One of the major factors that causes pump failure is vibration, which usually causes seal damage and oil leakage. Vibration in pumps is caused by numerous factors such as cavitation, impeller unbalance, loose pump impeller on the impeller shaft, loose bearings, seals, and pipe pulsations.

As the mechanical integrity of the pump system changes, the amplitudes of vibration levels change. In some cases, to identify the source of vibration, pump speed may have to be varied, as these problems are frequency- or resonance-dependent. Pump impeller imbalance and cavitation are related to this category.

It is advisable in most of these cases to use accelerometers. Displacement probes will not give the high-frequency signals and velocity probes because their mechanical design is very directional and prone to deterioration. Figure 10-112 shows the signal from the various types of probes.

Typically, large-amplitude vibration occurs when the frequency of vibration coincides with that of the natural frequency of the pump system. This results in a catastrophic operating condition that should be avoided. If the natural frequency is close to the upper end of the operating speed range, then the pump system should be stiffened to reduce vibration. On the other hand, if the natural frequency is close to the lower end of the operating range, the unit should be made more flexible. During startup, the pump system may go through its system natural frequency, and vibration can occur. Continuous operation at this operating point should be avoided.

ASME recommends periodic monitoring of all pumps. The pump vibration level should fall within the prescribed limits. The reference vibration level is measured during acceptance testing. This level is specified by the manufacturer.

During periodic maintenance, the vibration level should not exceed the alert level (see Table 10-17). If the measured level exceeds the alert level, then preventive maintenance should be performed, by diagnosing the cause of vibration and reducing the vibration level prior to continued operation.

Typical problems and their vibration frequency ranges are shown in Fig. 10-113.

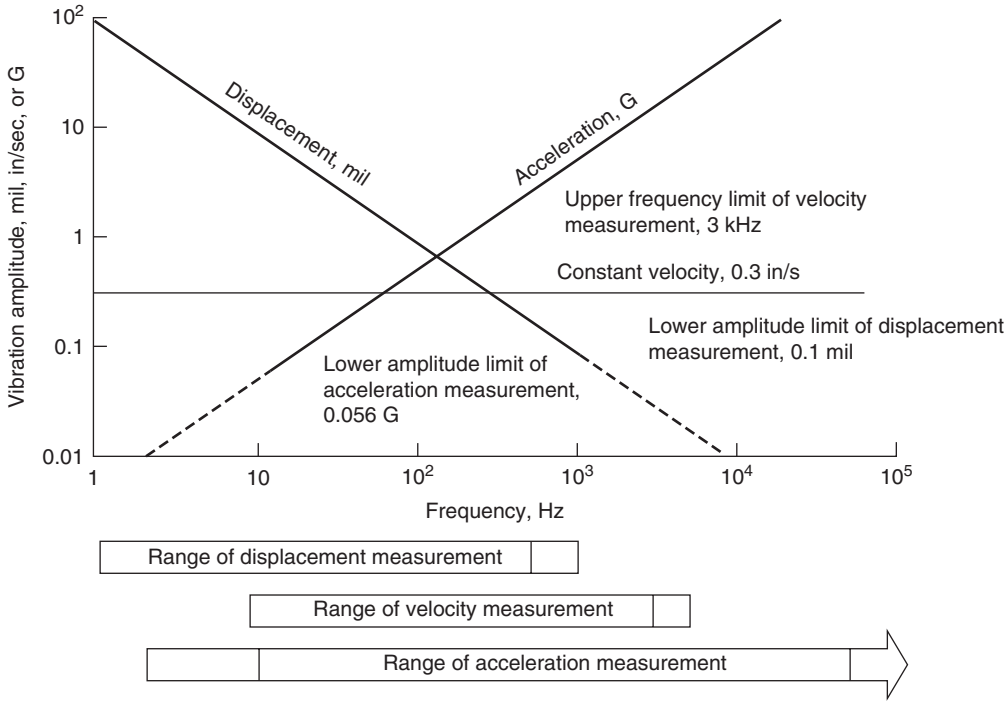

**FIG. 10-112** Limitations on machinery vibrations analysis systems and transducers.

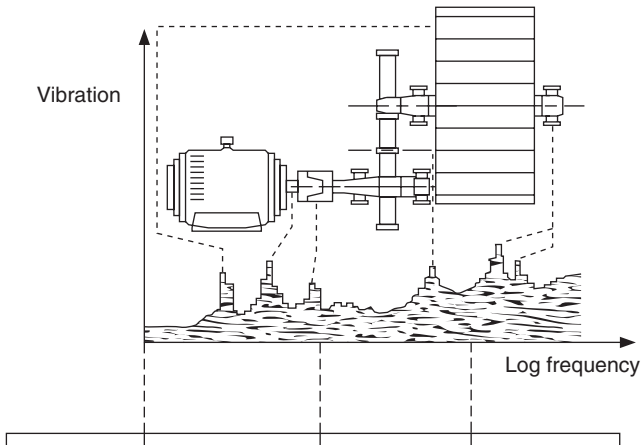
**TABLE 10-17 Alert Levels**

| Reference value, mils | Alert, mils, μm | Action required, mils, μm |
|---|---|---|
| $V_r < 0.5$ | 1.0 | 1.5 |
| $0.5 < V_r < 2.0$ | $2V_r$ | $3V_r$ |
| $2.0 < V_r < 5.0$ | $2 + V_r$ | $4 + V_r$ |
| $5.0 < V_r$ | $1.4V_r$ | $1.8V_r$ |



| Frequency range | Low | Medium | High |
|---|---|---|---|
| Fault to be detected | Unbalance<br>Misalignment<br>Bent shaft<br>Oil whirl<br>Eccentricity | Wear<br>Faults in gears | Faults in rolling element bearings |

**FIG. 10-113** Frequency range of typical machinery faults.

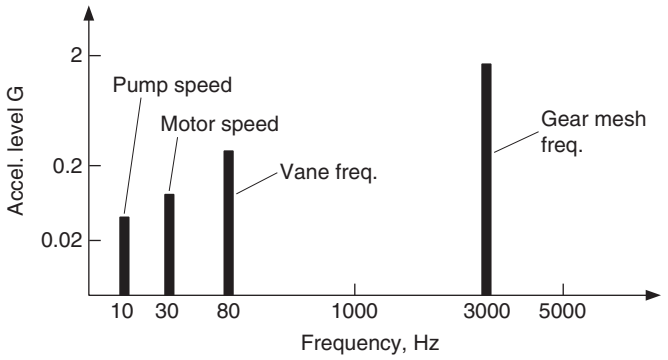


**FIG. 10-114** An ideal vibration spectrum from an electric motor pump assembly.

Collection and analysis of vibration signatures is a complex procedure. By looking at a vibration spectrum, one can identify which components of the pump system are responsible for a particular frequency component. Comparison of vibration signatures at periodic intervals reveals whether a particular component is deteriorating. Example 10-2 illustrates evaluation of the frequency composition of an electric motor gear pump system.

***Example 10-2 Vibration*** Consider an electric motor rotating at 1800 rpm driving an eight-vane centrifugal pump rotating at 600 rpm. For this 3:1 speed reduction, assume a gearbox having two gears of 100 and 300 teeth. Since 60 Hz is 1 rpm,

Motor frequency = 1800/60 = 30 Hz
Pump frequency = 600/60 = 10 Hz
Gear mesh frequency = 300 teeth × 600 rpm = 3000 Hz
Vane frequency = 8 × 600 rpm = 80 Hz

Ideal vibration spectra for this motor-gear pump assembly would appear as shown in Fig. 10-114.

Figure 10-115 shows actual pump vibration spectra. In the figure, several amplitude peaks occur at several frequencies.

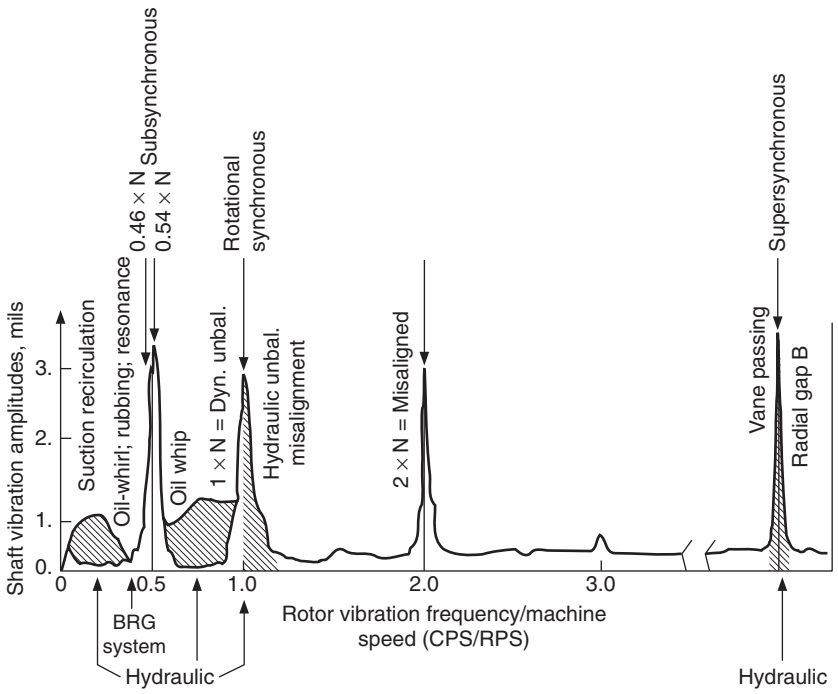

**FIG. 10-115** An actual pump vibration spectrum.

# PROCESS PLANT PIPING

## INTRODUCTION

This section provides general comments that are pertinent to the design of process plant piping. It is intended to provide a convenient summary of commonly used information from various sources. It is not intended to serve as a comprehensive source of requirements or as a substitute for referenced codes, standards, and specifications. It is intended that qualified designers obtain copies of all applicable codes, standards, and specifications and thoroughly review all pertinent requirements of these documents prior to execution of work.

## CODES AND STANDARDS

**Units: Pipe and Tubing Sizes and Ratings** In this subsection, pipe and tubing sizes are generally quoted in units of inches. To convert inches to millimeters, multiply by 25.4. Ratings are given in pounds. To convert pounds to kilograms, multiply by 0.454.

**Pressure-Piping Codes** The code for pressure piping (ASME B31) consists of a number of sections which collectively constitute the code. Table 10-18 shows the status of the B31 code as of July 2016. The sections are published as separate documents for simplicity and convenience. The sections differ extensively.

The *Process Piping* code (ASME B31.3) is a subsection of the ASME code for *Pressure Piping* B31. It was derived from a merging of the code groups for chemical plant (B31.6) and petroleum refinery (B31.3) piping into a single committee. Some of the significant requirements of ASME B31.3, *Process Piping* (2014 edition), are summarized in the following presentation.

Where the word *code* is used in this subsection of the text without other identification, it refers to the B31.3 section of ASME B31. The code has been extensively quoted in this subsection with the permission of the publisher. The code is published by, and copies are available from, the American Society of Mechanical Engineers (ASME), Three Park Avenue, New York, NY 10016–5990.

**National Standards** The American Society of Mechanical Engineers and the American Petroleum Institute (API) have established dimensional standards for the most widely used piping components. Lists of these standards as well as specifications for pipe and fitting materials and testing methods of the American Society for Testing and Materials (ASTM), American Welding Society (AWS) specifications, and standards of the Manufacturers Standardization Society of the Valve and Fittings Industry (MSS) can be found in the ASME B31 code sections. Many of these standards contain pressure-temperature ratings which will be of assistance to engineers in their design function. The use of published standards does not eliminate the need for engineering judgment. For example, although the code calculation formulas recognize the need to provide an allowance for corrosion, the standard rating tables for valves, flanges, fittings, etc., do not incorporate a corresponding allowance. Judgments regarding the suitability of these components are left to the designer.

The introduction to the code sets forth engineering requirements deemed necessary for the safe design and construction of piping systems. While safety is the basic consideration of the code, this factor alone will not necessarily govern final specifications for any pressure piping system.

Designers are cautioned that the code is not a design handbook and does not do away with the need for competent engineering judgment.

**Government Regulations: OSHA** Sections of the ASME B31 code have been adopted with certain reservations or revisions by some state and local authorities as local codes.

The specific requirements for piping systems in certain services have been promulgated as Occupational Safety and Health Administration (OSHA) regulations. These rules and regulations will presumably be revised and supplemented from time to time and may include specific requirements not addressed by the ASME B31 sections.

**International Regulations** ASME piping codes have been widely used throughout the world for the design of facilities falling within their defined scopes. Although the use of ASME codes is widely acceptable in areas outside the United States, it is essential to identify additional local or national codes or standards that may apply. Such documents may require qualified third-party review and approval of project specifications, facility design, fabrication, material documentation, inspection, and testing. For example, within the European Community, such requirements are imposed by the Pressure Equipment Directive 97/23/EC (also known as the PED). These requirements must be recognized early in the project to avoid costly error.

## CODE CONTENTS AND SCOPE

The code prescribes minimum requirements for materials, design, fabrication, assembly, support, erection, examination, inspection, and testing of piping systems subject to pressure or vacuum. The scope of

**TABLE 10-18 Status of ASME B31 Code for Pressure Piping**

| ASME B31.3 section number, latest issue, and title | General scope and application |
|---|---|
| B31.1-2014, *Power Piping* | Addresses piping typically found in electric power generating stations, industrial and institutional plants, geothermal heating systems, and central and district heating and cooling systems. |
| B31.2, *Fuel Gas Piping* | Withdrawn as a National Standard and replaced by ANSI/NFPA Z223.1 includes piping between the outlet of the consumer's meter and the outlet of the first pressure-containing valve upstream of the gas utilization device. |
| B31.3-2014, *Process Piping* | Addresses piping typically found in petroleum refineries; chemical, pharmaceutical, textile, paper, semiconductor, and cryogenic plants; and related processing plants and terminals. |
| B31.4-2016, *Pipeline Transportation Systems for Liquids and Slurries and Other Liquids* | Addresses piping transporting products which are predominately liquid between plants and terminals. Included are terminals, tank farms, and pumping, regulating, and metering stations. |
| B31.5-2013, *Refrigeration Piping and Heat Transfer Components* | Addresses refrigeration piping in packaged units and in commercial and public buildings. |
| B31.7, *Nuclear Power Piping* | Withdrawn; see *ASME Boiler and Pressure Vessel Code*, Sec. 3. |
| B31.8-2014, *Gas Transmission and Distribution Piping Systems* | Addresses piping transporting products which are predominately gas between sources and terminals. Included are gas-gathering pipelines and compressor, regulating, and metering stations. |
| B31.8S-2014, *Managing System Integrity of Gas Pipelines* | Addresses development and implementation of integrity management systems for gas pipelines. |
| B31.9-2014, *Building Services Piping* | Addresses piping outside the scope of ASME B31.1 that is typically found in multiunit residences and in industrial, institutional, commercial, and public buildings. |
| B31.11-2002, *Slurry Transportation Piping Systems* | Addresses piping transporting aqueous slurries between plants and terminals and within terminals, pumping, and regulating stations. |
| B31.12-2014, *Hydrogen Piping and Pipelines* | Addresses piping design, construction, operation, and maintenance requirements for piping, pipelines, and distribution systems in hydrogen service. |
| B31E-2008, *Standard for the Seismic Design and Retrofit of Above-Ground Piping Systems* | Addresses a more explicit and structured guidance for seismic design of new piping systems, as well as retrofit of existing systems. |
| B31G-2012, *Manual for Determining the Remaining Strength of Corroded Pipelines: A Supplement to ASME B31 Code for Pressure Piping* | Addresses methods of determining the remaining strength of corroded pipelines that are within the scope of the *ASME B31 Code for Pressure Piping.* |
| B31J-2008, *Standard Test Method for Determining Stress Intensification Factors (i-Factors) for Metallic Piping Components* | Addresses a uniform approach to the development of SIFs for standard, nonstandard, and proprietary piping components and joints of all types. |
| B31Q-2014, *Pipeline Personnel Qualification* | Addresses general and specific requirements for the qualification of pipeline personnel. |
| B31T-2012, *Standard Toughness* | Addresses requirements for evaluating the suitability of materials used |
| *Requirements for Piping* | in piping systems for piping that may be subject to brittle failure due to low-temperature service conditions. |

Addenda are issued at intervals between publication of complete editions. Information on the latest issues can be obtained from the American Society of Mechanical Engineers, Three Park Avenue, New York, NY 10016-5990; or on the World Wide Web at ASME.org.

the piping covered by B31.3 is illustrated in Fig. 10-116. It applies to all fluids including fluidized solids and to all services except as noted in the figure.

The code also excludes piping systems designed for internal gauge pressures at or above zero but less than 0.105 MPa (15 lbf/in$^2$) provided the fluid handled is nonflammable, nontoxic, and not damaging to human tissues, and its design temperature is from −29°C (−20°F) through 186°C (366°F). Refer to the code for definitions of nonflammable and nontoxic.

Some of the more significant requirements of ASME B31.3 (2014 edition) have been summarized and incorporated in this section of the text. For a more comprehensive treatment of code requirements, engineers are referred to the B31.3 code and the standards referenced therein.

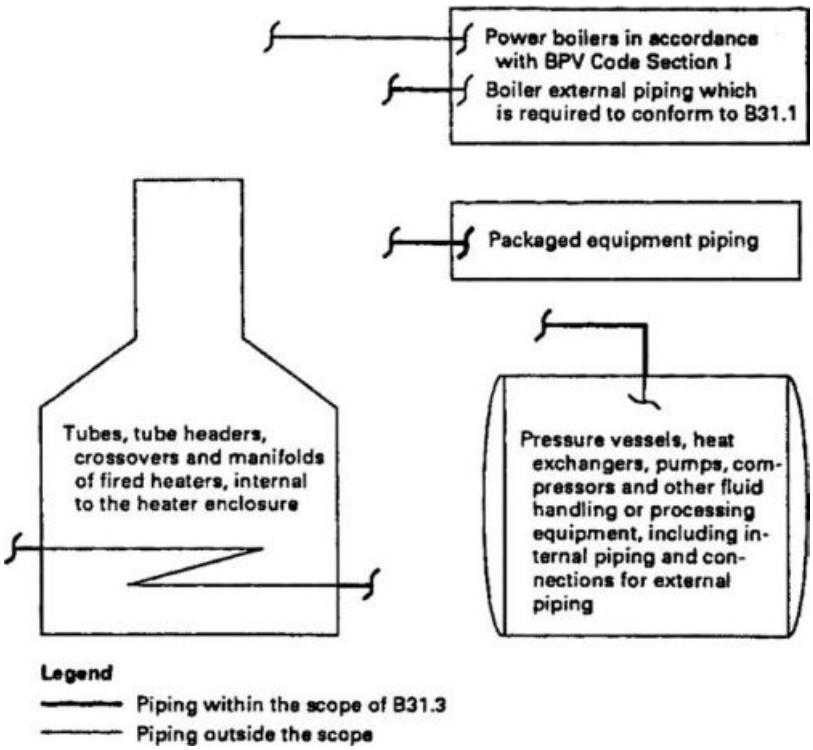

**FIG. 10-116** Scope of work covered by process piping code ASME B31.3-2014.

## SELECTION OF PIPE SYSTEM MATERIALS

The selection of material to resist deterioration in service is outside the scope of the B31.3 code (see Sec. 25). Experience has, however, resulted in the following material considerations extracted from the code with the permission of the publisher, the American Society of Mechanical Engineers, New York.

**General Considerations*** Following are some general considerations which should be evaluated when selecting and applying materials in piping:

1. The possibility of exposure of the piping to fire and the melting point, degradation temperature, loss of strength at elevated temperature, and combustibility of the piping material under such exposure
2. The susceptibility to brittle failure or failure from thermal shock of the piping material when exposed to fire or to firefighting measures, and possible hazards from fragmentation of the material in the event of failure
3. The ability of thermal insulation to protect piping against failure under fire exposure (e.g., its stability, fire resistance, and ability to remain in place during a fire)
4. The susceptibility of the piping material to crevice corrosion under backing rings, in threaded joints, in socket-welded joints, and in other stagnant, confined areas
5. The possibility of adverse electrolytic effects if the metal is subject to contact with a dissimilar metal
6. The compatibility of lubricants or sealants used on threads with the fluid service
7. The compatibility of packing, seals, and O-rings with the fluid service
8. The compatibility of materials, such as cements, solvents, solders, and brazing materials, with the fluid service
9. The chilling effect of sudden loss of pressure on highly volatile fluids as a factor in determining the lowest expected service temperature
10. The possibility of pipe support failure resulting from exposure to low temperatures (which may embrittle the supports) or high temperatures (which may weaken them)
11. The compatibility of materials, including sealants, gaskets, lubricants, and insulation, used in strong oxidizer fluid service (e.g., oxygen or fluorine)
12. The possibility of adverse effects from microbiologically influenced corrosion (MIC) or its remediation

**Specific Material Considerations—Metals*** Following are some specific considerations which should be evaluated when applying certain metals in piping.

1. *Irons—cast, malleable, and high silicon (14.5 percent).* Their lack of ductility and their sensitivity to thermal and mechanical shock.
2. *Carbon steel, and low and intermediate alloy steels.*
   *a.* The possibility of embrittlement when handling alkaline or strong caustic fluids.
   *b.* The possible conversion of carbides to graphite during long time exposure to temperatures above 427°C (800°F) of carbon steels, plain nickel steel, carbon-manganese steel, manganese-vanadium steel, and carbon-silicon steel.
   *c.* The possible conversion of carbides to graphite during long time exposure to temperatures above 468°C (875°F) of carbon-molybdenum steel, manganese-molybdenum-vanadium steel, and chromium-vanadium steel.
   *d.* The advantages of silicon-killed carbon steel (0.1 percent silicon minimum) for temperatures above 482°C (900°F).
   *e.* The possibility of damage due to hydrogen exposure at elevated temperature (see API RP941); possible hydrogen damage (blistering) at lower temperatures under exposure to aqueous acid solutions.†
   *f.* The possibility of stress corrosion cracking when exposed to cyanides, acids, acid salts, or wet hydrogen sulfide; a maximum hardness limit is usually specified (see NACE MR0175, or MR0103, and RP0472).†
   *g.* The possibility of sulfidation in the presence of hydrogen sulfide at elevated temperatures.
3. *High-alloy (stainless) steels.*
   *a.* The possibility of stress corrosion cracking of austenitic stainless steels exposed to media such as chlorides and other halides either internally or externally; the latter can result from improper selection or application of thermal insulation, or from use of marking inks, paints, labels, tapes, adhesives, and other accessory materials containing chlorides or other halides.
   *b.* The susceptibility to intergranular corrosion of austenitic stainless steels sensitized by exposure to temperatures between 427 and 871°C (800 and 1600°F); as an example, stress corrosion cracking of sensitized metal at room temperature by polythionic acid (reaction of oxidizable sulfur compound, water, and air); stabilized or low-carbon grades may provide improved resistance (see NACE RP0170).†
   *c.* The susceptibility to intercrystalline attack of austenitic stainless steels on contact with liquid metals (including aluminum, antimony, bismuth, cadmium, gallium, lead, magnesium, tin, and zinc) or their compounds.
   *d.* The brittleness of ferritic stainless steels at room temperature after service at temperature above 371°C (700°F).
4. *Nickel and nickel-base alloys.*
   *a.* The susceptibility to grain boundary attack of nickel and nickel-base alloys not containing [OL] chromium when exposed to small quantities of sulfur at temperatures above 316°C (600°F).
   *b.* The susceptibility to grain boundary attack of nickel-base alloys containing chromium at temperatures above 593°C (1100°F) under reducing conditions and above 760°C (1400°F) under oxidizing conditions.
   *c.* The possibility of stress corrosion cracking of nickel-copper Alloy 400 in hydrofluoric acid vapor in the presence of air, if the alloy is highly stressed (including residual stresses from forming or welding).
5. *Aluminum and aluminum alloys.*
   *a.* The compatibility with aluminum of thread compounds used in aluminum threaded joints to prevent seizing and galling.
   *b.* The possibility of corrosion from concrete, mortar, lime, plaster, or other alkaline materials used in buildings or structures.
   *c.* The susceptibility of Alloys 5083, 5086, 5154, and 5456 to exfoliation or intergranular attack; and the upper temperature limit of 66°C (150°F) shown in Appendix A to avoid such deterioration.
6. *Copper and copper alloys.*
   *a.* The possibility of dezincification of brass alloys.
   *b.* The susceptibility to stress corrosion cracking of copper-based alloys exposed to fluids such as ammonia or ammonium compounds.
   *c.* The possibility of unstable acetylide formation when exposed to acetylene.
7. *Titanium and titanium alloys.* The possibility of deterioration of titanium and its alloys above 316°C (600°F).
8. *Zirconium and zirconium alloys.* The possibility of deterioration of zirconium and zirconium alloys above 316°C (600°F).
9. *Tantalum.* Above 299°C (570°F), the possibility of reactivity of tantalum with all gases except the inert gases. Below 299°C, the possibility of embrittlement of tantalum by nascent (monatomic) hydrogen (but not molecular hydrogen). Nascent hydrogen is produced by galvanic action or as a product of corrosion by certain chemicals.
10. *Metals with enhanced properties.* The possible loss of strength, in a material whose properties have been enhanced by heat treatment, during long, continued exposure to temperatures above the tempering temperature.
11. The desirability of specifying some degree of production impact testing, in addition to the weld procedure qualification tests, when using materials with limited low-temperature service experience below the minimum temperature stated in ASME B31.3 Table A-1.

**Specific Material Considerations—Nonmetals** Following are some considerations to be evaluated when applying nonmetals in piping. Refer to Tables 10-19, 10-20, and 10-21 for typical temperature limits.

1. *Static charges.* Because of the possibility of producing hazardous electrostatic charges in nonmetallic piping and metallic piping lined with nonmetals, consideration should be given to grounding the metallic components of such systems conveying nonconductive fluids.
2. *Thermoplastics.* If thermoplastic piping is used aboveground for compressed air or other compressed gases, special precautions should be observed. In determining the needed safeguarding for such services, the energetics and the specific failure mechanism need to be evaluated. Encasement of the plastic piping in shatter-resistant material may be considered.
3. *Borosilicate glass.* Take into account its lack of ductility and its sensitivity to thermal and mechanical shock.

## METALLIC PIPING SYSTEM COMPONENTS

Metallic pipe systems comprise the majority of applications. Metallic pipe, tubing, and pipe fittings are divided into two main categories: seamless and welded. Both have advantages and disadvantages in terms of economy

NOTES:

*These recommended limits are for low pressure applications with water and other fluids that do not significantly affect the properties of the thermoplastic. The upper temperature limits are reduced at higher pressures, depending on the combination of fluid and expected service life. Lower temperature limits are affected more by the environment, safeguarding, and installation conditions than by strength.

†These recommended limits apply only to materials listed. Manufacturers should be consulted for temperature limits on specific types and kinds of materials not listed.

‡Use these hydrostatic design stress (HDS) values at all lower temperatures.

and function. Specifications governing the production of these products dictate the permissible mechanical and dimensional variations, and code design calculations account for these variations.

**Seamless Pipe and Tubing** Seamless pipe and tubing may be formed by various methods. A common technique involves piercing solid round forgings, followed by rolling and drawing. Other techniques include forging and boring, extrusion, and static and centrifugal casting. Piercing frequently produces pipe with a less uniform wall thickness and concentricity of bore than is the case with products produced by other methods. Since seamless products have no weld joints, there is no reduction of strength due to weld joint efficiency.

**Welded Pipe and Tubing** These products are typically made by forming strips or plate into cylinders and seam-welding by various methods. Manufacturing by welding permits the production of larger-diameter pipe than is possible with seamless manufacturing methods, as well as larger diameter/wall thickness ratios. While strip and plate thickness may be more closely controlled than is possible for some seamless products, the specifications governing production are not always more stringent for welded products.

Weld quality has the potential of making the weld weaker than the base material. Depending on the welding method and the degree of nondestructive examination required by the product specification or dictated by the designer, the code assigns a joint efficiency ranging from 60 to 100 percent of the strength of the base material. Although some welding methods have the potential of producing short sections of partially fused joints that may develop into small leaks in corrosive conditions, proper matching of the

**TABLE 10-20 Recommended Temperature Limits for Thermoplastics Used as Linings***

NOTE: These temperature limits are based on material tests and do not necessarily reflect evidence of successful use as piping component linings in specific fluid services at these temperatures. The designer should consult the manufacturer for specific applications, particularly as temperature limits are approached.

weld method and the type and extent of examination will result in highly reliable joints that are suitable for use in critical services. Welds must be considered when developing specifications for bending, flaring, or expanding welded pipe or tubing.

**Tubing** Tubing sizes typically reflect the actual outside diameter of the product. Pipe is manufactured to nominal diameters, which are not the same as the actual outside diameters for sizes 12 in and smaller. Facilities within the scope of the ASME B31 codes nearly exclusively use pipe, rather than tubing, for applications external to equipment. Tubing is commonly classified as suitable for either mechanical or pressure applications. Tubing is available in size and wall thickness combinations not normally produced as pipe. Tubing wall thickness (gauge) is specified as either average wall or minimum wall. Minimum wall is more costly than average wall, and because of closer tolerances on thickness and diameter, tubing of either gauge system is generally more costly than pipe. Tubing having outside diameters of 2⅜, 2⅞, 3½, and 4½ in are commonly available; however, these sizes are generally considered to be nonstandard for typical piping applications.

Table 10-22 gives some of the more common standard size and wall-thickness combinations together with capacity and weight.

**Methods of Joining Pipe** Piping joints must be reliably leak-tight and provide adequate mechanical strength to resist external loads due to thermal expansion, weight, wind, seismic activity, and other factors. Joints for pipe buried in soil may be subjected to unique external loads resulting from thermal expansion and contraction, settlement, and other factors. Joint designs that permit rotation about an axis perpendicular to the longitudinal axis of the pipe may be advantageous in certain situations.

Disassembly frequency and ease should be considered when selecting joining methods. Ideally the method for joining piping system components provides minimum installed cost, maintains its integrity throughout the lifetime of the facility, provides restraint against axial thrust due to internal pressure, provides strength against external loads equal to that of the pipe, permits unrestricted flow with minimum pressure drop, and is free from crevices that may be detrimental to the product or contribute to corrosion or erosion problems.

**TABLE 10-21 Recommended Temperature Limits for Reinforced Thermosetting Resin Pipe***

| Materials | | Recommended temperature limits | | | |

*Reprinted from ASME B31.3-2014, Table A323.4.2C, with permission of the publisher, the American Society of Mechanical Engineers, New York. All rights reserved.

NOTE: These temperature limits apply only to materials listed and do not reflect evidence of successful use in specific fluid services at these temperatures. The designer should consult the manufacturer for specific applications, particularly as the temperature limits are approached.

Joint design and selection generally involve compromising between the ideal and practical. A number of manufacturers produce patented or "proprietary" joints that embody many ideal characteristics. Some are excellent products and are well suited to special applications. Valves and fittings are often available with proprietary joints that have gained wide acceptance; however, consideration should be given to the possible impact on product delivery time and cost.

***Welded Joints*** The most widely used joint in piping systems is the *butt-weld joint* (Fig. 10-117). In all ductile pipe metals which can be welded, pipe, elbows, tees, laterals, reducers, caps, valves, flanges, and V-clamp joints are available in all sizes and wall thicknesses with ends prepared for butt welding. Joint strength equal to the original pipe (except for work-hardened pipes which are annealed by the welding), unimpaired flow pattern, and generally unimpaired corrosion resistance more than compensate for the necessary careful alignment, skilled labor, and equipment required.

Plain-end pipe used for socket-weld joints (Fig. 10-118) is available in all sizes, but fittings and valves with socket-weld ends are limited to sizes 3 in and smaller, for which the extra cost of the socket is outweighed by much easier alignment and less skill needed in welding.

Socket-welded joints are not as resistant to externally applied bending moments as are butt-welded joints, are not easily examined by volumetric nondestructive examination methods such as radiography and ultrasonic, and should not be used where crevice corrosion has been determined to be of concern. However, they are widely used in sizes 2 in and smaller and are quite satisfactory for most applications when used within the limits established by code restrictions and good engineering judgment. Components with socket-welded ends are generally specified as requiring compliance with ASME B16.11, *Forged-Fittings, Socket-Welding and Threaded.*

***Branch Connections*** Branch connections may be made with manufactured tees, fabricated reinforced and nonreinforced branch connections (Fig. 10-119), or manufactured integrally reinforced branch connections. Butt-welded fittings offer the best opportunity for nondestructive examination; however, branch connections are commonly specified for branches smaller than the header, and often best satisfy the design and economic requirements. Design of fabricated branch connections is addressed in the subsection Pressure Design of Metallic Components: Wall Thickness. Integrally reinforced fittings are generally specified as requiring compliance with Manufacturer's Standardization Society specification MSS SP-97, *Integrally Reinforced Forged Branch Outlet Fittings—Socket Welding, Threaded, and Butt Welding Ends.*

***Threaded Joints*** Pipe with *taper-pipe-thread* ends (Fig. 10-120), per ASME B1.20.1, is available 12 in and smaller, subject to minimum-wall limitations. Fittings and valves with taper-pipe-thread ends are available in most pipe metals.

Principal use of threaded joints is in sizes 2 in and smaller, in metals for which the most economically produced walls are thick enough to withstand pressure and corrosion after reduction in thickness due to threading. For threaded joints over 2 in, assembly difficulty and cost of tools increase rapidly. Careful alignment, required at the start of assembly and during rotation of the components, as well as variation in length produced by diametral tolerances in the threads, severely limits preassembly of the components. Threading is not a precise machining operation, and filler materials known as "pipe dope" are necessary to block the spiral leakage path.

Threads notch the pipe and cause loss of strength and fatigue resistance. Enlargement and contraction of the flow passage at threaded joints creates turbulence; sometimes corrosion and erosion are aggravated at the point where the pipe has already been thinned by threading. The tendency of pipe wrenches to crush pipe and fittings limits the torque available for tightening threaded joints. For low-pressure systems, a slight rotation in the joint may be used to impart flexibility to the system, but this same rotation, unwanted, may cause leaks to develop in higher-pressure systems. In some metals, galling occurs when threaded joints are disassembled.

***Straight Pipe Threads*** These are confined to lightweight couplings in sizes 2 in and smaller (Fig. 10-121). Manufacturers of threaded pipe ship it with such couplings installed on one end of each pipe. The joint obtained is inferior to that obtained with taper threads. The code limits the joint shown in Fig. 10-121 to 1.0 MPa (150 lbf/in$^2$) gauge maximum, 186°C (366°F) maximum, and to nonflammable, nontoxic fluids.

When both components of a threaded joint are of weldable metal, the joint may be *seal-welded* as shown in Fig. 10-122. Seal welds may be used only to prevent leakage of threaded joints. They are not considered as contributing any strength to the joint. This type of joint is limited to new construction and is not suitable as a repair procedure, since pipe dope in the threads would interfere with welding. Careful consideration should be given to the

5S, 10S, 40S, and 80S are extracted from *Stainless Steel Pipe*, ASME B36.19M-2004, with permission of the publisher, the American Society of Mechanical Engineers, New York. All rights reserved. ST = standard wall, XS = extra strong wall, XX = double extra strong wall, and Schedules 10 through 160 are extracted *from Welded and Seamless Wrought Steel Pipe*, ASME B36.10M-2004, with permission of the same publisher. Refer to these standards for a more comprehensive listing of material sizes and wall thicknesses. Decimal thicknesses for respective pipe sizes represent their nominal or average wall dimensions. Mill tolerances as high as ±12½ percent are permitted.

Plain-end pipe is produced by a square cut. Pipe is also shipped from the mills threaded, with a threaded coupling on one end, or with the ends beveled for welding, or grooved or sized for patented couplings.

To convert inches to millimeters, multiply by 25.4; to convert square inches to square millimeters, multiply by 645; to convert feet to meters, multiply by 0.3048; to convert square feet to square meters, multiply by 0.0929; to convert pounds per foot to kilograms per meter, multiply by 1.49; to convert gallons to cubic meters, multiply by $3.7854 \times 10^{-3}$; and to convert pounds to kilograms, multiply by 0.4536.

suitability of threaded joints when joining metals having significantly different coefficients of expansion. Thermal expansion and temperature cycling may eventually result in leakage.

To assist in assembly and disassembly of both threaded and welded systems, *union joints* (Fig. 10-123) are used. They comprise metal-to-metal or gasketed seats drawn together by a shouldered straight thread nut and are available both in couplings for joining two lengths of pipe and on the ends of some fittings. On threaded piping systems in which disassembly is not contemplated, union joints installed at intervals permit future further tightening of threaded joints. Tightening of heavy unions yields tight joints even if the pipe is slightly misaligned at the start of tightening.

**Flanged Joints** For sizes larger than 2 in when disassembly is contemplated, the flanged joint (Fig. 10-124) is the most widely used. Figures 10-125 and 10-126 illustrate the wide variety of types and facings available. Though

**FIG. 10-117** Butt weld.

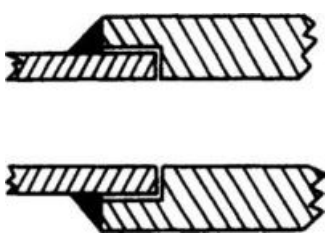

**FIG. 10-118** Socket weld.

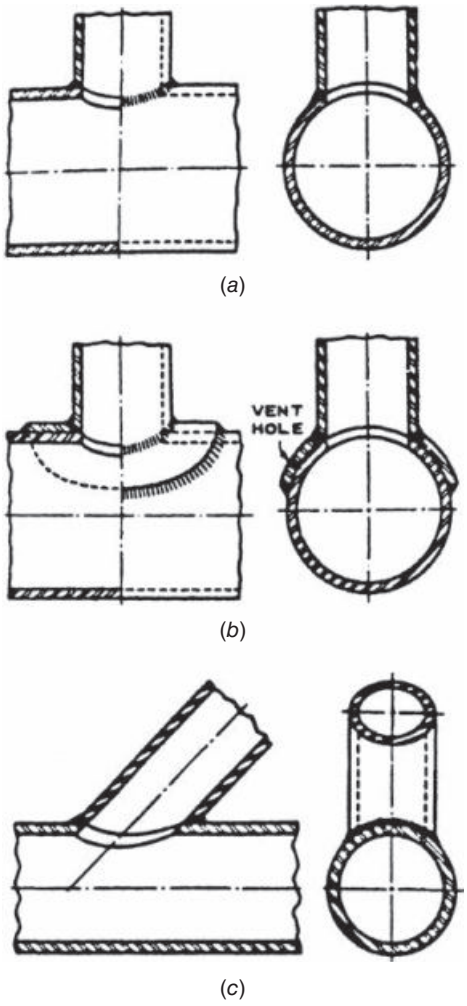

**FIG. 10-119** Branch welds. (*a*) Without added reinforcement. (*b*) With added reinforcement. (*c*) Angular branch.

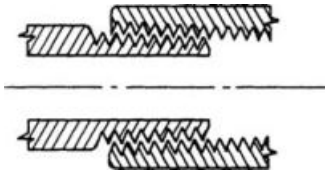

**FIG. 10-120** Taper pipe thread.

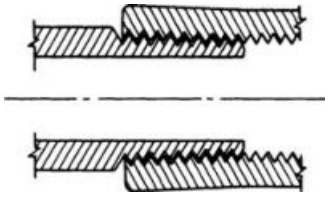

**FIG. 10-121** Taper pipe to straight coupling thread.

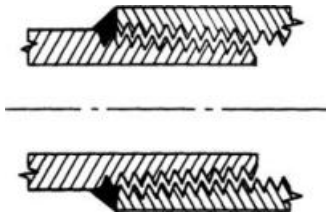

**FIG. 10-122** Taper pipe thread seal-welded.

flanged joints consume a large volume of metal, precise machining is required only on the facing. Flanged joints do not impose severe diametral tolerances on the pipe. Alignment tolerances required for flanged joints are reasonably achieved with quality construction practices, and in comparison, with taper threaded joints, required wrench sizes are smaller and sealing is more easily and reliably obtained.

Manufacturers offer *flanged-end pipe* in only a few metals. Otherwise, flanges are attached to pipe by various types of joints (Fig. 10-125). The lap joint involves a modification of the pipe which may be formed from the pipe itself or by welding a ring or a lap-joint stub end to it. *Flanged-end fittings* and valves are available in all sizes of most pipe metals.

Of the flange types shown in Fig. 10-125, welding-neck flanges offer the highest mechanical strength and are the type most suitable for extreme temperatures and cyclic loading. Regardless of the type selected, designers must be aware that the flange's capability to resist external bending moments and maintain its seal does not necessarily match the bending moment capability of the attached pipe.

When selecting the flange type, the designer should review the usage restrictions contained in each section of the ASME B31 code. Each of the other types shown provides significant fabrication and economic advantages and is suitable for many of the routine applications. Lap-joint flanges permit adjustment of the bolt-hole orientation and can greatly simplify construction when configurations are complex and bolt-hole orientations are difficult to ensure.

Dimensions for alloy and carbon-steel pipe flanges are given in Tables 10-23 through 10-27. The dimensions were extracted from *Pipe Flanges and Flanged Fittings*, ASME B16.5–2013, with permission of the publisher, the American Society of Mechanical Engineers, New York. Class 400 and 2500 are not included due to the limited use of these ratings. If needed, the user can refer to ASME B16.5 for dimensions. Dimensions for cast-iron flanges are provided in *Cast Iron Pipe Flanges and Flanged Fittings*, ASME B16.1. Bolt patterns and bolt sizes for Class 125 cast-iron flanges match the ASME B16.5 Class 150 flange dimensions, and bolt patterns for Class 250 cast-iron flanges match the ASME B16.5 Class 300 flange dimensions.

When mating with cast-iron flanged fittings or valves, steel pipe flanges are often preferred to cast-iron flanges because they permit welded rather than screwed assembly to the pipe and because cast-iron pipe flanges, not being reinforced by the pipe, are not so resistant to abuse as flanges cast integrally on cast-iron fittings.

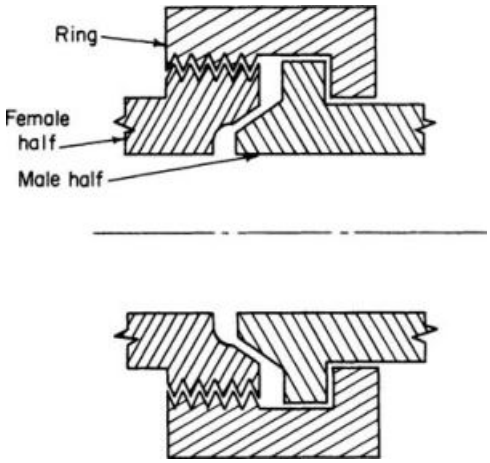

**FIG. 10-123** Union.

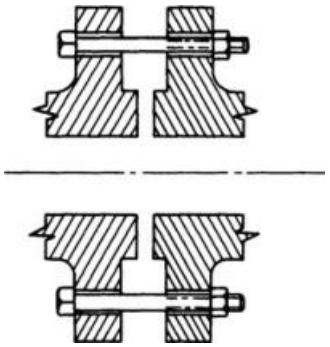

**FIG. 10-124** Flanged joint.

Facing of flanges for alloy and carbon-steel pipe and fittings is shown in Fig. 10-126; Class 125 cast-iron pipe and fitting flanges have flat faces, which with full-face gaskets minimize bending stresses; Class 250 cast-iron pipe and fitting flanges have 1.5-mm (1/16-in) raised faces (wider than on steel flanges) for the same purpose. Carbon-steel and ductile- (nodular-) iron lap-joint flanges are widely used as backup flanges with stub ends in piping systems of austenitic stainless steel and other expensive materials to reduce costs (see Fig. 10-125). The code prohibits the use of ductile-iron flanges at temperatures above 343°C (650°F). When the type of facing affects the length through the hub dimension of flanges, correct dimensions for commonly used facings can be determined from the dimensional data in Tables 10-23 through 10-27.

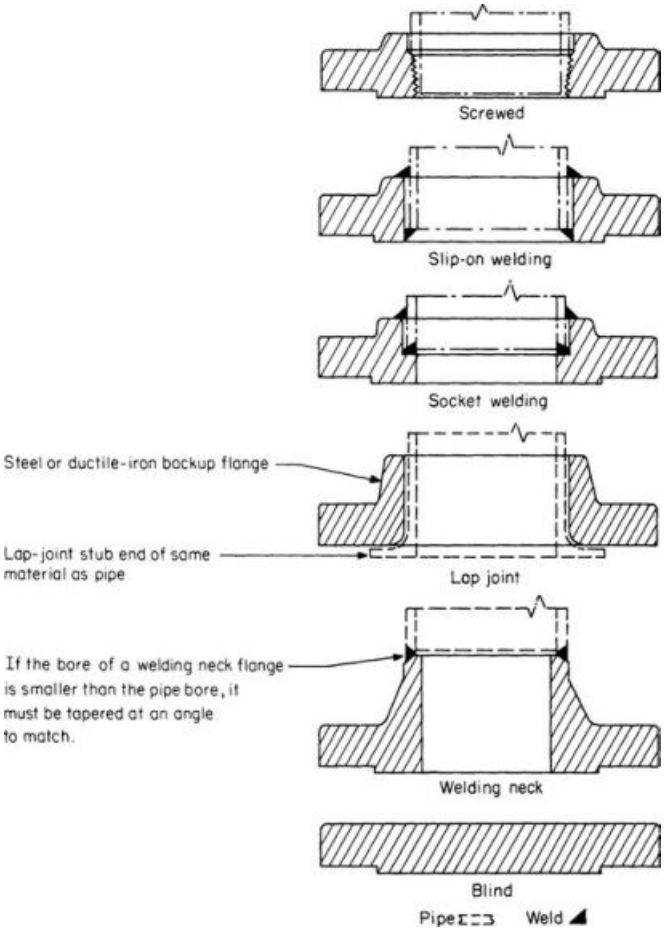

**FIG. 10-125** Types of carbon and alloy steel flanges.

***Gaskets*** Gaskets must resist corrosion by the fluids handled. The more expensive male-and-female or tongue-and-groove facings may be required to seat hard gaskets adequately. With these facings the gasket generally cannot blow out. Flanged joints, by placing the gasket material under heavy compression and permitting only edge attack by the fluid handled, can use gasket materials which in other joints might not satisfactorily resist the fluid handled.

Standards to which flanges are manufactured (e.g., ASME B16.1, ASME B16.5, ASME B16.47) typically specify a standard surface finish for the gasket seal area. Flange rating and type, flange size, flange facing type, gasket style, commodity, design conditions, and bolting must all be considered to ensure proper seating of the gasket and reliable performance. Unless the user is familiar with gasket design and the particular application being considered, it is highly recommended that the gasket manufacturer be consulted regarding gasket selection. Upon request, gasket manufacturers typically provide assistance in determining the proper material selection and the proper gasket style to ensure an economical choice and a reliable system.

When appropriate for the commodity, elastomer sheet gaskets without fillers are generally the least expensive gasket type. They are typically limited to Class 150 and temperatures below 120°C (250°F). Composition sheet gaskets are somewhat more expensive than elastomer sheet gaskets. They are generally composed of an elastomer binder with fiber filler. Their use is generally limited to Class 150 and Class 300, and depending on the filler selected the upper temperature limit typically ranges between 205°C (400°F) and 370°C (700°F). Nonelastomer sheet gaskets, such as graphite sheet gaskets, are generally somewhat more expensive than composition sheet gaskets. Their use is typically limited to Class 150 and Class 300, and the upper temperature limit may be 535°C (1000°F) or higher. Spiral-wound gaskets with graphite, PTFE, or other filler are generally appropriate for applications more demanding than those handled by sheet gaskets. They are generally more expensive than sheet gaskets and are commonly used in Class 150 through Class 1500 services (and higher) class ratings. Because of their breadth of capabilities and the advantages of standardizing, they are often used when less expensive gaskets would suffice. The solid metal outer ring on spiral-wound gaskets serves to center the gasket and provide blowout resistance. With the proper filler, spiral-wound gaskets and some sheet gaskets provide good sealing under fire conditions.

**Ring Joint Flanges** Ring joint (RTJ) flanges provide sealing capability for pressure-temperature combinations higher than those for which spiral-wound gaskets are typically used. Depending on the service, use of RTJ flanges is often considered in Class 900 and higher applications. RTJ flange facings and gaskets are more expensive than the spiral-wound counterparts. The ring material must be softer than the flange seating surface and corrosion-resistant to the service. They provide good resistance to leakage under fire conditions. RTJ flanges must be separated in the axial direction to permit insertion and removal of the gasket.

**Bolting** Bolt strength requirements are addressed to some extent by the code and by code-referenced flange standards. Bolts are categorized by the code as high strength, intermediate strength, and low strength. Bolting materials having allowable stresses meeting or exceeding those of ASTM A193 Grade B7 are categorized as high strength. Bolting materials having specified minimum yield strengths of 207 MPa (30 ksi) or less are categorized as low strength. ASTM A307 Grade B is a commonly used specification for low-strength bolting.

The suitability of the strength of any bolting throughout the required temperature range should be verified by the designer. Verification of the suitability of intermediate-strength bolting for the intended joint design is required prior to its use. The code restricts the use of low-strength bolting to nonmetallic gaskets and flanges rated ASME B16.5 Class 300 and lower having bolt temperatures at −29 to 204°C (−20 to 400°F) inclusive. Low-strength bolting is not permitted for use under severe cyclic conditions as defined by the code.

Except when bolting brittle flange materials such as gray cast iron, the code permits the use of high-strength bolting for any style of flanged joint and gasket type of combination. Per the code, if either mating flange is specified in accordance with ASME B16.1, ASME B16.24, MSS SP-42, or MSS SP-51, then the bolting material shall be no stronger than low-strength unless both mating flanges have a flat face and a full-face gasket is used. Exception to this requirement is permitted if sequence and torque limits for bolt-up are specified, with consideration given to sustained and occasional loads, and displacement strains. When both flanges are flat face and the gasket is full face extending to the outside diameter of the flange, intermediate-strength and high-strength bolts may be used.

**Miscellaneous Mechanical Joints**

***Packed-Gland Joints*** These joints (Fig. 10-127) require no special end preparation of pipe but do require careful control of the diameter of the pipe. Thus the supplier of the pipe should be notified when packed-gland joints are to be used. Cast- and ductile-iron pipe, fittings, and valves are

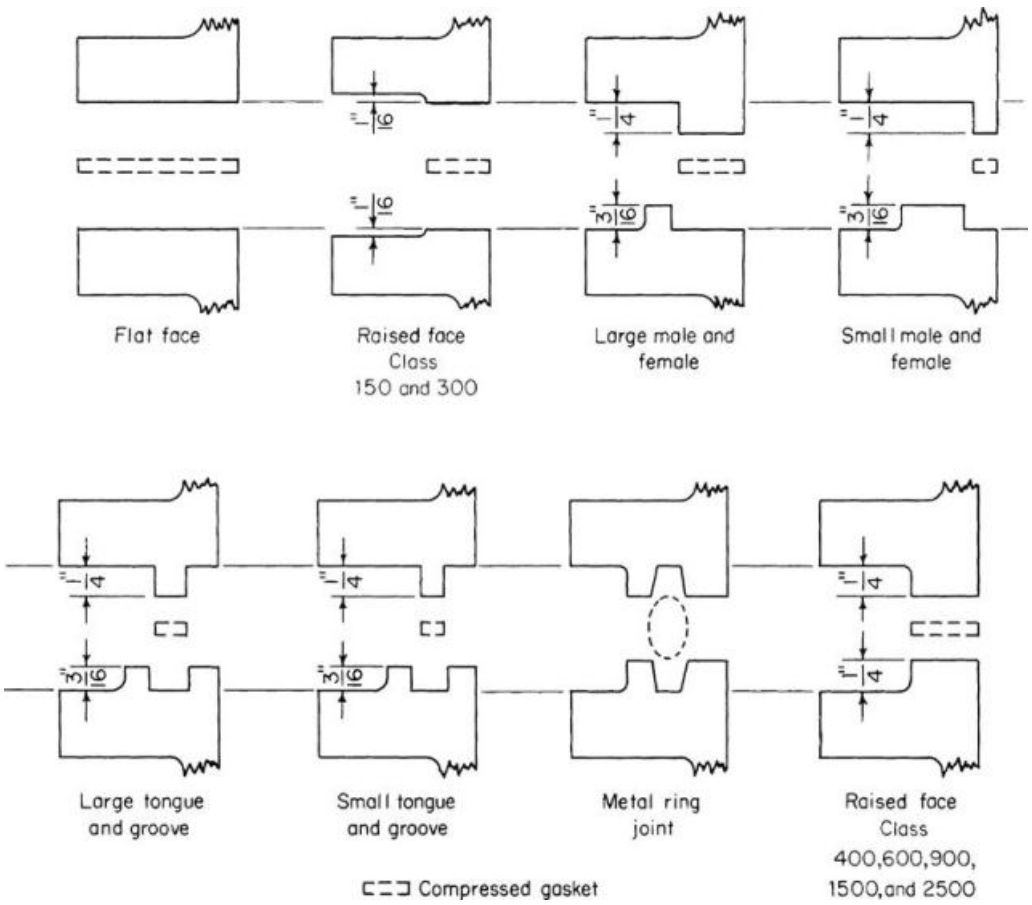

**FIG. 10-126** Flange facings, illustrated on welding-neck flanges. (On small male-and-female facings the outside diameter of the male face is less than the outside diameter of the pipe, so this facing does not apply to screwed or slip-on flanges. A similar joint can be made with screwed flanges and threaded pipe by projecting the pipe through one flange and recessing it in the other. However, pipe thicker than Schedule 40 is required to avoid crushing gaskets.) To convert inches to millimeters, multiply by 25.4.

available with the bell cast on one or more ends. Glands, bolts, and gaskets are shipped with the pipe. Couplings equipped with packed glands at each end, known as *Dresser couplings*, are available in several metals. The joints can be assembled with small wrenches and unskilled labor, in limited space, and if necessary, under water.

Packed-gland joints are designed to take the same hoop stress as the pipe. They do not resist bending moments or axial forces tending to separate the joints, but yield to them to an extent indicated by the manufacturer's allowable-angular-deflection and end movement specifications. Further angular or end movement produces leakage, but end movement can be limited by harnessing or bridling with a combination of rods and welded clips or clamps, or by anchoring to existing or new structures. The crevice between the bell and the spigot may promote corrosion. The joints are widely used in underground lines. They are not affected by limited earth settlement, and friction of the earth is often adequate to prevent end separation. When disassembly by moving pipe axially is not practical, packed-joint couplings which can be slid entirely onto one of the two lengths joined are available.

***Poured Joints*** Figure 10-128 illustrates a poured joint design. With regard to performance and ease of installation, most other joint designs are preferable to poured joints, and their use can generally be avoided.

**TABLE 10-23 Dimensions of ASME B16.5 Class 150 Flanges***

All dimensions in inches

| Nominal pipe size | Outside diameter of flange | Thickness of flange, minimum | Diameter of bolt circle | Diameter of bolts | No. of bolts | Length through hub | | | |
|---|---|---|---|---|---|---|---|---|---|
| | | | | | | Threaded slip-on socket welding | Lap joint | Welding neck | ANSI B16.1, screwed (125-lb) |
| 1 | 4.25 | 0.56 | 3.12 | ½ | 4 | 0.69 | 0.69 | 2.19 | 0.69 |

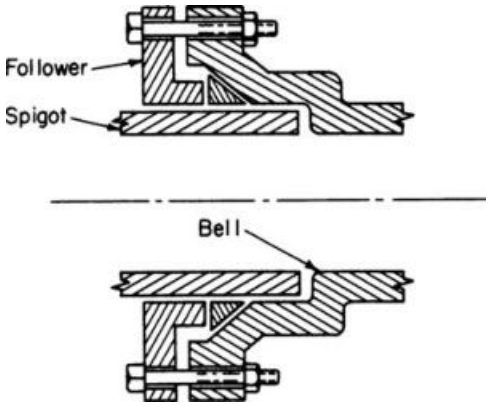

**FIG. 10-127** Packed-gland joint.

***Push-on Joints*** These joints (Fig. 10-129) require diametral control of the end of the pipe. They are used for brittle and nonmetallic materials. Pipe, fittings, and valves are furnished with the bells on one or more ends.

Push-on joints do not resist bending moments or axial forces tending to separate the joints but yield to them to an extent limited by the manufacturer's allowable-angular-deflection and end-movement specifications. End movement can be limited by harnessing or bridling with a combination of rods and clamps, or by anchoring to existing or new structures. Some manufacturers offer O-rings with metallic embedments that grip the pipe and prevent axial separation under internal pressure loading. The joints are widely used on underground lines. They are not affected by limited earth settlement, and friction of the earth is often adequate to prevent end separation. A lubricant is used on the O-ring during assembly. After this disappears, the O-ring bonds somewhat to the spigot and disassembly is very difficult. Disassembly for maintenance is accomplished by cutting the pipe and reassembly by use of a coupling with a packed-gland joint on each end.

***Expanded Joints*** These joints (Fig. 10-130) are confined to the smaller pipe sizes and ductile metals. Various proprietary designs are available in which either the pipe is expanded into the coupling or the coupling is crimped down onto the pipe. In some designs, the seal between the pipe and coupling is metal to metal, while in others elastomer O-rings are employed. Joints of these types typically are quickly and easily made with specialized equipment, and they may be particularly attractive in maintenance applications since no welding is involved. The designer should clearly understand the limitations of the joint design and should verify the success of its long-term service in similar applications.

***Grooved Joints*** These joints (Fig. 10-131) are divided into two classes: cut grooves and rolled grooves. Rolled grooves are preferred because, compared with cut grooves, they are easier to form and reduce the metal wall less. However, they slightly reduce the flow area. They are limited to thin walls of ductile material, while cut grooves, because of their reduction of the pipe wall, are limited to thicker walls. In the larger pipe sizes, some commonly used wall thicknesses are too thick for rolled grooves but too thin for cut grooves. The thinning of the walls impairs resistance to corrosion and erosion but not to internal pressure, because the thinned area is reinforced by the coupling.

Control of outside diameter is important. Permissible minus tolerance is limited, since it impairs the grip of the couplings. Plus tolerance makes it necessary to cut the cut grooves more deeply, increasing the thinning of the wall. Plus tolerance is not a problem with rolled grooves, since they are confined to walls thin enough that the couplings can compress the pipe.

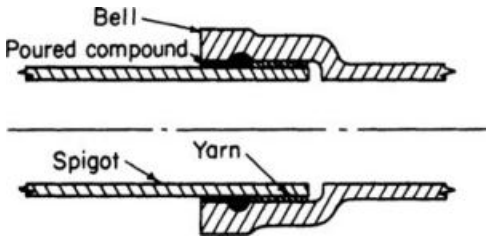

**FIG. 10-128** Poured joint.

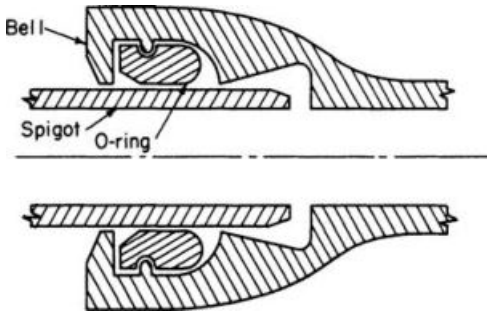

**FIG. 10-129** Push-on joint.

Pipe is available from vendors already grooved and also with heavier-wall grooved ends welded on.

Grooved joints resist axial forces tending to separate the joints. Angular deflection, up to the limit specified by the manufacturer, may be used to absorb thermal expansion and to permit the piping to be laid on uneven ground. Grooved joints provide quick and easy assembly and disassembly when compared with flanges, but may require greater support than welded joints.

Gaskets are self-sealing against both internal and external pressure and are available in a wide variety of elastomers. However, successful performance of an elastomer as a flange gasket does not necessarily mean equally satisfactory performance in a grooved joint, since exposure to the fluid in the latter is much greater and hardening has a greater unfavorable effect. It is advisable to select coupling material that is suitably corrosion-resistant with respect to the service; but with proper gasket style it may be permissible to use a coupling material that might otherwise be unacceptable with respect to fluid contamination.

***V-Clamp Joints*** These joints (Fig. 10-132) are attached to the pipe by butt-weld or expanded joints. Theoretically, there is only one relative position of the parts in which the conical surfaces of the clamp are completely in contact with the conical surfaces of the stub ends. In actual practice, there is considerable flexing of the stub ends and the clamp; also complete contact is not required. This permits use of elastomeric gaskets as well as metal gaskets. Fittings are also available with integral conical shouldered ends.

Conical ends vary from machined forgings to roll-formed tubing, and clamps vary from machined forgings to bands to which several roll-formed channels are attached at their centers by spot welding. A hinge may be inserted in the band as a substitute for one of the draw bolts. Latches may also be substituted for draw bolts.

Compared with flanges, V-clamp joints use less metal, require less labor for assembly, and are less likely to leak under wide-range rapid temperature cycling. However, they are more susceptible to failure or damage from overtightening. They are widely used for high-alloy piping subject to periodic cleaning or relocation. Manufactured as forgings, they are used in carbon steel with metal gaskets for very high pressures. They resist both axial strain and bending moments. Each size of each type of joint is customarily rated by the vendor for both internal pressure and bending moment.

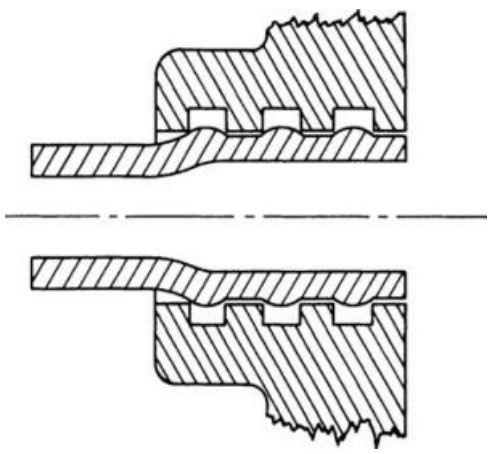

**FIG. 10-130** Expanded joint.

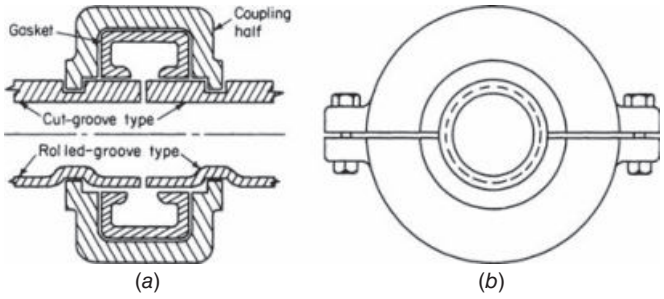

**FIG. 10-131** Grooved joint. (*a*) Section. (*b*) End view.

***Seal Ring Joints*** These joints (Fig. 10-133) consist of hubs that are attached to pipe ends by welding. Joints of this type are proprietary, and their pressure/temperature ratings and external loading capabilities are established by the manufacturers. Variations of this design are offered by various manufacturers. Many of these designs have been widely used in critical high-pressure/temperature applications. They are particularly cost-effective in high-pressure alloy material applications.

***Pressure-Seal Joints*** These joints (Fig. 10-134) are used for pressures of ASME Class 600 and higher. They use less metal than flanged joints but require much greater machining of surfaces. There are several designs, in all of which the increasing fluid pressure increases the force holding the sealing surfaces against each other. These joints are widely used as bonnet joints in carbon and alloy steel valves.

***Tubing Joints*** *Flared-fitting joints* (see Fig. 10-135) are used for ductile tubing when the ratio of wall thickness to the diameter is small enough to permit flaring without cracking the inside surface. The tubing must have a smooth interior surface. The three-piece type avoids torsional strain on the tubing and minimizes vibration fatigue on the flared portion of the tubing. More labor is required for assembly, but the fitting is more resistant to temperature cycling than other tubing fittings and is less likely to be damaged by overtightening. Its efficiency is not impaired by repeated assembly and disassembly. Size is limited because of the large number of machined surfaces. The nut and, in the three-piece type, the sleeve need not be of the same material as the tubing. For these fittings, less control of tubing diameter is required.

***Compression-Fitting Joints*** These joints (Fig. 10-136) are used for ductile tubing with thin walls. The outside of the tubing must be clean and smooth. Assembly consists only of inserting the tubing and tightening the nut. These are the least costly tubing fittings but are not resistant to vibration or temperature cycling.

***Bite-Type-Fitting Joints*** These joints (Fig. 10-137) are used when the tubing has too high a ratio of wall thickness to diameter for flaring, when the tubing lacks sufficient ductility for flaring, and for low assembly-labor cost. The outside of the tubing must be clean and smooth. Assembly consists in merely inserting the tubing and tightening the nut. The sleeve must be considerably harder than the tubing yet still ductile enough to be diametrally compressed and must be as resistant to corrosion by the fluid handled as the tubing. The fittings are resistant to vibration but not to wide-range rapid temperature cycling. Compared with flared fittings, they are less suited for repeated assembly and disassembly, require closer diametral control of the tubing, and are more susceptible to damage from overtightening. They are widely used for oil-filled hydraulic systems at all pressures.

***O-ring Seal Joints*** These joints (Fig. 10-138) are also used for applications requiring heavy-wall tubing. The outside of the tubing must be clean and smooth. The joint may be assembled repeatedly, and as long as the tubing is not damaged, leaks can usually be corrected by replacing the O-ring and the antiextrusion washer. This joint is used extensively in oil-filled hydraulic systems.

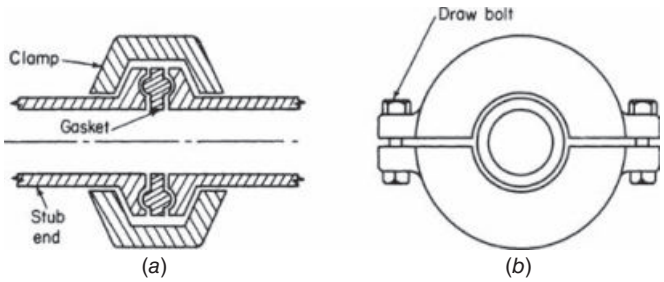

**FIG. 10-132** V-clamp joint. (*a*) Section. (*b*) End view.

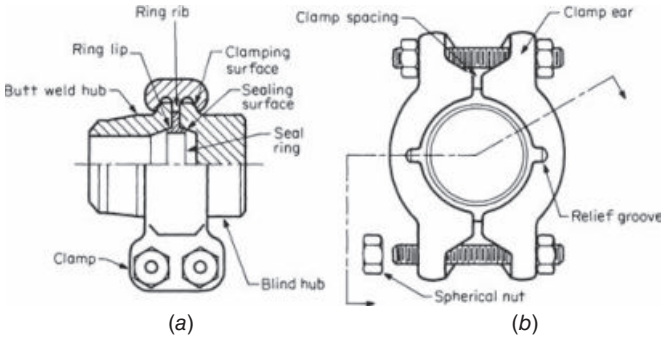

**FIG. 10-133** Seal-ring joint. (*Courtesy of Gray Tool Co.*)

***Soldered Joints*** These joints (Fig. 10-139) require precise control of the diameter of the pipe or tubing and of the cup or socket in the fitting in order to cause the solder to draw into the clearance between the cup and the tubing by capillary action (Fig. 10-139). Extrusion provides this diametral control, and the joints are most widely used in copper. A 50 percent lead, 50 percent tin solder is used for temperatures up to 93°C (200°F). Careful cleaning of the outside of the tubing and inside of the cup is required.

Heat for soldering is usually obtained from torches. The high conductivity of copper makes it necessary to use large flames for the larger sizes, and for this reason the location in which the joint will be made must be carefully considered. Soldered joints are most widely used in sizes 2 in and smaller for which heat requirements are less burdensome. Soldered joints should not be used in areas where plant fires are likely because exposure to fires results in rapid and complete failure of the joints. Properly made, the joints are completely impervious. The code permits the use of soldered joints only for Category D fluid service and then only if the system is not subject to severe cyclic conditions.

***Silver Brazed Joints*** These are similar to soldered joints except that a temperature of about 600°C (1100°F) is required. A 15 percent silver, 80 percent copper, 5 percent phosphorus solder are used for copper and copper alloys, while 45 percent silver, 15 percent copper, 16 percent zinc, 24 percent cadmium solders are used for copper, copper alloys, carbon steel, and alloy steel. Silver-brazed joints are used for temperatures up to 200°C (400°F). Cast-bronze fittings and valves with preinserted rings of 15 percent silver, 80 percent copper, 5 percent phosphorus brazing alloy are available.

Silver-brazed joints are used when temperature or the combination of temperature and pressure is beyond the range of soldered joints. They are also more reliable in the event of plant fires and are more resistant to vibration. If they are used for fluids that are flammable, toxic, or damaging to human tissue, appropriate safeguarding is required by the code. There are OSHA regulations governing the use of silver brazing alloys containing cadmium and other toxic materials.

**Pipe Fittings and Bends** Directional changes in piping systems are typically made with bends or welded fittings. Bends are made as either hot bends or cold bends. Cold bending is done at temperatures below the material transformation temperature. Depending on the material and the amount of strain involved, annealing or stress relief may be required after bending. The bend radius that may be achieved for pipe of a given size, material, and thickness depends on the bending machine capabilities and bending procedures used. When contemplating bending, the bending limitations should be reviewed with the pipe fabricators being considered for the project. Because bends are not generally made to radii as small as those of standard butt-weld or socket-weld fittings, the use of bends must be considered during piping layout. Wall thinning resulting from bending must also be considered when specifying the wall thickness of material to be bent. A detailed bending specification that addresses all aspects of bending, including requirements for bending procedure specifications, availability of bending procedure qualification records and bending operator qualification records, the range of bends covered by a single bending procedure qualification, in-process nondestructive examination requirements (including minimum wall thickness verification), dimensional tolerance requirements, etc., should be part of the bending agreement. Some bending operations and subsequent heat treatment can result in tenacious oxide formation on certain materials (such as 9Cr-1Mo-V). Removal of this oxide by conventional means such as abrasive blasting may be very difficult. Methods of avoiding this formation or of removing it should be discussed prior to bending when

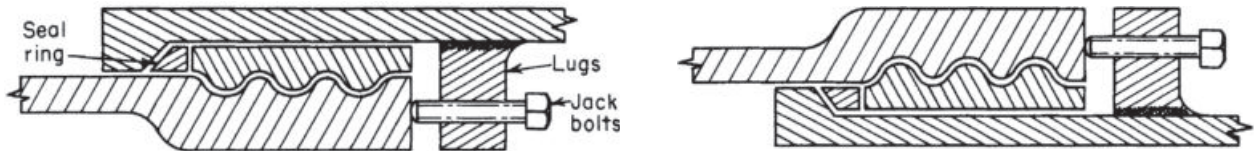

**FIG. 10-134** Pressure-seal joint.

the application requires a high level of cleanliness, such as is the case with steam supply lines to turbines.

***Elbow Fittings*** These fittings may be cast, forged, or hot- or cold-formed from short pieces of pipe or made by welding together pieces of miter-cut pipe. The thinning of pipe during the forming of elbows is compensated for by starting with heavier walls.

Flow in bends and elbow fittings is more turbulent than in straight pipe, thus increasing corrosion and erosion. This can be countered by selecting a component with greater radius of curvature, thicker wall, or smoother interior contour, but this is seldom economical in miter elbows.

Compared with elbow fittings, bends with a centerline radius of three or five nominal pipe diameters save the cost of joints and reduce pressure drop. It is sometimes difficult to nest bends of unequal pipe size when they lie in the same plane.

Flanged fittings are used when pipe is likely to be dismantled for frequent cleaning or extensive revision, or for lined piping systems. They are also used in areas where welding is not permitted. Cast fittings are usually flanged. Table 10-28 gives dimensions for flanged fittings.

Dimensions of carbon and alloy steel *butt-welding fittings* are shown in Table 10-29. Butt-welding fittings are available in the wall thicknesses shown in Table 10-22. Larger sizes and other wall thicknesses are also available. Schedule 5 and Schedule 10 stainless-steel butt-welding fittings are available with extensions for expanding into stainless-steel hubs mechanically locked in carbon-steel ASME B16.5 dimension flanges. The use of expanded joints (Fig. 10-130) is restricted by the code.

Depending on the size, forged fittings are available with socket-weld (Fig. 10-118) or screwed ends in sizes 4 in and smaller; however, 2 in is the upper size limit normally used. ASME B16.11 gives minimum dimensions for Class 3000, 6000, and 9000 socket-weld fittings, and for Class 2000, 3000, and 6000 threaded fittings. The use of socket-weld and threaded fittings is restricted by the code.

Steel forged fittings with screwed ends may be installed without pipe dope in the threads and seal-welded (Fig. 10-122) to secure bubble-tight joints.

ASME B16.3–2011 gives pressure ratings and dimensions for Class 150 and Class 300 *malleable-iron threaded fittings.* Primary usage is 2 in and smaller; however, Class 150 fittings are available in 6 in and smaller, and Class 300 fittings are available in 3 in and smaller. Malleable-iron fittings are generally less expensive than forged carbon-steel fittings, but cannot be seal-welded. Threaded ends are typically female; however, male threads or a combination of male and female is available in some fittings. Among other restrictions, the code does not permit the use of malleable iron in severe cyclic conditions, in situations subject to thermal or mechanical shock, or in any fluid service below −29°C (−20°F) or above 343°C (650°F). It also does not permit its use in flammable fluid service at temperatures above 149°C (300°F) or at gauge pressures above 2.76 MPa (400 lbf/in$^2$). ASME B16.3 ratings for Class 150 fittings are 2.07 MPa (300 lbf/in$^2$) at 66°C (150°F) and below and 1.03 MPa (150 lbf/in$^2$) at 186°C (366°F). ASME B16.3 ratings for Class 300 fittings are size-dependent, but at least 6.89 MPa (1000 lbf/in$^2$) at 66°C (150°F) and below and 2.07 MPa (300 lbf/in$^2$) at 288°C (550°F).

ASME B16.4–2011 gives pressure ratings and dimensions for Class 125 and Class 250 *gray-iron (cast-iron) threaded fittings.* Threaded fittings in both classes are available in sizes 12 in and smaller; however, consideration should be given to other types of end connections prior to using threaded fittings in sizes larger than 2 in. Threaded ends are typically female. Cast-iron fittings are less expensive than forged carbon-steel fittings, but cannot be seal-welded. The code places significant restrictions on the use of cast iron, and its use is typically limited to low-pressure, noncritical, nonflammable services. Its brittle nature should be considered before using it for compressed gas services. The minimum permissible design temperature is 29°C (−20°F). ASME B16.4 ratings for Class 125 fittings are 1.21 MPa (175 lbf/in$^2$) at 66°C (150°F) and below and 0.86 MPa (125 lbf/in$^2$) at 178°C (353°F). ASME B16.4 ratings for Class 250 fittings are 2.76 MPa (400 lbf/in$^2$) at 66°C (150°F) and below and 1.72 MPa (250 lbf/in$^2$) at 208°C (406°F).

***Tees*** Tees may be cast, forged, or hot- or cold-formed from plate or pipe. Tees are typically stocked with both header (run) ends of the same size. In general, run ends of different sizes are not typically stocked or specified; however, occasionally run ends of different sizes are specified in threaded or socket-welded sizes. Branch connections may be full size or reducing sizes. Branch reductions two sizes smaller than the header are routinely stocked, and it is not typically difficult to purchase reducing tees with branches as small as those listed in ASME B16.9 (i.e., approximately one-half the header size). Economics, stress intensification factors, and nondestructive examination requirements typically dictate the branch connection type.

***Reducers*** Reducers may be cast, forged, or hot- or cold-formed from pipe or plate. End connections may be concentric or eccentric, that is, tangent to the same plane at one point on their circumference. For pipe supported by hangers, concentric reducers permit maintenance of the same hanger length; for pipe laid on structural steel, eccentric reducers permit maintaining the same elevation of top of steel. Eccentric reducers with the common tangent plane on the bottom side permit complete drainage of branched horizontal piping systems. With the common tangent plane on the top side, they permit liquid flow in horizontal lines to sweep the line free of gas or vapor.

***Reducing Elbow Fittings*** These permit change of direction and concentric size reduction in the same fitting.

**Valves** Valve bodies may be cast, forged, machined from bar stock, or fabricated from welded plate. Steel valves are available with screwed or socket-weld ends in the smaller sizes. Bronze and brass screwed-end valves are widely used for low-pressure service in steel systems. Table 10-30 gives contact-surface-of-face to contact-surface-of-face dimensions for flanged ferrous valves and end-to-end dimensions for butt-welding ferrous valves. Drilling of end flanges is shown in Tables 10-23 to 10-27. Bolt holes are located so that the stem is equidistant from the centerline of two bolt holes. Even if removal for maintenance is not anticipated, flanged valves

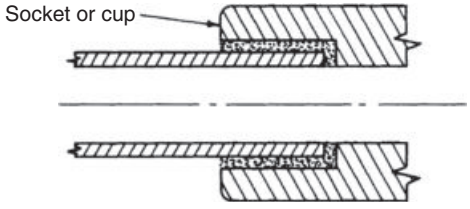

**FIG. 10-139** Soldered, brazed, or cemented joint.

are frequently used instead of butt-welding-end valves because they permit insertion of blanks for isolating sections of a loop piping system.

Ferrous valves are also available in nodular (ductile) iron, which has tensile strength and yield point approximately equal to those of cast carbon steel at temperatures of 343°C (650°F) and below and only slightly less elongation.

Valves serve not only to regulate the flow of fluids but also to isolate piping or equipment for maintenance without interrupting other connected units. Valve designers attempt to minimize body distortion due to pressure, changes in temperature, and applied loads. The sealing mechanisms of certain valve designs are inherently more tolerant of these factors than are others. The selection of valve type and materials of construction should provide a valve that functions reliably and that is acceptably tight across the sealing surfaces for the lowest lifetime cost. Valve manufacturers are a valuable source of information when evaluating the suitability of specific designs. The principal types are named, described, compared, and illustrated with line diagrams in subsequent subsections. In the line diagrams, the operating stem is shown in solid black, direction of flow by arrows on a thin solid line, and motion of valve parts by arrows on a dotted line. Moving parts are drawn with solid lines in the nearly closed position and with dotted lines in the fully open position. Packing is represented by an X in a square.

***Gate Valves*** These valves are designed in two types. The wedge-shaped-gate, *inclined-seat* type (Fig. 10-140) is most commonly used. The wedge gate may be solid or flexible (partly cut into halves by a plane at right angles to the pipe) or split (completely cleft by such a plane). Flexible and split wedges minimize galling of the sealing surfaces by distorting more easily to match angularly misaligned seats. In the double-disk *parallel-seat* type, an inclined-plane device mounted between the disks converts stem force to axial force, pressing the disks against the seats after the disks have been positioned for closing. This gate assembly distorts automatically to match both angular misalignment of the seats and longitudinal shrinkage of the valve body on cooling.

During opening and closing, some parallel-seat designs are more subject to vibration resulting from fluid flow than are wedge gates. Specific applications should be discussed with the manufacturer. In some applications it may be advisable to use a small bypass around the in-line valve to help lower opening and closing forces and to relieve binding between the gate and the seat due to high differential pressure or temperature. Double-disk parallel-seat valves should be installed with the stem essentially vertical unless otherwise recommended by the manufacturer. All wedge gate valves are equipped with tongue-and-groove guides to keep the gate sealing surfaces from clattering on the seats and marring them during opening and closing. Depending on the velocity and density of the fluid stream being sheared, these guiding surfaces may be specified as cast, machined, or hard-surfaced and ground.

Gate valves may have nonrising stems, inside-screw rising stems, or outside-screw rising stems, listed in order of decreasing exposure of the stem threads to the fluid handled. Rising-stem valves require greater space, but the position of the stem visually indicates the position of the gate. Indication is clearest on the outside-screw rising-stem valves, and on these the stem threads and thrust collars may be lubricated, reducing operating effort. The stem connection to the gate assembly prevents the stem from rotating.

Gate valves are used to minimize pressure drop in the open position and to stop the flow of fluid rather than to regulate it. The problem, when the valve is closed, of pressure buildup in the bonnet from cold liquids expanding or chemical action between fluid and bonnet should be solved by a relief valve or by notching the upstream seat ring.

***Globe Valves*** (Fig. 10-141) These are designed as either inside-screw rising stem or outside-screw rising stem. In most designs the disk is free to rotate on the stem; this prevents galling between the disk and the seat. Various designs are used to maintain alignment between the disk and the seat, and to keep the fluid flow from vibrating or rotating the disk. Disks are typically guided either by the valve stem or against the valve body. Body guiding reduces side thrust loads on the stem. The suitability of each design can be determined by reviewing specific applications with valve manufacturers.

Disk shapes are commonly flat or conical. Conical designs provide either line or area contact between the seat and disk, and are generally more suitable than flat disks for high pressures and temperatures. Needle-type disks provide better flow control and are commonly available in valves 1 in and smaller.

For certain valve designs, sizes, and applications, globe valves may be installed with the stem in the horizontal position; however, unless approved by the manufacturer, the stem orientation should be vertical. Globe valves are not symmetric with respect to flow. Generally, globe valves are installed with pressure under the seat when the valve is in the closed position, and with the flow direction coming from under the seat. Opposite-flow direction provides pressure-assisted seating, lower seating torque requirements,

NOTE: Outline drawings for flanged valves show ¼-in raised face machined onto flange, as for Class 600 cast-steel valves; Class 150 and 300 cast-steel valves and Class 250 cast-iron valves have $\frac{1}{16}$-in raised faces; Class 125 cast-iron has no raised faces.

*Extracted from *Face-to-Face and End-to-End Dimensions of Valves,* ASME B16.10, with permission of the publisher, the American Society of Mechanical Engineers, New York. All rights reserved. To convert inches to millimeters, multiply by 25.4.

†Not shown in ANSI B16.10 but commercially available.

‡These dimensions apply to pressure-seal or flangeless bonnet valves only.

§Solid wedge only.

and higher opening torques, and may result in blockage in dirty services. Consult the manufacturer before installing globe valves in the opposite-flow direction.

Pressure drop through globe valves is much greater than that for gate valves. In Y-type globe valves, the stem and seat are at about 45° to the pipe instead of 90°. This reduces pressure drop but presents design challenges with regard to disk alignment.

Globe valves in horizontal lines prevent complete drainage.

***Angle Valves*** These valves are similar to globe valves; the same bonnet, stem, and disk are used for both (Fig. 10-142). They combine an elbow fitting and a globe valve into one component with a substantial saving in pressure drop.

***Diaphragm Valves*** These valves are limited to pressures of approximately 50 lbf/in$^2$ (Fig. 10-143). The fabric-reinforced diaphragms may be made from natural rubber, from a synthetic rubber, or from natural or synthetic rubbers faced with Teflon* fluorocarbon resin. The simple shape of the body makes lining it economical. Elastomers have shorter lives as diaphragms than as linings because of flexing but still provide satisfactory service. Plastic bodies, which have low moduli of elasticity compared with metals, are practical in diaphragm valves since alignment and distortion are minor problems.

These valves are excellent for fluids containing suspended solids and can be installed in any position. Models are available in which the dam is very low, reducing pressure drop to a negligible quantity and permitting complete drainage in horizontal lines. However, drainage can be obtained with any model simply by installing it with the stem horizontal. The only maintenance required is replacement of the diaphragm, which can be done very quickly without removing the valve from the line.

*Du Pont PTFE fluorocarbon resin.

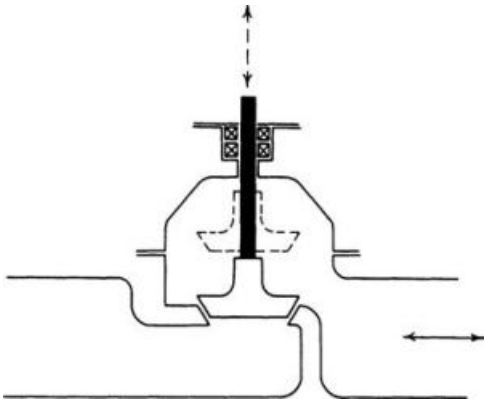

**FIG. 10-141** Globe valve.

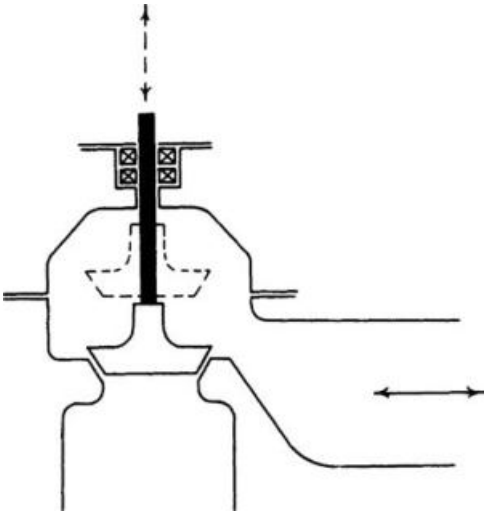

**FIG. 10-142** Angle valve.

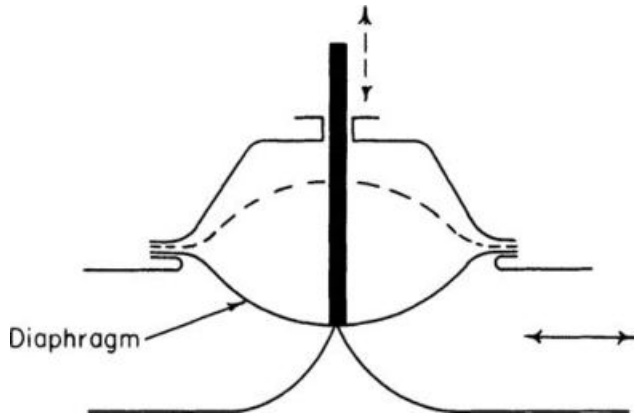

**FIG. 10-143** Diaphragm valve.

***Plug Valves*** These valves (Fig. 10-144) are typically limited to temperatures below 260°C (500°F) since differential expansion between the plug and the body results in seizure. The size and shape of the port divide these valves into different types. In order of increasing cost, they are short venturi, reduced rectangular port; long venturi, reduced rectangular port; full rectangular port; and full round port.

In lever-sealed plug valves, tapered plugs are used. The plugs are raised by turning one lever, rotated by another lever, and reseated by the first lever. *Lubricated* plug valves may use straight or tapered plugs. The tapered plugs may be raised slightly, to reduce turning effort, by injection of the lubricant, which also acts as a seal. Plastic is used in nonlubricated plug valves as a body liner, a plug coating, or port seals in the body or on the plug.

In plug valves other than lever-sealed plug valves, the contact area between plug and body is large, and gearing is usually used in sizes 6 in and larger to minimize operating effort. There are several lever-sealed plug valves incorporating mechanisms which convert the rotary motion of a handwheel into sequenced motion of the two levers.

For lubricated plug valves, the lubricant must have limited viscosity change over the range of operating temperature, must have low solubility in the fluid handled, and must be applied regularly. There must be no chemical reaction between the lubricant and the fluid which would harden or soften the lubricant or contaminate the fluid. For these reasons, lubricated plug valves are most often used when there are a large number handling the same or closely related fluids at approximately the same temperature.

Lever-sealed plug valves are used for throttling service. Because of the large contact area between plug and body, if a plug valve is operable, there is little likelihood of leakage when closed, and the handle position is a clearly visible indication of the valve position.

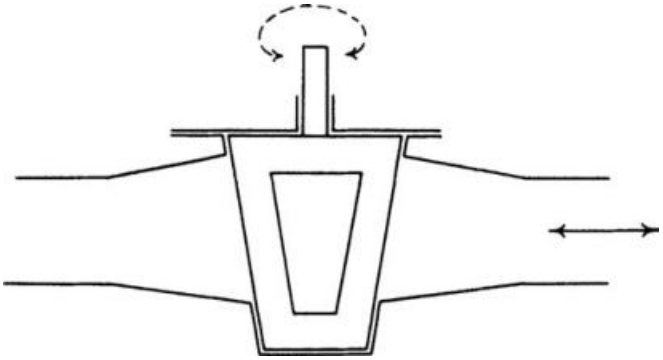

**FIG. 10-144** Plug valve.

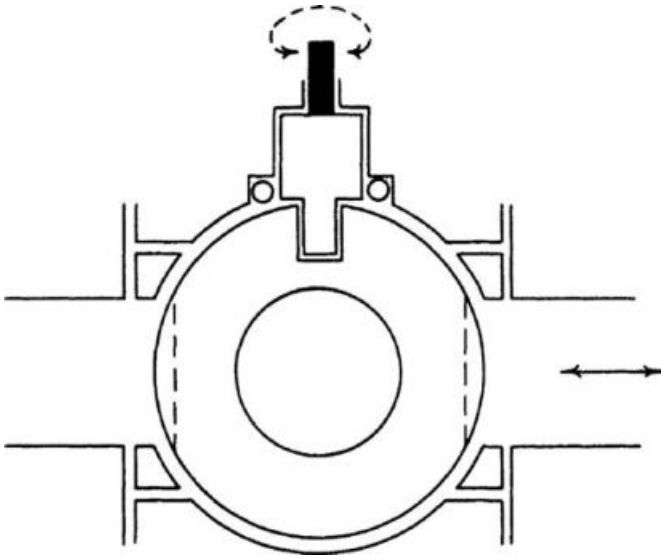

**FIG. 10-145** Ball valve; floating ball.

***Ball Valves*** Ball valves are of two primary designs: floating ball (Fig. 10-145) and trunnion-mounted ball (Fig. 10-146). In floating ball designs, the ball is supported by the downstream seat. In trunnion ball designs, the ball is supported by the trunnion, and the seat loads are less than those in floating ball valves. Because of operating torque and shutoff pressure ratings, trunnion ball valves are available in larger sizes and higher pressure ratings than floating ball valves.

Both floating and trunnion-mounted designs are available with other design variations that include metal seated valves, soft seated valves, top-entry valves, end-entry valves, and split body valves. Valves in all these design variations are available as either full port or reduced port. *Port* refers to the round-bore fluid flow area through the ball. Full port valves have a bore that is approximately equal to the inside diameter of the mating pipe. Reduced port valves have a bore that is approximately equal to the inside diameter of pipe one size smaller than full bore.

A variety of soft seat materials are available, including PTFE and nylon. Since the shutoff pressure capability of ball valves is limited by the load capabilities of the seat material, the upper temperature limit of soft seated valves is limited by the seat material selection. The shutoff pressure rating of soft seated valves typically declines rapidly with increasing temperature, and the shutoff rating is often less than the body pressure rating. Metal seated valves do not share this characteristic.

For equal port size, ball valves share the low pressure drop characteristics of gate valves. Also as is the case with gate valves, consideration must be given to venting the valve when the expansion of fluid trapped within the body cavity could overpressurize the valve body. Some seat designs are inherently self-venting to either the upstream or downstream side of the valve. In floating ball valves, venting may result in a unidirectional valve that seats against flow in only one direction.

With split body designs, internals must be removed by separating the valve body in the axial direction of the mating pipe. Top-entry design permits removal of the internals through the top of the valve. When valves are butt-welded, top entry may be specified to permit repair without removing the valve from the piping. Top-entry valves are significantly more expensive than split body and end-entry valves, and full port valves are more expensive than reduced port in any body design. Metal seated valves are significantly more expensive than soft seated valves and are typically used only when other types of valves are unsuitable for the application.

***Butterfly Valves*** These valves (Fig. 10-147) occupy less space, are much lighter than other types of block valves, and are available in body styles that include wafer, lugged (drilled-through or tapped), and flanged. They are available in ASME Class 900 and lower pressure ratings. The maximum size available varies with pressure rating. Valves in Class 150 are available in sizes exceeding 60-in diameter. Within limits, they may be used for throttling. Their relatively high pressure drop must be considered during design.

Like ball valves, butterfly valves are fully opened in one-quarter turn and are therefore well suited to automation. *Butterfly Valves: Double Flange, Lug- and Wafer-Type*, API 609, is one of the standards commonly used to specify butterfly valves. API 609 defines two major categories of butterfly valves: Category A and Category B. Category A valves are typically soft seated valves with shell pressure ratings that may be less than the flange rating of the valve. They are typically used for utility services and are commonly referred to as *utility* valves. Category B may be soft seated or metal seated, and must have shell pressure ratings equal to the full pressure rating of the valve flange, and seat ratings that essentially meet the shell rating within the temperature capability of the seat material. Within Category B, valves may be further divided into concentric shaft, double-offset shaft, and triple-offset shaft designs. *Offset* refers to the position of the shaft with respect to the seat area. With minor exception, double- and triple-offset valve designs are metal-to-metal seated. They are distinguished from other designs by their exceptional seat tightness (often "zero" leakage) that is maintained throughout the life of the valve. Their tightness exceeds the seat tightness capability and reliability of wedge-type gate valves. Double-offset valves minimize rubbing between the disk and the seat, and triple-offset valves virtually eliminate rubbing. Although double- and triple-offset valves are more expensive than other butterfly valve designs, because of their weight they are often more economical than gate valves for some combinations of pressure class, size, and materials.

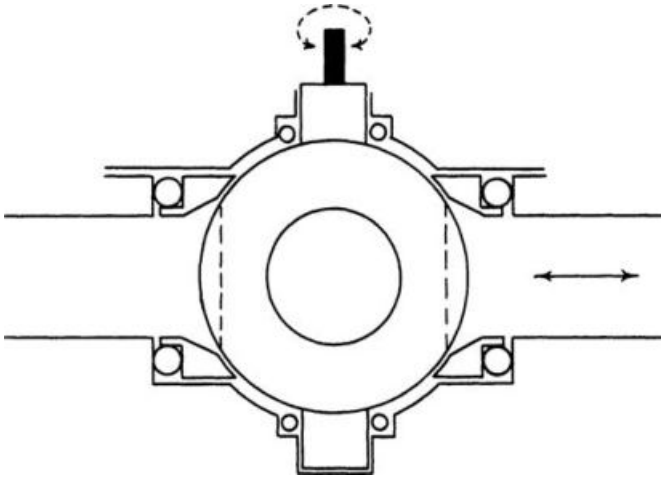

**FIG. 10-146** Ball valve; trunnion-mounted ball.

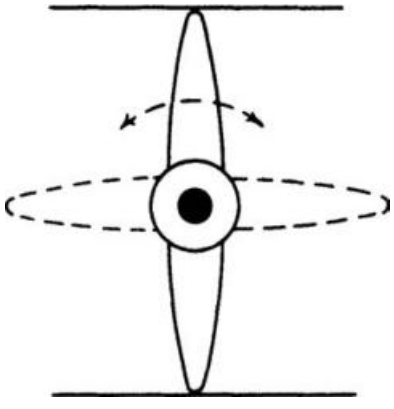

**FIG. 10-147** Butterfly valve.

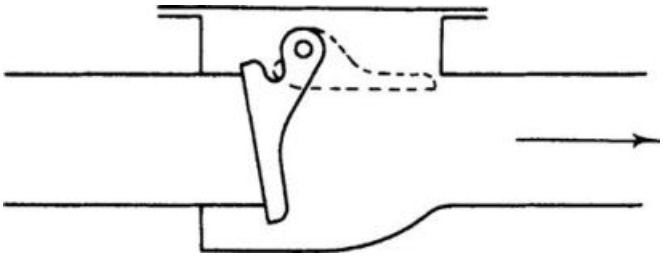

**FIG. 10-148** Swing check valve.

***Check Valves*** These valves are used to prevent reversal of flow. They must be located where flow turbulence or instability does not result in chatter (high-frequency opening and closing of the valve) and in systems designed to prevent sudden high-velocity flow reversal which results in slamming upon closure. Many valve manufacturers can provide application advice.

***Swing Check Valves*** These valves (Fig. 10-148) are normally designed for use in horizontal lines or in vertical lines with normally upward flow. Since their seating force is primarily due to pipeline pressure, they may not seal as tightly at low pressures as at higher pressures. When suitable, nonmetallic seats may be used to minimize this problem.

***Lift Check Valves*** These valves (Figs. 10-149 through 10-151) are made in three styles. Vertical lift check valves are for installation in vertical lines with flow normally upward. Globe (or piston) valves with a 90° bonnet (Fig. 10-149) are for installation in horizontal lines, although inclined bonnet versions (approximately 45°) with spring assist may be used in vertical lines with normally upward flow. Globe and angle check valves often incorporate mechanisms to control the opening or closing rate of the piston, or to promote full opening under low-flow conditions. In some designs, spring-assisted closure is available, but this increases pressure drop. Lift check valves should not be used when the fluid contains suspended solids. Ball check valves having designs similar to those in Figs. 10-150 and 10-151 are available in sizes 2 in and smaller. They promote even wear of the seat area and are more suitable for viscous services, or services with limited solids.

***Tilting-Disk Check Valves*** These valves (Fig. 10-152) may be installed in a horizontal line or in lines in which the flow is vertically upward. The pivot point is located so that the distribution of pressure in the fluid handled speeds the closing but arrests slamming. Compared with swing check valves of the same size, pressure drop is less at low velocities but greater at high velocities.

Closure at the instant of flow reversal is most nearly attained with tilting-disk, dual-plate, and specialty axial-flow check valves. However, quick closure is not the solution to all noise, shock, and water hammer problems. External dashpots are available when a controlled rate of closure is desired. Nonmetallic seats are also available.

***Dual-Plate Check Valves*** These valves (Fig. 10-152) occupy less space, are much lighter than other types of check valves, and are available in body

†To convert from inches to millimeters, multiply by 25.4; to convert pounds-force per square inch to megapascals, multiply by 0.006895.
‡These pipe walls are adequate for the rated working pressure plus a surge allowance of 100 lbf/in². For the effect of laying conditions and depth of bury, see ANSI A21.51.

styles that include wafer, lugged (drilled-through or tapped), and flanged. They are available in all ASME pressure classes. The maximum size available varies with pressure rating. Valves in Class 150 are available in sizes 60 in or larger. They are available with either metallic or nonmetallic seats. Pressure drop is greater than that in a fully open swing check valve. Plate closure is spring-assisted, and the rate of closure can be controlled with proper spring selection. High-performance valves with fast closure rates are available to address water hammer problems. They typically weigh as little as 15 to 30 percent as much as swing check valves. Because of their weight they are often more economical than other types of check valves.

***Valve Trim*** Various alloys are available for valve parts such as seats, disks, and stems which must retain smooth finish for successful operation. The problem in seat materials is fivefold: (1) resistance to corrosion by the fluid handled and to oxidation at high temperatures, (2) resistance to erosion by suspended solids in the fluid, (3) prevention of galling (seizure at point of contact) by differences in material or hardness or both, (4) maintenance of high strength at high temperature, and (5) avoidance of distortion.

Standard valve trims are defined by standards such as API 600 and API 602. Elastomer or plastic inserts may be specified to achieve bubble-tight shutoff. Valve manufacturers may be consulted for recommended trims.

## CAST IRON, DUCTILE IRON, AND HIGH-SILICON IRON PIPING SYSTEMS

**Cast Iron and Ductile Iron** Cast iron and ductile iron provide more metal for less cost than steel in piping systems and are widely used in low-pressure services in which internal and external corrosion may cause a considerable loss of metal. They are widely used for underground water distribution. Cement lining is available at a nominal cost for handling water causing tuberculation.

Ductile iron has an elongation of 10 percent or more compared with essentially nil elongation for cast iron and for all practical purposes has supplanted cast iron as a cast piping material. It is usually centrifugally cast. This manufacturing method improves tensile strength and reduces porosity. Ductile-iron pipe is manufactured to AWWA C151/A21.51-2002 and is available in nominal sizes from 3 through 64 in. Wall thicknesses are specified by seven standard thickness classes. Table 10-31 gives the outside diameter and standard thickness for various rated water working pressures for centrifugally cast ductile-iron pipe. The required wall thickness for underground installations increases with internal pressure, depth of laying, and weight of vehicles operating over the pipe. It is reduced by the degree to which the soil surrounding the pipe provides uniform support along the pipe and around the lower 180°. Tables are provided in AWWA C151/A21.51 for determining wall-thickness-class recommendations for various installation conditions. The poured joint (Fig. 10-128) has been almost entirely superseded by the mechanical joint (Fig. 10-127) and the push-on joint (Fig. 10-129), which are better suited to wet trenches, bad weather, and unskilled labor. Such joints also minimize strain on the pipe from ground settlement. Lengths vary between 5 and 6 m (between 18 and 20 ft), depending on the supplier. Stock fittings are designed for 1.72 MPa (250 lbf/in²) cast iron or 2.41 MPa (350 lbf/in²) ductile iron in sizes through 12 in and for 1.0 and 1.72 MPa (150 and 250 lbf/in²) cast iron or 2.41 MPa (350 lbf/in²) ductile iron in sizes 14 in and larger. Stock fittings include 22½° and 11¼° bends. Ductile-iron pipe is also supplied with flanges that match the dimensions of Class 125 flanges shown in ASME B16.1 (see Table 10-23). These flanges are assembled to the pipe barrel by threaded joints.

**High-Silicon Iron** Pipe and fittings are cast products of material typically conforming to ASTM A518. Nominal silicon content is 14.5 percent, and nominal carbon content is approximately 0.85 percent. This material is corrosion-resistant to most chemicals, highly abrasion-resistant, and suitable for applications to 260°C (500°F). Applications are primarily gravity drain. Pipe and fittings are available under the trade name Duriron.

Pipe and fitting sizes typically available are shown in Table 10-32. Pipe and fitting dimensions commonly conform to ASTM A861. Bell and spigot

**TABLE 10-32 High-Silicon Iron Pipe***

| Size, inside diam., in | No hub (MJ) ends | | | | Bell-and-spigot ends | | | |
|---|---|---|---|---|---|---|---|---|

*Extracted from *Standard Specification for High-Silicon Iron Pipe and Fittings,* ASTM A861-2004, with permission of the American Society for Testing and Materials, West Conshohocken, Pa.

connections are sealed with chemical-resistant rope packing and molten lead. Mechanical joint connections are made with TFE gaskets and stainless steel clamps.

The coefficient of linear expansion of this alloy in the temperature range of 21 to 100°C (70 to 212°F) is $12.2 \times 10^{-6}$/°C ($6.8 \times 10^{-6}$/°F), which is slightly above that of cast iron (National Bureau of Standards). Since this material has practically no elasticity, the need for expansion joints should be considered. Connections for flanged pipe, fittings, valves, and pumps are made to ASME B16.1, Class 125.

The use of high-silicon iron in flammable-fluid service or in Category M fluid service is prohibited by the code.

## NONFERROUS METAL PIPING SYSTEMS

**Aluminum** Seamless aluminum pipe and tube are produced by extrusion in essentially pure aluminum and in several alloys; 6-, 9-, and 12-m (20-, 30-, and 40-ft) lengths are available. Alloying and mill treatment improve physical properties, but welding reduces them. Essentially pure aluminum has an ultimate tensile strength of 58.6 MPa (8500 lbf/in$^2$) subject to a slight increase by mill treatment which is lost during welding. Alloy 6061, which contains 0.25 percent copper, 0.6 percent silicon, 1 percent magnesium, and 0.25 percent chromium, has an ultimate tensile strength of 124 MPa (18,000 lbf/in$^2$) in the annealed condition, 262 MPa (38,000 lbf/in$^2$), mill-treated as 6061-T6, and 165 MPa (24,000 lbf/in$^2$) at welded joints. Extensive use is made of alloy 1060, which is 99.6 percent pure aluminum, for hydrogen peroxide; of alloy 3003, which contains 1.2 percent manganese, for high-purity chemicals; and of alloys 6063 and 6061 for many other services. Alloy 6063 is the same as 6061 minus the chromium and has slightly lower mechanical properties.

Aluminum is not embrittled by low temperatures and is not subject to external corrosion when exposed to normal atmospheres. At 200°C (400°F) its strength is less than one-half that at room temperature. It is attacked by alkalies, by traces of copper, nickel, mercury, and other heavy-metal ions, and by prolonged contact with wet insulation. It suffers from galvanic corrosion when coupled to copper, nickel, or lead-base alloys but not when coupled to galvanized iron.

Aluminum pipe schedules conform to those in Table 10-22. Consult suppliers for available sizes and schedules.

Threaded aluminum fittings are seldom recommended for process piping. Wrought fittings with welding ends (see Table 10-28 for dimensions) and with grooved joint ends are available. Wrought 6061-T6 flanges with dimensions per Table 10-23 are also available. Consult suppliers on the availability of cast flanges and fittings. Castings manufactured in accordance with ASTM B26 are available in several grades. Refer to Table 10-28 for dimensions. The low strength and modulus of elasticity of aluminum must be considered when using flanged connections.

Aluminum-body diaphragm and ball valves are used extensively.

**Copper and Copper Alloys** Seamless pipe and tubing manufactured from copper, bronze, brass, and copper-nickel alloys are produced by extrusion. The availability of pipe or tubing depends on the metallurgy and size. Copper tubing is widely used for plumbing, steam tracing, compressed air, instrument air, and inert gas applications. Copper tubing specifications are generally segregated into three types: water and general service, refrigeration service (characterized by cleanliness requirements), and drain/waste/vent (DWV) service. Tubing is available in the annealed or hard-drawn condition. Hard-drawn products are available only as straight lengths. Annealed products are often available in coils or as straight lengths. Suppliers should be consulted regarding wall thickness availability and standard lengths; however, many products are available in 3.0-m (10-ft) and 6.1-m (20-ft) straight lengths. Coil lengths are generally 12.2 m (40 ft) to 30 m (100 ft).

ASTM copper tubing specifications for water and general-purpose applications include B75 and B88 (Table 10-33). Tubing, fittings, and solders specified for potable water services must always be approved by the appropriate authority, such as the National Sanitation Foundation (NSF). ASTM copper tubing specifications for refrigeration services include B68 and B280 (Table 10-34). ASTM specifications for DWV services include B306 (1¼ through 8-in OD). Pipe conforming to the diameters shown in Table 10-35 is available as ASTM B42 and B302. ASTM B302 has diameters matching ASTM B42, but is available with thinner walls (Table 10-36). Red brass pipe is available as ASTM B43.

Joints are typically soldered, silver-brazed, or mechanical. When using flare, compression, or other mechanical joint fittings, consideration must be given to the fitting manufacturer's recommendations regarding hardness, minimum and maximum wall thickness, finish requirements, and diameter tolerances. Flanges and flanged fittings are seldom used since soldered and brazed joints can be easily disassembled. Brass and bronze valves are available with female ends for soldering.

Seventy percent copper, 30 percent nickel and 90 percent copper, 10 percent nickel ASTM B466 are available as seamless pipe (ASTM B466) or welded pipe (ASTM B467) and welding fittings for handling brackish water in Schedule 10 and regular copper pipe thicknesses.

**Nickel and Nickel Alloys** A wide range of ferrous and nonferrous nickel and nickel-bearing alloys are available. They are usually selected because of their improved resistance to chemical attack or their superior resistance to the effects of high temperature. In general terms their cost

**TABLE 10-33 Dimensions, Weights, and Tolerances in Diameter and Wall Thickness for Nominal or Standard Copper Water Tube Sizes (ASTM B88-2014)***

[A]The average outside diameter of a tube is the average of the maximum and minimum outside diameters as determined at any one cross section of the tube.
[B]The tolerances listed represent the maximum deviation at any point.

and corrosion resistance are somewhat a function of their nickel content. The 300 Series stainless steels are the most generally used. Some other frequently used alloys are listed in Table 10-37 together with their nominal compositions. For metallurgical and corrosion resistance data, see Sec. 25.

**Titanium** Seamless pipe is available as ASTM B861 and welded pipe as ASTM B862. Both standards offer numerous grades of unalloyed and alloyed materials. While the alloys often have higher tensile strengths, corrosion resistance may be sacrificed. Forged or wrought fittings and forged or cast valves are available. For many applications, elastomer-lined valves having carbon-steel or ductile-iron bodies and titanium trim offer an economical alternative to valves with titanium bodies. Titanium pipe is available with wall thicknesses conforming to many of those listed in Table 10-22, including Schedule 10S and Standard Weight. Properly selected and specified, titanium can be a good choice for seawater systems such as offshore fire water systems. Seamless and welded tubing is manufactured to ASTM B338; however, availability may be limited.

**Flexible Metal Hose** Flexible hoses provide flexible connections for conveying gases or liquids, wherever rigid pipes are impractical. There are two basic types of flexible hose: corrugated hoses and interlocked hoses. These flexible hoses can absorb vibrations and noise. They can also provide some flexibility for misaligned rigid piping or equipment during construction. Corrugated or interlocked thin brass, bronze, Monel, aluminum, and steel tubes are covered with flexible braided-wire jackets to form flexible metal hose. Both tube and braid are brazed or welded to pipe-thread, union, or flanged ends. Failures are often the result of corrosion of the braided-wire jacket or of a poor jacket-to-fitting weld. Maximum recommended temperature for bronze hose is approximately 230°C (450°F). Metal thickness is much less than for straight tube for the same pressure-temperature conditions; so accurate data on corrosion and erosion are required to make proper selection.

## NONMETALLIC PIPE AND METALLIC PIPING SYSTEMS WITH NONMETALLIC LININGS

**Cement-Lined Carbon-Steel Pipe** Cement-lined carbon-steel pipe is made by lining steel pipe with special cement. The cement lining prevents pickup of iron by the fluid handled, corrosion of the metal by brackish or saline water, and growth of tuberculation. Various grades of cement are available, and the proper grade should be selected to match the application.

Cement-lined pipe in sizes smaller than 1½ in is not generally recommended. Cement-lined carbon-steel pipe can be supplied with butt-welded or flanged ends. Butt-welded construction involves the use of special joint grouts at the weld joint and controlled welding procedures. See Table 10-38.

American Water Works Association Standard C205 addresses shop-applied cement mortar lining of pipe sizes 4 in and larger. Fittings are available as cement mortar–lined butt-weld or flanged carbon steel, flanged cast iron, or flanged ductile iron. AWWA C602 addresses in-place (i.e., in situ or field) application of cement mortar lining for pipe sizes 4 in and larger.

**Concrete Pipe** Concrete piping and nonmetallic piping such as PVC, RTR, and HDPE are commonly used for buried gravity drain and pressurized applications. Common applications for both include construction culverts and forced water mains, sewage, industrial waste, and stormwater systems. Some of the factors to be considered when deciding whether to use concrete or nonmetallic piping include local code requirements, pipe size, soil and commodity corrosivity, commodity temperature and pressure, resistance to tuberculin growth, traffic and burial loads, soil conditions and bedding requirements, groundwater level and buoyancy issues, suitability of available joining methods, ability of joints to resist internal pressure thrust without the use of thrust blocks, availability of pressure-rated and non-pressure-rated fittings, shipping weight, load capacity of available construction equipment, requirements for special equipment such as fusion bonding

**TABLE 10-35 Copper and Red-Brass Pipe (ASTM B42-2015a and B43-2015)*: Standard Dimensions, Weights, and Tolerances**

machines, contractor's experience and labor skill level requirements, and final installed cost.

Non-reinforced-concrete culvert pipe for gravity drain applications is manufactured to ASTM C14 in strength Classes 1, 2, and 3. It is available with internal diameters 4 through 36 in. Reinforced concrete culvert for gravity drain applications is manufactured to ASTM C76 with internal diameters of 12 through 144 in. Metric sizes are manufactured to ASTM C14M and C76M. Joints are typically bell and spigot (or a similar variation) with rubber gaskets.

Concrete pressure pipe is typically custom-designed to three different specifications. Each design provides a cement mortar lining or concrete interior. It is advisable to consult manufacturers regarding the most appropriate specification for a given application and the availability of fittings. The names of some manufacturers can be obtained through the American Concrete Pressure Pipe Association. American Water Works Association standard AWWA C300 addresses steel cylinder reinforced-concrete pressure pipe in inside-diameter sizes 30 through 144 in. AWWA C301 addresses prestressed reinforced pipe with a steel cylinder wrapped with steel wire. Inside-diameter sizes are 16 through 144 in. AWWA C302 addresses circumferentially reinforced pipe without a steel cylinder or prestress. Inside-diameter sizes are 12 through 144 in, with continuous pressure ratings to 0.38 MPa (55 lbf/in$^2$) and total pressure (including surge) to 0.45 MPa (65 lbf/in$^2$). AWWA C303 addresses reinforced pipe with a steel cylinder helically wrapped with steel bar. Inside-diameter sizes are 10 through 60 in, with pressure ratings to 2.7 MPa (400 lbf/in$^2$) working pressure. Joints are typically bell and spigot (or a similar variation) with rubber gaskets. In addition to the gasket, grouting is used on the exterior and interior of the joint to seal otherwise exposed steel.

**Glass Pipe and Fittings** These are made from heat- and chemical-resistant borosilicate glass in accordance with ASTM E-438 Type 1, Class A. This glass is resistant to chemical attack by almost all products, which makes its resistance much more comprehensive than that of other well-known materials. It is highly resistant to water, saline solutions, organic substances, halogens such as chlorine and bromine, and many acids. Only a few chemicals can cause noticeable corrosion of the glass surface, such as hydrofluoric acid, concentrated phosphoric acid, and strong caustic solutions at elevated temperatures. Some important physical properties are as follows:

Mean linear expansion coefficient between 20 and 300°C: $[(3.3 \pm 0.1) \times 10^{-6}]$/K
Mean thermal conductivity between 20 and 200°C: 1.2 W/(m · K)
Mean specific heat capacity between 20 and 100°C: 0.8 kJ/(kg · K)
Mean specific heat capacity between 101 and 200°C: 0.9 kJ/(kg · K)
Density at 20°C: 2.23 kg/dm$^3$

Flanged glass pipe with conical ends (Fig. 10-153) should be used in applications requiring a pressure rating or that are expected to see thermal cycling. Flanged ends are normally required to mate with other glass components (vessels, coil heat exchangers, etc). The flanges are specially designed plastic backing flanges that are cushioned from the glass by either molded plastic or fiber inserts. The liquid seal is provided by means of a gasket that is gripped between the grooved pipe ends.

*Adapted with permission of De Dietrich Process Systems, Mountainside, N.J.

Glass pipe is made in the sizes shown in Table 10-39. Depending on the nominal diameter, lengths range from 0.075 to 3 m. Design pressure ranges from −0.10 MPa (−14.5 lbf/in$^2$) vacuum to 0.40 MPa (58 lbf/in$^2$) for nominal diameters of 15 through 50 mm, 3 MPa (43 lbf/in$^2$) for nominal diameter of 80 mm, 0.20 MPa (29 lbf/in$^2$) for nominal diameters of 100 and 150 mm, and 0.10 MPa (14.5 lbf/in$^2$) for nominal diameters of 200 and 300 mm. Maximum permissible thermal shock, as a general guide, is 120 K. Maximum operating temperature is 200°C (248°F). A complete line of fittings is available, and special parts can be made to order. Thermal expansion stresses should be completely relieved by tied PTFE corrugated expansion joints and offsets. Temperature rating may be limited by joint design and materials.

Beaded pipe is used for process waste lines and vent lines. Some applications have also been made in low-pressure and vacuum lines. Beaded end pipe is available in nominal diameters of 1½ through 6 in. For operating conditions, manufacturers should be consulted. In this system the ends of the pipe and fittings are formed into a bead, as shown in Fig. 10-155. The coupling consists of a stainless steel outer shell, a rubber collar, and a TFE liner gasket. When the single coupling nut is tightened, the thick rubber sleeve forces the TFE gasket against the glass to make the seal.

**Glass-Lined Steel Pipe and Fittings** This pipe is fully resistant to all acids except hydrofluoric and concentrated phosphoric acids at temperatures up to 120°C (248°F). It is also resistant to alkaline solutions at moderate temperatures. Glass-lined steel pipe can be used at temperatures up to 220°C (428°F) under some exposure conditions provided there are no excessive temperature changes. The operating pressure rating of commonly available systems is 1 MPa (145 lbf/in$^2$). The glass lining is approximately 1.6 mm ($\frac{1}{16}$ in) thick. It is made by lining Schedule 40 steel pipe. Fittings are available in glass-lined cast steel. Standard nominal pipe sizes available are 1½ through 8 in. Larger-diameter pipe up to 48 in is available on a custom-order basis. A range of lengths are generally available. See Table 10-40 for dimensional data. Steel split flanges drilled to ANSI B16.5 Class 150 dimensions along with PTFE envelope gaskets are used for the assembly of the system.

**Fused Silica or Fused Quartz** Containing 99.8 percent silicon dioxide, fused silica or fused quartz can be obtained as opaque or transparent pipe and tubing. The melting point is 1710°C (3100°F). Tensile strength is approximately 48 MPa (7000 lbf/in$^2$); specific gravity is about 2.2. The pipe and tubing can be used continuously at temperatures up to 1000°C (1830°F) and intermittently up to 1500°C (2730°F). The material's chief assets are noncontamination of most chemicals in high-temperature service, thermal-shock resistance, and high-temperature electrical insulating characteristics.

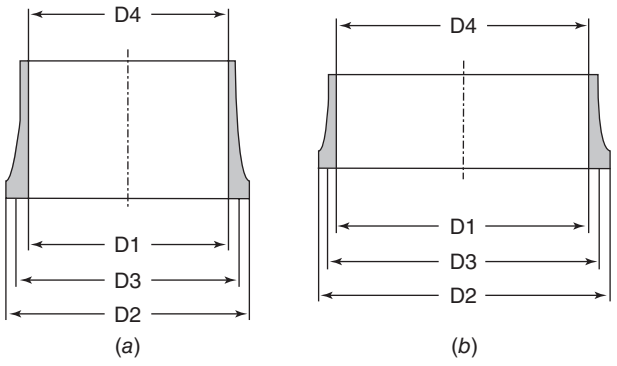

**FIG. 10-154** Flanged pipe ends. (*Adapted with permission of De Dietrich Process Systems, Mountainside, N.J.*)

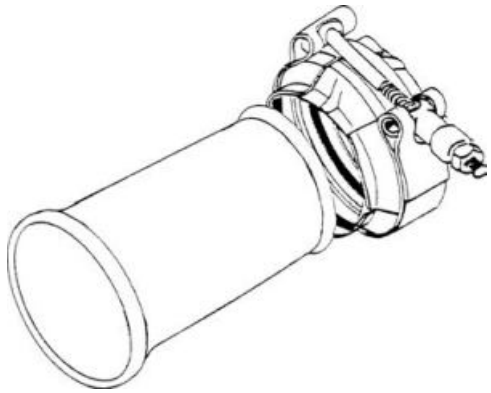

**FIG. 10-155** Joint with beaded pipe ends. (*Adapted with permission of De Dietrich Process Systems, Mountainside, N.J.*)

Transparent tubing is available in inside diameters from 1 to 125 mm in a range of wall thicknesses. Satin-surface tubing is available in inside diameters from $\frac{1}{8}$ to 2 in, and sand-surface pipe and tubing are available in ½- to 24-in inside diameters and lengths up to 6 m (20 ft). Sand-surface pipe and tubing are obtainable in wall thicknesses varying from ⅛ to 1 in. Pipe and tubing sections in both opaque and transparent fused silica or fused quartz can be readily machine-ground to special tolerances for pressure joints or other purposes. Also, fused-silica piping and tubing can be reprocessed to meet special design requirements. Manufacturers should be consulted for specific details.

**Plastic-Lined Steel Pipe** Use of a variety of polymeric materials as liners for steel pipe rather than as piping systems solves problems which the relatively low tensile strength of the polymer at elevated temperature and high thermal expansion, compared with steel, would produce. The steel outer shell permits much wider spacing of supports, reliable flanged joints, and higher pressure and temperature in the piping. The size range is 1 through 12 in. The systems are flanged with 125-lb cast-iron, 150-lb ductile-iron, and 150- and 300-lb steel flanges. The linings are factory-installed in both pipe and fittings. Lengths are available up to 6 m (20 ft). Lined ball, diaphragm, and check valves and plug cocks are available.

One method of manufacture consists of inserting the liner into an oversize, approximately Schedule 40 steel tube and swaging the assembly to produce iron-pipe-size outside diameter, firmly engaging the liner which projects from both ends of the pipe. Flanges are then screwed onto the pipe, and the projecting liner is hot-flared over the flange faces nearly to the bolt holes. In another method, the liner is pushed into steel pipe having cold-flared laps backed up by flanges at the ends and then is hot-flared over the faces of the laps. Pipe lengths made by either method may be shortened in the field and reflared with special procedures and tools. Square and tapered spacers are furnished to adjust for small discrepancies in assembly.

Liner types available are suitable for a wide variety of chemical services, including acids, alkalies, and various solvents. All liners are permeable to some degree, and manufacturers use various methods to vent gas out of the interspace between the liner and casing. All plastics are subject to *environmental stress cracking* (ESC). ESC can occur even when the liner is chemically resistant to the service. Lined pipe manufacturers should always be consulted regarding liner selections and service applications. Also consult manufacturers regarding vacuum service limits.

**TABLE 10-40 Glass-Lined Steel Pipe***

| Size, in | Outside diameter, in | Range of standard lengths, in | |
|---|---|---|---|
| | | Minimum | Maximum |
| 1½ | 1.900 | 6 | 60 |
| 2 | 2.375 | 6 | 84 |
| 3 | 3.500 | 6 | 120 |
| 4 | 4.500 | 6 | 120 |
| 6 | 6.625 | 6 | 120 |
| 8 | 8.625 | 6 | 120 |

*Adapted with permission of De Dietrich Process Systems, Mountainside, N.J. Other manufacturers may offer different standard lengths.

***Polyvinylidene Chloride Liners*** Polyvinylidene chloride liners have excellent resistance to hydrochloric acid. Maximum temperature is 80°C (175°F). Polyvinylidene chloride is also known as Saran, a product of Dow Chemical Co.

***Polypropylene Liners*** Polypropylene liners are used in sulfuric acid service. At 10 to 30 percent concentration the upper temperature limit is 93°C (200°F). Polypropylene is also suitable for higher concentrations at lower temperatures.

***Kynar Liners*** Kynar (Pennwalt Chemicals Corp.) polyvinylidene fluoride liners are used for many chemicals, including bromine and 50 percent hydrochloric acid.

***PTFE and PFA Lined Steel Pipe*** These are available in sizes from 1 through 12 in and in lengths through 6 m (20 ft). Experience has determined that practical upper temperature limits are approximately 204°C (400°F) for PTFE (polytetrafluoroethylene) and PFA (perfluoroalkoxy) and 149°C (300°F) for FEP (fluoroethylene polymer); Class 150 and 300 ductile-iron or steel flanged lined fittings and valves are used. The nonadhesive properties of the liner make it ideal for handling sticky or viscous substances. The thickness of the lining varies from 1.5 to 3.8 mm (60 to 150 mil), depending on the pipe size. Only flanged joints are used.

**Rubber-Lined Steel Pipe** This pipe is made in lengths up to 6 m (20 ft) with seamless, straight seam-welded and some types of spiral-welded pipe using various types of natural and synthetic adhering rubber. The type of rubber is selected to provide the most suitable lining for the specific service. In general, soft rubber is used for abrasion resistance, semihard for general service, and hard for the more severe service conditions. Multiple-ply lining and combinations of hard and soft rubber are available. The thickness of lining ranges from 3.2 to 6.4 mm (⅛ to ¼ in) depending on the service, the type of rubber, and the method of lining. Cast-steel, ductile-iron, and cast-iron flanged fittings are available rubber-lined. The fittings are usually purchased by the vendor since absence of porosity on the inner surface is essential. Pipe is flanged before rubber lining, and welding elbows and tees may be incorporated at one end of the length of pipe, subject to the conditions that the size of the pipe and the location of the fittings be such that the operator doing the lining can place a hand on any point on the interior surface of the fitting. Welds must be ground smooth on the inside, and a radius is required at the inner edge of the flange face.

The rubber lining is extended out over the face of flanges. With hard-rubber lining, a gasket is required. With soft-rubber lining, a release coating or a polyethylene sheet is required in place of a gasket to avoid bonding of the lining of one flange to the lining on the other and to permit disassembly of the flanged joint. Also, for pressures over 0.86 MPa (125 lbf/in$^2$), the tendency of soft-rubber linings to extrude out between the flanges may be prevented by terminating the lining inside the bolt holes and filling the balance of the space between the flange faces with a spacer of the proper thickness. Hard-rubber-lined gate, diaphragm, and swing check valves are available. In gate valves, the stem, wedge assembly, and seat rings—and in the check valves, the hinge pin, flapper arm, disk, and seat ring—must be made of metal resistant to the solution handled.

**Plastic Pipe** In contrast to other piping materials, plastic pipe is free from internal and external corrosion, is easily cut and joined, and does not cause galvanic corrosion when coupled to other materials. Allowable stresses and upper temperature limits are low. Normal operation is in the creep range. Fluids for which a plastic is not suited penetrate and soften it rather than dissolve surface layers. Coefficients of thermal expansion are high.

Plastic pipe or tubing may be used for a wide variety of services. As with all nonmetallic materials, code restrictions limit the applications in which their use is permitted. In general, their use in flammable or toxic service is limited. Plastic tubing of various types may be used for instrument air-signal connections; however, as is the case with all nonmetallic applications, the need for fire resistance must be considered. When it is used in specialized applications such as potable water or underground fire water, care should be taken to ensure that the specified products are certified by appropriate agencies such as the National Sanitation Foundation and Factory Mutual.

Support spacing must be much closer than for carbon steel. As temperature increases, the allowable stress for many plastic pipes decreases very rapidly, and heat from sunlight or adjacent hot uninsulated equipment has a marked effect. Many plastics deteriorate with exposure to ultraviolet light if not provided with a UV-resistant coating or other surface barrier. Successful economical underground use of plastic pipe does not necessarily indicate similar economies outdoors aboveground.

Methods of joining include threaded joints with IPS dimensions, solvent-welded joints, heat-fused joints, and insert fittings. Schedules 40 and 80 (see Table 10-22) have been used as a source for standardized dimensions at joints. Some plastics are available in several grades with allowable stresses varying by a factor of 2 to 1. For the same plastic, ½-in Schedule 40 pipe of the strongest grade may have 4 times the allowable internal pressure of the weakest grade of a 2-in Schedule 40 pipe. For this reason, the plastic-pipe industry is shifting to standard dimension ratios (approximately the same ratio of diameter to wall thickness over a wide range of pipe sizes).

ASTM and the Plastics Pipe Institute have established identifications for plastic pipe in which the first group of letters identifies the plastic, the two following numbers identify the grade of that plastic, and the last two numbers represent the design stress in the nearest lower 0.7 MPa (100 lbf/in$^2$) unit at 23°C (73.4°F).

***Polyethylene*** The Plastics Pipe Institute (www.plasticpipe.org) is an excellent source of information regarding specification, design, fabrication, and testing of polyethylene piping. Polyethylene (PE) pipe and tubing are available in sizes 48 in and smaller. They have excellent resistance at room temperature to salts, sodium and ammonium hydroxides, and sulfuric, nitric, and hydrochloric acids. *High-density polyethylene* (HDPE) is often used for underground fire water. Pipe and tubing are produced by extrusion from resins whose density varies with the manufacturing process. Physical properties and therefore wall thickness depend on the particular resin used. In some products, about 3 percent carbon black is added to provide resistance to ultraviolet light. Use of higher-density resin reduces splitting and pinholing in service and increases the strength of the material and the maximum service temperature.

ASTM D2104 covers PE pipe in sizes ½ through 6 in with IPS Schedule 40 outside and inside diameters for insert-fitting joints. ASTM D2239 covers six standard dimension ratios of pipe diameter to wall thickness in sizes ½ through 6 in. ASTM D2447 covers sizes ½ through 12 in with IPS Schedule 40 and 80 outside and inside diameters for use with heat-fusion socket-type and butt-type fittings. ASTM D3035 covers 10 standard dimension ratios of pipe sizes from ½ through 24 in with IPS outside diameters. All these specifications cover various PE materials. Hydrostatic design stresses within the recommended temperature limits are given in App. B, Table B-1, of the code. The hydrostatic design stress is the maximum tensile hoop stress due to internal hydrostatic water pressure that can be applied continuously with a high degree of certainty that failure of the pipe will not occur. Both manufacturers and the Plastic Pipe Institute publish literature describing design calculations required to determine the required wall thickness.

Polyethylene water piping is not damaged by freezing. Pipe and tubing 2 in and smaller are shipped in coils several hundred feet in length.

Clamped-insert joints (Fig. 10-156) are used for flexible plastic pipe up through the 2-in size. Friction between the pipe and the spud is developed both by forcing the spud into the pipe and by tightening the clamp. For the larger sizes, which have thicker walls, these methods cannot develop adequate friction. Insert joints also have high pressure drop. Stainless steel bands are available. Inserts are available in nylon, polypropylene, and a variety of metals.

Joints of all sizes may be made with heat fusion techniques. Fused joints may be made with either electrofusion or conventional heat fusion. Electrofusion joints are made with fittings that have embedded heating wires. Conventional fusion joints are made with special machines that trim the pipe ends, apply heat, and then force them together to form a bond. Consult the manufacturer regarding the sizes for which electrofusion fittings are available.

A significant use for PE and PP pipe is the technique of rehabilitating deteriorated pipe lines by lining them with plastic pipe. Lining an existing pipe with plastic pipe has a large cost advantage over replacing the line, particularly if replacement of the old line would require excavation.

***Polyvinyl Chloride*** Polyvinyl chloride (PVC) pipe and tubing are available with socket fittings for solvent-cemented joints in sizes 24 in and smaller. PVC with gasketed bell and spigot joints is available in sizes 4 through 48 in. Chlorinated polyvinyl chloride (CPVC) pipe and tubing are available with socket fittings for solvent-cemented joints in sizes 4 in and smaller. PVC and CPVC are suitable for a variety of chemical services and

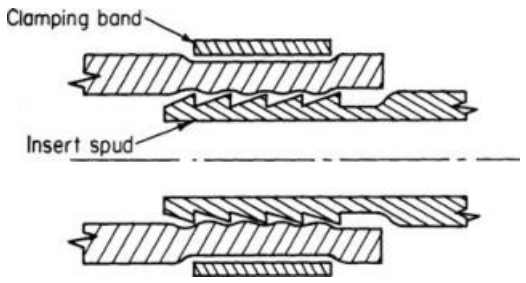

**FIG. 10-156** Clamped-insert joint.

are commonly used for potable water. Consult manufacturers or the Plastics Pipe Institute for chemical resistance data. Hydrostatic design stresses within the temperature limits are given in App. B, Table B-1, of the code.

ASTM D1785 covers sizes from ⅛ through 12 in of PVC pipe in IPS Schedules 40, 80, and 120, except that Schedule 120 starts at ½ in and is not IPS for sizes from ½ through 3 in. ASTM D2241 covers sizes ⅛ through 36 in but with IPS outside diameter and seven standard dimension ratios: 13.5, 17, 21, 26, 32.5, 41, and 64.

ASTM D2513 specifies requirements for thermoplastic materials for buried fuel gas and relining applications. Materials addressed include PE, PVC, and *crosslinked polyethylene* (PEX). Tubing sizes covered are ¼ through 1¼ in. IPS sizes covered are ½ through 12 in. Size availability depends upon the material.

Solvent-cemented joints (Fig. 10-139) are standard, but screwed joints are sometimes used with Schedule 80 pipe. Cemented joints must not be disturbed for 5 min and achieve full strength in 1 day. A wide variety of valve types are available in PVC and CPVC.

***Polypropylene*** Polypropylene (PP) pipe and fittings have excellent resistance to most common organic and mineral acids and their salts, strong and weak alkalies, and many organic chemicals. They are available in sizes ½ through 6 in, in Schedules 40 and 80, but are not covered as such by ASTM specifications.

**Reinforced-Thermosetting-Resin (RTR) Pipe** Glass-reinforced epoxy resin has good resistance to nonoxidizing acids, alkalies, saltwater, and corrosive gases. The glass reinforcement is many times stronger at room temperature than plastics are, does not lose strength with increasing temperature, and reinforces the resin effectively up to 149°C (300°F). (See Table 10-21 for temperature limits.) The glass reinforcement is located near the outside wall, protected from the contents by a thick wall of resin and protected from the atmosphere by a thin wall of resin. Stock sizes are 2 through 12 in.

Pipe is supplied in 6- and 12-m (20- and 40-ft) lengths. It is more economical for long, straight runs than for systems containing numerous fittings. When the pipe is sawed to nonfactory lengths, it must be sawed very carefully to avoid cracking the interior plastic zone. A two-component cement may be used to bond lengths into socket couplings or flanges or cemented-joint fittings. Curing of the cement is temperature-sensitive; it sets to full strength in 45 min at 93°C (200°F), in 12 h at 38°C (100°F), and in 24 h at 10°C (50°F). Extensive use is made of shop-fabricated flanged preassemblies. Only flanged joints are used to connect to metallic piping systems. Compared with that of other plastics, the ratio of fitting cost to pipe cost is high. Cemented-joint fittings and flanged fittings are available. Internally lined flanged metallic valves are used.

RTR is more flexible than metallic pipe and consequently requires closer support spacing. While the recommended spacing varies among manufacturers and with the type of product, Table 10-41 gives typical hanger-spacing ranges. The pipe fabricator should be consulted for recommended hanger spacing on the specific pipe-wall construction being used.

Epoxy resin has a higher strength at elevated temperatures than polyester resins but is not as resistant to attack by some fluids. Some glass-reinforced epoxy-resin pipe is made with a polyester-resin liner. The coefficient of thermal expansion of glass-reinforced resin pipe is higher than that for carbon steel but much less than that for plastics.

Glass-reinforced polyester is the most widely used reinforced-resin system. A wide choice of polyester resins are available. The bisphenol resins resist strong acids as well as alkaline solutions. The size range is 2 through at least 36 in; the temperature range is shown in Table 10-21. Diameters are not standardized. Adhesive-cemented socket joints and hand-layup reinforced butt joints are used. For the latter, reinforcement consists of layers of glass cloth saturated with adhesive cement.

## DESIGN OF PIPING-SYSTEMS

**Safeguarding** *Safeguarding* may be defined as the provision of protective measures as required to ensure the safe operation of a proposed piping system. General considerations to be evaluated should include (1) the hazardous properties of the fluid, (2) the quantity of fluid that could be released by a piping failure, (3) the effect of a failure (such as possible loss of cooling water) on overall plant safety, (4) evaluation of effects on a reaction with the environment (i.e., possibility of a nearby source of ignition), (5) the probable extent of exposure of operating or maintenance personnel, and (6) the relative inherent safety of the piping by virtue of materials of construction, methods of joining, and history of service reliability.

Evaluation of safeguarding requirements might include engineered protection against possible failures such as thermal insulation, armor, guards, barricades, and damping for protection against severe vibration, water hammer, or cyclic operating conditions. Simple means to protect people and property such as shields for valve bonnets, flanged joints, and sight glasses should not be overlooked. The necessity for means to shut off or control flow in the event of a piping failure such as block valves or excess-flow valves should be examined.

**Classification of Fluid Services** The code applies to piping systems as illustrated in Fig. 10-116, but two categories of fluid services are segregated for special consideration as follows:

**Category D** *Category D fluid service* is defined as a fluid service to which all the following apply: (1) the fluid handled is nonflammable and nontoxic; (2) the design gage pressure does not exceed 150 psi (1.0 MPa); and (3) the design temperature is between −20°F (−29°C) and 366°F (186°C).

**Category M** *Category M fluid service* is defined as a fluid service in which a single exposure to a very small quantity of a toxic fluid, caused by leakage, can produce serious irreversible harm to persons on breathing or bodily contact, even when prompt restorative measures are taken.

The code assigns to the owner the responsibility for identifying those fluid services which are in Categories D and M. The design and fabrication requirements for Class M toxic-service piping are beyond the scope of this text. See ASME B31.3-2014, chap. VIII.

**Design Conditions** Definitions of the temperatures, pressures, and various forces applicable to the design of piping systems are as follows:

***Design Pressure*** The design pressure of a piping system shall not be less than the pressure at the most severe condition of coincident internal or external pressure and temperature resulting in the greatest required component thickness or rating.

***Design Temperature*** The design temperature is the material temperature representing the most severe condition of coincident pressure and temperature. For uninsulated metallic pipe with fluid below 65°C (150°F), the metal temperature is taken as the fluid temperature.

With fluid at or above 65°C (150°F) and without external insulation, the metal temperature is taken as a percentage of the fluid temperature unless a lower temperature is determined by test or calculation. For pipe, threaded and welding-end valves, fittings, and other components with a wall thickness comparable with that of the pipe, the percentage is 95 percent; for flanges and flanged valves and fittings, 90 percent; for lap-joint flanges, 85 percent; and for bolting, 80 percent.

With external insulation, the metal temperature is taken as the fluid temperature unless service data, tests, or calculations justify lower values. For internally insulated pipe, the design metal temperature shall be calculated or obtained from tests.

***Ambient Influences*** If cooling results in a vacuum, the design must provide for external pressure or a vacuum breaker installed; also provision must be made for thermal expansion of contents trapped between or in closed valves. Nonmetallic or nonmetallic-lined pipe may require protection when the ambient temperature exceeds the design temperature.

Occasional variations of pressure or temperature, or both, above operating levels are characteristic of certain services. If the following criteria are met, such variations need not be considered in determining pressure-temperature design conditions. Otherwise, the most severe conditions of coincident pressure and temperature during the variation shall be used to determine design conditions. (Application of pressures exceeding pressure-temperature ratings of valves may, under certain conditions, cause loss of seat tightness or difficulty of operation. Such an application is the owner's responsibility.)

All the following criteria must be met:

1. The piping system shall have no pressure-containing components of cast iron or other nonductile metal.
2. Nominal pressure stresses shall not exceed the yield strength at temperature (see $S_y$ data in ASME Boiler Pressure Vessel Code, Sec. II, Part D).
3. Combined longitudinal stresses $S_L$ shall not exceed the limits established in the code (see pressure design of piping components for $S_L$ limitations).
4. The total number of pressure-temperature variations above the design condition shall not exceed 1000 during the life of the piping system.
5. Occasional variations above design conditions shall remain within one of the following limits for pressure design:
   - When the variation lasts no more than 10 h at any one time and no more than 100 h/yr, it is permissible to exceed the pressure rating or the allowable stress for pressure design at the temperature of the increased condition by not more than 33 percent.

**TABLE 10-41 Typical Hanger-Spacing Ranges Recommended for Reinforced-Thermosetting-Resin Pipe**

| Nominal pipe size, in | 2 | 3 | 4 | 6 | 8 | 10 | 12 |
|---|---|---|---|---|---|---|---|
| Hanger-spacing range, ft | 5–8 | 6–9 | 6–10 | 8–11 | 9–13 | 10–14 | 11–15 |

NOTE: Consult pipe manufacturer for recommended hanger spacing for the specific RTR pipe being used. Tabulated values are based on a specific gravity of 1.25 for the contents of the pipe. To convert feet to meters, multiply by 0.3048.

- When the variation lasts no more than 50 h at any one time and not more than 500 h/yr, it is permissible to exceed the pressure rating or the allowable stress for pressure design at the temperature of the increased condition by not more than 20 percent.

***Dynamic Effects*** Design must provide for impact (hydraulic shock, etc.), wind (exposed piping), earthquake, discharge reactions, and vibrations (of piping arrangement and support).

***Weight Effects*** Weight considerations include (1) live loads (contents, ice, and snow), (2) dead loads (pipe, valves, insulation, etc.), and (3) test loads (test fluid).

***Thermal Expansion and Contraction Effects*** Thermal expansion and thermal contraction loads occur when a piping system is prevented from free thermal expansion or contraction as a result of anchors and restraints or undergoes large, rapid temperature changes or unequal temperature distribution because of an injection of cold liquid striking the wall of a pipe carrying hot gas.

**Effects of Support, Anchor, and Terminal Movements** The effects of movements of piping supports, anchors, and connected equipment shall be taken into account in the design of piping. These movements may result from the flexibility and/or thermal expansion of equipment, supports, or anchors; and from settlement, tidal movements, or wind sway.

**Reduced Ductility** The harmful effects of reduced ductility shall be taken into account in the design of piping. The effects may, for example, result from welding, heat treatment, forming, bending, or low operating temperatures, including the chilling effect of sudden loss of pressure on highly volatile fluids. Low ambient temperatures expected during operation shall be considered.

**Cyclic Effects** Fatigue due to pressure cycling, thermal cycling, and other cyclic loading shall be considered in the design.

**Air Condensation Effects** At operating temperatures below −191°C (−312°F) in ambient air, condensation and oxygen enrichment occur. These shall be considered in selecting materials, including insulation, and adequate shielding and/or disposal shall be provided.

**Design Criteria: Metallic Pipe** The code uses three different approaches to design:

1. It provides for the use of dimensionally standardized components at their published pressure-temperature ratings.
2. It provides design formulas and maximum stresses.
3. It prohibits the use of materials, components, or assembly methods in certain conditions.

***Components Having Specific Ratings*** These are listed in ASME, API, and industry standards. These ratings are acceptable for design pressures and temperatures unless limited in the code. A list of component standards is given in Appendix E of the ASME B31.3 code. Table 10-42 lists pressure-temperature ratings for flanges, flanged fittings, and flanged valves, and it has been extracted from ASME B16.5 with permission of the publisher, the American Society of Mechanical Engineers, New York. Only a few of the more common materials of construction of piping are reproduced here. See ASME B16.5 for other materials. Flanged joints, flanged valves in the open position, and flanged fittings may be subjected to system hydrostatic tests at a pressure not to exceed

(3) Not to be used over 1000°F.

the hydrostatic-shell test pressure. Flanged valves in the closed position may be subjected to a system hydrostatic test at a pressure not to exceed 110 percent of the 100°F rating of the valve unless otherwise limited by the manufacturer.

Pressure-temperature ratings for soldered tubing joints are given in ASME B16.22-2013.

***Components without Specific Ratings*** Components such as pipe and butt-welding fittings are generally furnished in nominal thicknesses. Fittings are rated for the same allowable pressures as pipe of the same nominal thickness and, along with pipe, are rated by the rules for pressure design and other provisions of the code.

**TABLE 10-42*e* Pressure–Temperature Ratings for Group 2.3 Materials (Type 304L and 316L Stainless Steel)**

NOTE:
(1) Not to be used over 800°F.

**Limits of Calculated Stresses Due to Sustained Loads and Displacement Strains**

1. *Internal pressure stresses.* Stresses due to internal pressure shall be considered safe when the wall thickness of the piping component, including any reinforcement, meets the requirements of the pressure design of components defined by the ASME B31.3 code.

2. *External pressure stresses.* Stresses due to external pressure shall be considered safe when both the wall thickness of the piping component and its means of stiffening meet the requirements of the pressure design of components defined by the ASME B31.3 code.

3. *Longitudinal stresses $S_L$.* The sum of longitudinal stresses $S_L$ in any component in a piping system, due to sustained loads such as pressure and weight, shall not exceed the product $S_hW$, where $S_h$ is the basic allowable stress at maximum metal temperature expected during the displacement cycle under analysis and $W$ is the weld joint strength reduction factor.

4. *Allowable displacement stress range $S_A$.* The computed displacement stress range $S_E$ in a piping system shall not exceed the allowable displacement stress range $S_A$.

$$S_A = f(1.25S_c + 0.25S_h) \tag{10-91}$$

When $S_h$ is greater than $S_L$, the difference between them may be added to the term $0.25S_h$ in Eq. (10-91). In that case, the allowable stress range is calculated by

$$S_A = f[1.25(S_c + S_h) - S_L] \tag{10-92}$$

where $S_A$ = allowable displacement stress range
$f$ = stress range factor (see Fig. 10-157)
$S_c$ = basic allowable stress at minimum metal temperature expected during displacement cycle under analysis
$S_h$ = basic allowable stress at maximum metal temperature expected during displacement cycle under analysis
$S_L$ = longitudinal stresses, including pressure and weight

5. *Weld joint strength reduction factor W.* It is very important to include the weld joint strength reduction factor $W$ in the design consideration. Especially, at elevated temperatures, the long-term strength of weld joints may be lower than the long-term strength of the base material. The weld joint strength reduction factor only applies at specific weld locations.

**Pressure Design of Metallic Components** External-pressure stress evaluation of piping is the same as for pressure vessels. But an important difference exists when one is establishing design pressure and wall thickness for internal pressure as a result of the ASME Boiler and Pressure Vessel Code's requirement that the relief-valve setting be not higher than the design pressure. For vessels this means that the design is for a pressure 10 percent more or less above the intended maximum operating pressure to avoid popping or leakage from the valve during normal operation. However, on piping the design pressure and temperature are taken as the maximum intended operating pressure and coincident temperature combination which results in the maximum thickness. The temporary increased operating conditions listed under "Design Criteria" cover temporary operation at pressures that cause relief valves to leak or open fully. Allowable stresses for nearly 1000 materials are contained in the code.

For *straight metal pipe under internal pressure* the formula for minimum required wall thickness $t_m$ is applicable for:

1. $t < D/6$. The internal pressure design thickness for straight pipe shall be not less than that calculated in accordance with the equation below. The more conservative Barlow and Lamé equations may also be used. Equation (10-93) includes a factor $Y$ varying with material and temperature to account for the redistribution of circumferential stress which occurs under steady-state creep at high temperature and permits slightly lesser thickness at this range.

$$t_m = \frac{PD_o}{2(SE + PY)} \div C \tag{10-93}$$

where (in consistent units)
$P$ = design pressure
$D_o$ = outside diameter of pipe
$C$ = sum of allowances for corrosion, erosion, and any thread or groove depth. For threaded components the depth is $h$ of ASME B1.20.1, and for grooved components the depth is the depth removed (0.02 in when no tolerance is specified).
$SE$ = allowable stress
$S$ = basic allowable stress for materials, excluding casting, joint, or structural-grade quality factors

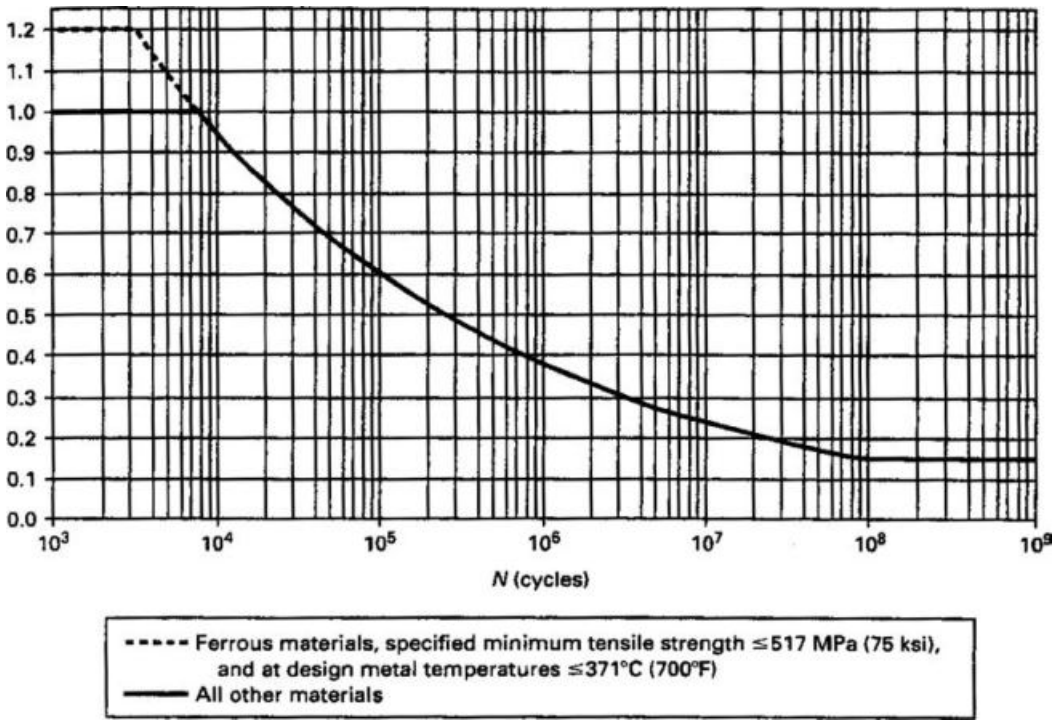

**FIG. 10-157** Stress range reduction factor *f*. (*Reproduced from ASME B31.3-2004 with permission of the publisher, the American Society of Mechanical Engineers, New York. All rights reserved.*)

$E$ = quality factor, which is one or the product of more than one of the following quality factors: casting quality factor $E_c$, joint quality factor $E_j$ (see Fig. 10-158)
$W$ = weld joint strength reduction factor in accordance with ASME B31.3.
$Y$ = coefficient having value in Table 10-43 valid for $t < D/6$ and for materials shown
$t_m$ = minimum required thickness, in, including mechanical, corrosion, and erosion allowances

2. $t \geq D/6$ or $P/SE > 0.385$. Calculation of pressure design thickness for straight pipe requires special consideration of factors such as theory of failure, effects of fatigue, and thermal stress.

For flanges of nonstandard dimensions or for sizes beyond the scope of the approved standards, design shall be in accordance with the requirements of the ASME Boiler and Pressure Vessel Code, Sec. VIII, except that requirements for fabrication, assembly, inspection testing, and the pressure and temperature limits for materials of the Piping Code are to prevail. Countermoment flanges of flat face or otherwise providing a reaction outside the bolt circle are permitted if designed or tested in accordance with code requirements under pressure-containing components "not covered by standards and for which design formulas or procedures are not given."

**Test Conditions** The shell pressure test for flanged fittings shall be at a pressure no less than 1.5 times the 38°C (100°F) pressure rating rounded off to the next higher 1-bar (25 psi) increment.

In accordance with listed standards, *blind flanges* may be used at their pressure-temperature ratings. The minimum thickness of nonstandard blind flanges shall be the same as for a bolted flat cover, in accordance with the rules of the ASME Boiler and Pressure Vessel Code, Sec. VIII.

*Operational blanks* shall be of the same thickness as blind flanges or may be calculated by the following formula (use consistent units):

$$t = d\sqrt{3P/16SE} + C \tag{10-94}$$

where $d$ = inside diameter of gasket for raised- or flat (plain)-face flanges, or gasket pitch diameter for retained gasketed flanges
$P$ = internal design pressure or external design pressure
$S$ = applicable allowable stress
$E$ = quality factor
$C$ = sum of the mechanical allowances

*Valves* must comply with the applicable standards listed in Table 326.1 and App. E of the code and with the allowable pressure-temperature limits established thereby but not beyond the code-established service or materials limitations. Special valves must meet the same requirements as for countermoment flanges.

The code contains no specific rules for the design of *fittings* other than as branch openings. Ratings established by recognized standards are acceptable, however. ASME Standard B16.5 for steel-flanged fittings incorporates a 1.5 shape factor and thus requires the entire fitting to be 50 percent heavier than a simple cylinder in order to provide reinforcement for openings and/or general shape. ASME B16.9 for butt-welded fittings, on the other hand, requires only that the fittings be able to withstand the calculated bursting strength of the straight pipe with which they are to be used.

The thickness of *pipe bends* shall be determined as for straight pipe, provided the bending operation does not result in a difference between maximum and minimum diameters greater than 8 and 3 percent of the nominal outside diameter of the pipe for internal and external pressure, respectively.

The maximum allowable internal pressure for multiple miter bends shall be the lesser value calculated from Eqs. (10-95) and (10-96). These equations are not applicable when θ exceeds 22.5°.

$$P_m = \frac{SEW(T-C)}{r^2} = \frac{T-C}{(T-C)+0.643\ \tan\theta\sqrt{r_2(T-C)}} \tag{10-95}$$

$$P_m = \frac{SEW(T-C)}{r^2} = \frac{R_1 - r_2}{R_1 - 0.5r_2} \tag{10-96}$$

where the nomenclature is the same as for straight pipe except as follows (see Fig. 10-159):
$S$ = stress value for material
$C$ = sum of mechanical allowances
$r_2$ = mean radius of pipe
$R_1$ = effective radius of miter bend, defined as the shortest distance from the pipe centerline to the intersection of the planes of adjacent miter joints
θ = angle of miter cut
α = angle of change in direction at miter joint = 2θ
$T$ = pipe wall thickness
$W$ = weld joint strength reduction factor
$E$ = quality factor

| No. | Type of joint | | Type of seam | Examination | Factor, $E_j$ |

For compliance with the code, the value of $R_1$ shall not be less than that given by Eq. (10-97):

$$R_1 = A/\tan\theta + D/2 \tag{10-97}$$

where $A$ has the following empirical values:

| $t$, in | $A$ |
|---|---|
| $t \le 0.5$ | 1.0 |
| $0.5 < t < 0.88$ | $2(T - C)$ |
| $t \ge 0.88$ | $[2(T - C)/3] + 1.17$ |

*Piping branch connections* involve the same considerations as pressure-vessel nozzles. However, outlet size in proportion to piping header size is unavoidably much greater for piping. The current Piping Code rules for calculation of branch-connection reinforcement are similar to those of the ASME Boiler and Pressure Vessel Code, Sec. VIII, Division I-2014 for a branch with axis at right angles to the header axis. If the branch connection makes an angle β with the header axis from 45 to 90°, the Piping Code requires that the area to be replaced be increased by dividing it by sin β. In such cases the half width of the reinforcing zone measured along the header axis is similarly increased, except that it may not exceed the outside diameter of the header. Some details of commonly used reinforced branch connections are given in Fig. 10-160.

The rules provide that a branch connection has adequate strength for pressure if a fitting (tee, lateral, or cross) is in accordance with an approved standard and is used within the pressure-temperature limitations or if the connection is made by welding a coupling or half coupling (wall thickness not less than the branch anywhere in reinforcement zone or less than extra heavy or 3000 lb) to the run and provided the ratio of branch to run diameters is not greater than one-fourth and that the branch is not greater than 2 in nominal diameter.

Dimensions of extra-heavy couplings are given in the *Steel Products Manual* published by the American Iron and Steel Institute. In ASME B16.11-2014, 2000-lb couplings were superseded by 3000-lb couplings.

ASME B31.3 states that the reinforcement area for resistance to external pressure is to be at least one-half of that required to resist internal pressure.

The code provides no guidance for analysis but requires that external and internal *attachments* be designed to avoid flattening of the pipe, excessive localized bending stresses, or harmful thermal gradients, with further emphasis on minimizing stress concentrations in cyclic service.

The code provides design requirements for *closures* which are flat, ellipsoidal, spherically dished, hemispherical, conical (without transition knuckles), conical convex to pressure, toriconical concave to pressure, and toriconical convex to pressure.

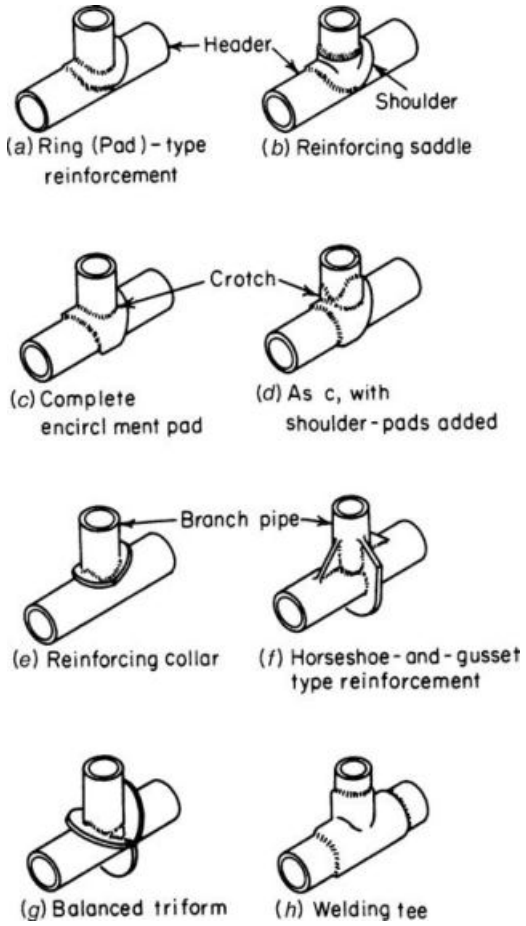

**FIG. 10-160** Types of reinforcement for branch connections. (From Kellogg, *Design of Piping Systems*, Wiley, New York, 1965.)

*Openings in closures* over 50 percent in diameter are designed as flanges in flat closures and as reducers in other closures. Openings of not over one-half of the diameter are to be reinforced as branch connections.

**Thermal Expansion and Flexibility: Metallic Piping** ASME B31.3 requires that piping systems have sufficient flexibility to prevent thermal expansion or contraction or the movement of piping supports or terminals from causing (1) failure of piping supports from overstress or fatigue; (2) leakage at joints; or (3) detrimental stresses or distortions in piping or in connected equipment (pumps, turbines, or valves, for example), resulting from excessive thrusts or movements in the piping.

To ensure that a system meets these requirements, the computed displacement–stress range $S_E$ shall not exceed the allowable stress range $S_A$ [Eqs. (10-91) and (10-92)], the reaction forces $R_m$ [Eq. (10-104)] shall not be detrimental to supports or connected equipment, and movement of the piping shall be within any prescribed limits.

***Displacement Strains*** Strains result from piping being displaced from its unrestrained position:

1. *Thermal displacements.* A piping system will undergo dimensional changes with any change in temperature. If it is constrained from free movement by terminals, guides, and anchors, then it will be displaced from its unrestrained position.

2. *Reaction displacements.* If the restraints are not considered rigid and there is a predictable movement of the restraint under load, this may be treated as a compensating displacement.

3. *Externally imposed displacements.* Externally caused movement of restraints will impose displacements on the piping in addition to those related to thermal effects. Such movements may result from causes such as wind sway or temperature changes in connected equipment.

***Total Displacement Strains*** Thermal displacements, reaction displacements, and externally imposed displacements all have equivalent effects on the piping system and must be considered together in determining the total displacement strains in a piping system.

Expansion strains may be taken up in three ways: by bending, by torsion, or by axial compression. In the first two cases, maximum stress occurs at the extreme fibers of the cross section at the critical location. In the third case, the entire cross-sectional area over the entire length for practical purposes is equally stressed.

Bending or torsional flexibility may be provided by bends, loops, or offsets; by corrugated pipe or expansion joints of the bellows type; or by other devices permitting rotational movement. These devices must be anchored or otherwise suitably connected to resist end forces from fluid pressure, frictional resistance to pipe movement, and other causes.

Axial flexibility may be provided by expansion joints of the slip-joint or bellows types, suitably anchored and guided to resist end forces from fluid pressure, frictional resistance to movement, and other causes.

***Displacement Stresses*** Stresses may be considered proportional to the total displacement strain only if the strains are well distributed and not excessive at any point. The methods outlined here and in the code are applicable only to such a system. Poor distribution of strains (unbalanced systems) may result from the following:

1. Highly stressed small-size pipe runs in series with large and relatively stiff pipe runs
2. Local reduction in size or wall thickness or local use of a material having reduced yield strength (for example, girth welds of substantially lower strength than the base metal)
3. A line configuration in a system of uniform size in which expansion or contraction must be absorbed largely in a short offset from the major portion of the run

If unbalanced layouts cannot be avoided, appropriate analytical methods must be applied to ensure adequate flexibility. If the designer determines that a piping system does not have adequate inherent flexibility, additional flexibility may be provided by adding bends, loops, offsets, swivel joints, corrugated pipe, expansion joints of the bellows or slip-joint type, or other devices. Suitable anchoring must be provided.

As contrasted with stress from sustained loads such as internal pressure or weight, displacement stresses may be permitted to cause limited overstrain in various portions of a piping system. When the system is operated initially at its greatest displacement condition, any yielding reduces stress. When the system is returned to its original condition, there occurs a redistribution of stresses which is referred to as *self-springing*. It is similar to cold springing in its effects.

Stresses resulting from thermal strain tend to diminish with time. However, the algebraic difference in displacement condition and in either the original (as-installed) condition or any anticipated condition with a greater opposite effect than the extreme displacement condition remains substantially constant during any one cycle of operation. This difference is defined as the *displacement-stress range*, and it is a determining factor in the design of piping for flexibility. See Eqs. (10-91) and (10-92) for the allowable stress range $S_A$ and Eq. (10-99) for the computed stress range $S_E$.

***Cold Spring*** The intentional deformation of piping during assembly to produce a desired initial displacement and stress is called *cold spring*. For pipe operating at a temperature higher than that at which it was installed, cold spring is accomplished by fabricating it slightly shorter than design length. Cold spring is beneficial in that it serves to balance the magnitude of stress under initial and extreme displacement conditions. When cold spring is properly applied, there is less likelihood of overstrain during initial operation; hence, it is recommended especially for piping materials of limited ductility. There is also less deviation from as-installed dimensions during initial operation, so that hangers will not be displaced as far from their original settings.

Inasmuch as the service life of a system is affected more by the range of stress variation than by the magnitude of stress at a given time, no credit for cold spring is permitted in stress-range calculations. However, in calculating the thrusts and moments when actual reactions as well as their range of variations are significant, credit is given for cold spring.

Values of thermal expansion coefficients to be used in determining total displacement strains for computing the stress range are determined from Table 10-44 as the algebraic difference between the value at the design maximum temperature and that at the design minimum temperature for the thermal cycle under analysis.

***Values for Reactions*** Values of thermal displacements to be used in determining total displacement strains for the computation of reactions on supports and connected equipment shall be determined as the algebraic difference between the value at design maximum (or minimum) temperature for the thermal cycle under analysis and the value at the temperature expected during installation.

The as-installed and maximum or minimum moduli of elasticity $E_a$ and $E_m$, respectively, shall be taken as the values shown in Table 10-45.

Poisson's ratio may be taken as 0.3 at all temperatures for all metals.

The allowable stress range for displacement stresses $S_A$ and permissible additive stresses shall be as specified in Eqs. (10-91) and (10-92) for systems primarily stressed in bending and/or torsion. For pipe or piping components containing longitudinal welds, the basic allowable stress $S$ may be used to determine $S_A$.

Nominal thicknesses and outside diameters of pipe and fittings shall be used in flexibility calculations.

In the absence of more directly applicable data, the flexibility factor $k$ and stress intensification factor $i$ shown in Table 10-46 may be used in flexibility calculations in Eq. (10-100). For piping components or attachments (such as valves, strainers, anchor rings, and bands) not covered in the table, suitable stress intensification factors may be assumed by comparison of their significant geometry with that of the components shown.

***Requirements for Analysis*** No formal analysis of adequate flexibility is required in systems which (1) are duplicates of successfully operating installations or replacements without significant change of systems with a satisfactory service record; (2) can readily be judged adequate by comparison with previously analyzed systems; or (3) are of uniform size, have no more than two points of fixation, have no intermediate restraints, and fall within the limitations of empirical Eq. (10-98)*

$$\frac{Dy}{(L-U)^2} \le K_1 \tag{10-98}$$

where $D$ = outside diameter of pipe, in (mm)
$y$ = resultant of total displacement strains, in (mm), to be absorbed by the piping system
$L$ = developed length of piping between anchors, ft (m)
$U$ = anchor distance, straight line between anchors, ft (m)
$K_1 = 208{,}000\ S_A/E_{ar}$, $(\text{mm/m})^2$
$= 30\ S_A/E_{ar}$ $(\text{in/ft})^2$
= 208.0 for SI units listed in parentheses

1. All systems not meeting these criteria shall be analyzed by simplified, approximate, or comprehensive methods of analysis appropriate for the specific case.
2. Approximate or simplified methods may be applied only if they are used in the range of configurations for which their adequacy has been demonstrated.
3. Acceptable comprehensive methods of analysis include analytical and chart methods that provide an evaluation of the forces, moments, and stresses caused by displacement strains.
4. Comprehensive analysis shall take into account stress-intensification factors for any component other than straight pipe. Credit may be taken for the extra flexibility of such a component.

In calculating the flexibility of a piping system between anchor points, the system shall be treated as a whole. The significance of all parts of the line and of all restraints introduced for the purpose of reducing moments and forces on equipment or small branch lines and also the restraint introduced by support friction shall be recognized. Consider all displacements over the temperature range defined by the operating and shutdown conditions.

***Flexibility Stresses*** Bending and torsional stresses shall be computed using the as-installed modulus of elasticity $E_a$ and then combined in accordance with Eq. (10-99) to determine the computed displacement stress range $S_E$, which shall not exceed the allowable stress range $S_A$ [Eqs. (10-91) and (10-92)]:

$$S_E = \sqrt{S_b^2 + 4S_t^2} \tag{10-99}$$

where $S_a$ = axial stress range due to displacement strains
$= i_a F_a / A_p$
$A_p$ = cross-sectional area of pipe; nominal thickness and outside diameters of pipe
$F_a$ = axial force range between any two conditions being evaluated
$i_a$ = axial stress intensification factor
$i_t$ = torsional stress intensification factor
$S_b$ = resultant bending stress, $\text{lbf/in}^2$ (MPa)
$S_t = M_t/2Z$ = torsional stress, $\text{lbf/in}^2$ (MPa)
$M_t$ = torsional moment, in · lbf (N · mm)
$Z$ = section modulus of pipe, $\text{in}^3$ ($\text{mm}^3$)

**Warning:* No general proof can be offered that this equation will yield accurate or consistently conservative results. It is not applicable to systems used under severe cyclic conditions. It should be used with caution in configurations such as unequal leg U bends ($L/U > 2.5$) or near-straight sawtooth runs, or for large thin-wall pipe ($i \ge 5$), or when extraneous displacements (not in the direction connecting anchor points) constitute a large part of the total displacement. There is no assurance that terminal reactions will be acceptably low even if a piping system falls within the limitations of Eq. (10-98).

## TABLE 10-44 Thermal Coefficients, USCS Units, for Metals

Mean coefficient of linear thermal expansion between 70°F and indicated temperature, μin/(in · °F)

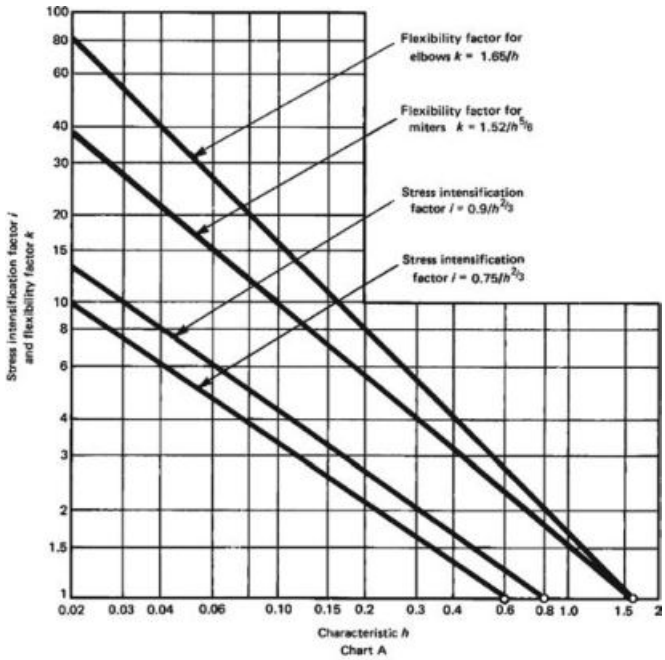
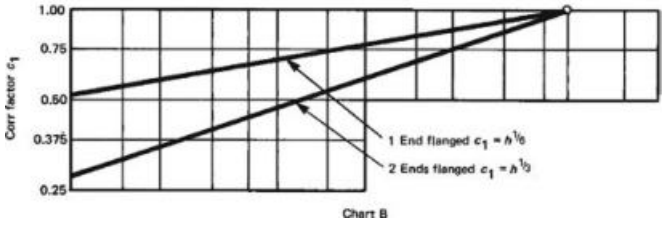
**TABLE 10-46 Flexibility Factor, *k*, and Stress Intensification Factor, *i***

| Description | Flexibility factor, $k$ | Stress Intensification Factor [Notes (1), (2)] | | Flexibility characteristic, $h$ | Sketch |
|---|---|---|---|---|---|
| | | Out-of-plane, $i_o$ | In-plane, $i_i$ | | |
| Welding elbow or pipe bend [Notes (1), (3)–(6)] | $\frac{1.65}{h}$ | $\frac{0.75}{h^{2/3}}$ | $\frac{0.9}{h^{2/3}}$ | $\frac{\bar{T}R_1}{r_2^2}$ |   |
| Closely spaced miter bend $s < r_2(1 + \tan\theta)$ [Notes (1), (3), (4), (6)] | $\frac{1.52}{h^{5/6}}$ | $\frac{0.9}{h^{2/3}}$ | $\frac{0.9}{h^{2/3}}$ | $\frac{\cot\theta}{2}\left(\frac{S\bar{T}}{r_2^2}\right)$ |   |
| Single miter bend or widely spaced miter bend $s \geq r_2(1 + \tan\theta)$ [Notes (1), (3), (6)] | $\frac{1.52}{h^{5/6}}$ | $\frac{0.9}{h^{2/3}}$ | $\frac{0.9}{h^{2/3}}$ | $\frac{1+\cot\theta}{2}\left(\frac{\bar{T}}{r_2}\right)$ |   |
| Welding tee in accordance with ASME B16.9 [Notes (1), (3), (5), (7), (8)] | 1 | $\frac{0.9}{h^{2/3}}$ | $\frac{3}{4}i_o + \frac{1}{4}$ | $3.1\frac{\bar{T}}{r_2}$ |   |
| Reinforced fabricated tee with pad or saddle [Notes (1), (3), (8), (9), (10)] | 1 | $\frac{0.9}{h^{2/3}}$ | $\frac{3}{4}i_o + \frac{1}{4}$ | $\frac{(\bar{T}+\frac{1}{2}\bar{T}_r)^{2.5}}{\bar{T}^{1.5}r_2}$ |   |
| Unreinforced fabricated tee [Notes (1), (3), (8), (10)] | 1 | $\frac{0.9}{h^{2/3}}$ | $\frac{3}{4}i_o + \frac{1}{4}$ | $\frac{\bar{T}}{r_2}$ |   |
| Extruded welding tee with $r_x \geq 0.05D_b$ $T_c < 1.5\bar{T}$ [Notes (1), (3), (8)] | 1 | $\frac{0.9}{h^{2/3}}$ | $\frac{3}{4}i_o + \frac{1}{4}$ | $\left(1+\frac{r_x}{r_2}\right)\frac{\bar{T}}{r_2}$ |   |
| Welded-in contour insert [Notes (1), (3), (7), (8)] | 1 | $\frac{0.9}{h^{2/3}}$ | $\frac{3}{4}i_o + \frac{1}{4}$ | $3.1\frac{\bar{T}}{r_2}$ |   |
| Branch welded-on fitting (integrally reinforced) [Notes (1), (3), (10), (11)] | 1 | $\frac{0.9}{h^{2/3}}$ | $\frac{0.9}{h^{2/3}}$ | $3.3\frac{\bar{T}}{r_2}$ |   |

**TABLE 10-46 Flexibility Factor, *k*, and Stress Intensification Factor, *i* (*Continued*)**

| Description | Flexibility factor, $k$ | Stress intensification factor, $i$ |
|---|---|---|
| Butt welded joint, reducer, or weld neck flange | 1 | 1.0 |
| Double-welded slip-on flange | 1 | 1.2 |
| Fillet or socket weld | 1 | 1.3 [Note (12)] |
| Lap joint flange (with ASME B16.9 lap joint stub) | 1 | 1.6 |
| Threaded pipe joint or threaded flange | 1 | 2.3 |
| Corrugated straight pipe, or corrugated or creased bend [Note (13)] | 5 | 2.5 |





GENERAL NOTE: Stress intensification and flexibility factor data in Table 10-46 are for use in the absence of more directly applicable data (see para. 319.3.6). Their validity has been demonstrated for $D/\overline{T} \le 100$.

NOTES:

(1) The flexibility factor, $k$, in the Table applies to bending in any plane; also see para. 319.3.6. The flexibility factors, $k$, and stress intensification factors, $i$, shall apply over the effective arc length (shown by heavy centerlines in the illustrations) for curved and miter bends, and to the intersection point for tees.

(2) A single intensification factor equal to $0.9/h^{2/3}$ may be used for both $i_i$ and $i_o$ if desired.

(3) The values of $k$ and $i$ can be read directly from Chart A by entering with the characteristic $h$ computed from the formulas given above. Nomenclature is as follows:

$D_b$ = outside diameter of branch
$R_1$ = bend radius of welding elbow or pipe bend
$r_x$ = see definition in para. 304.3.4(c)
$r_2$ = mean radius of matching pipe
$s$ = miter spacing at centerline
$\overline{T}$ = for elbows and miter bends, the nominal wall thickness of the fitting
= for tees, the nominal wall thickness of the matching pipe
$T_c$ = crotch thickness of branch connections measured at the center of the crotch where shown in the illustrations
$\overline{T}_r$ = pad or saddle thickness
$\theta$ = one-half angle between adjacent miter axes

(4) Where flanges are attached to one or both ends, the values of $k$ and $i$ in the Table shall be corrected by the factors $C_1$, which can be read directly from Chart B, entering with the computed $h$.

(5) The designer is cautioned that cast buttwelded fittings may have considerably heavier walls than that of the pipe with which they are used. Large errors may be introduced unless the effect of these greater thicknesses is considered.

(6) In large diameter thin-wall elbows and bends, pressure can significantly affect the magnitudes of $k$ and $i$. To correct values from the Table, divide $k$ by

$$1+6\left(\frac{P_j}{E_j}\right)\left(\frac{r_2}{\overline{T}}\right)^{7/3}\left(\frac{R_1}{r_2}\right)^{1/3}$$

divide $i$ by

$$1+3.25\left(\frac{P_j}{E_j}\right)\left(\frac{r_2}{\overline{T}}\right)^{5/2}\left(\frac{R_1}{r_2}\right)^{2/3}$$

For consistency, use kPa and mm for SI metric, and psi and in. for U.S. customary notation.

(7) If $r_x \ge \frac{1}{8} D_b$ and $T_c \ge 1.5\overline{T}$, a flexibility characteristic of $4.4\overline{T}/r_2$ may be used.

(8) Stress intensification factors for branch connections are based on tests with at least two diameters of straight run pipe on each side of the branch centerline. More closely loaded branches may require special consideration.

(9) When $\overline{T}_r$ is $> 1\frac{1}{2}\overline{T}$, use $h = 4\overline{T}/r_2$.

(10) The out-of-plane stress intensification factor (SIF) for a reducing branch connection with branch-to-run diameter ratio of $0.5 < d/D < 1.0$ may be nonconservative. A smooth concave weld contour has been shown to reduce the SIF. Selection of the appropriate SIF is the designer's responsibility.

(11) The designer must be satisfied that this fabrication has a pressure rating equivalent to straight pipe.

(12) For welds to socket welded fittings, the stress intensification factor is based on the assumption that the pipe and fitting are matched in accordance with ASME B16.11 and a fillet weld is made between the pipe and fitting. For welds to socket welded flanges, the stress intensification factor is based on the weld geometry and has been shown to envelope the results of the pipe to socket welded fitting tests. Blending the toe of the fillet weld smoothly into the pipe wall has been shown to improve the fatigue performance of the weld.

(13) Factors shown apply to bending. Flexibility factor for torsion equals 0.9.

The resultant bending stresses $S_b$ to be used in Eq. (10-99) for elbows and miter bends shall be calculated in accordance with Eq. (10-100), with moments as shown in Fig. 10-161:

$$S_b = \frac{\sqrt{(i_i M_i)^2 + (i_o M_o)^2}}{Z_e} \qquad (10\text{-}100)$$

where $S_b$ = resultant bending stress, lbf/in$^2$ (MPa)
$i_i$ = in-plane stress intensification factor from Table 10-46
$i_o$ = out-plane stress intensification factor from Table 10-46
$M_i$ = in-plane bending moment, in · lbf (N · mm)
$M_o$ = out-of-plane bending moment, in · lbf (N · mm)
$Z$ = section modulus of pipe, in$^3$ (mm$^3$)

The resultant bending stresses $S_b$ to be used in Eq. (10-99) for branch connections shall be calculated in accordance with Eqs. (10-101) and (10-102), with moments as shown in Fig. 10-162.

For header (legs 1 and 2):

$$S_b = \frac{\sqrt{(i_i M_i)^2 + (i_o M_o)^2}}{Z} \qquad (10\text{-}101)$$

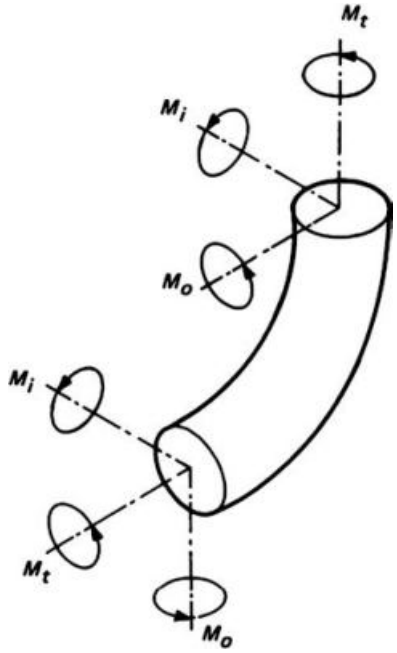


**FIG. 10-161** Moments in bends. (*Extracted from the Process Piping Code, B31.3-2014, with permission of the publisher, the American Society of Mechanical Engineers, New York. All rights reserved.*)

For branch (leg 3):

$$S_b = \frac{\sqrt{(i_i M_i)^2 + (i_o M_o)^2}}{Z_e} \tag{10-102}$$

where $S_b$ = resultant bending stress, lbf/in$^2$ (MPa)
$Z_e$ = effective section modulus for branch, in$^3$ (mm$^3$)

$$Z_e = \pi r_2^2 T_s \tag{10-103}$$

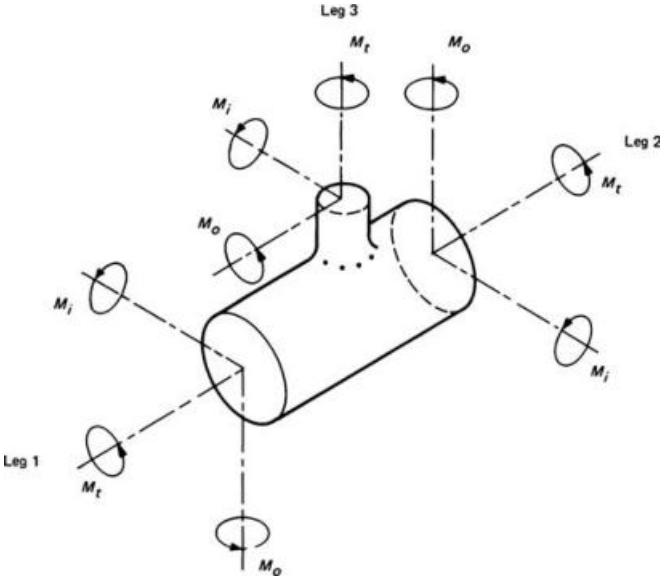

**FIG. 10-162** Moments in branch connections. (*Extracted from the Process Piping Code, B31.3-2004, with permission of the publisher, the American Society of Mechanical Engineers, New York. All rights reserved.*)

$r_2$ = mean branch cross-sectional radius, in (mm)
$T_s$ = effective branch wall thickness, in (mm) [lesser of $\overline{T}_h$ and $(i_o)(\overline{T}_b)$]
$\overline{T}_h$ = thickness of pipe matching run of tee or header exclusive of reinforcing elements, in (mm)
$\overline{T}_b$ = thickness of pipe matching branch, in (mm)
$i_o$ = out-of-plane stress – intensification factor (Table 10-46)
$i_i$ = in-plane stress – intensification factor (Table 10-46)

Allowable stress range $S_A$ and permissible additive stresses shall be computed in accordance with Eqs. (10-91) and (10-92).

***Required Weld Quality Assurance*** Any weld at which $S_E$ exceeds $0.8S_A$ for any portion of a piping system, and the equivalent number of cycles $N$ exceeds 7000, shall be fully examined in accordance with the requirements for severe cyclic service (presented later in this section).

**Reactions: Metallic Piping** Reaction forces and moments to be used in the design of restraints and supports and in evaluating the effects of piping displacements on connected equipment shall be based on the reaction range $R$ for the extreme displacement conditions, considering the range previously defined for reactions and using $E_a$. The designer shall consider instantaneous maximum values of forces and moments in the original and extreme displacement conditions as well as the reaction range in making these evaluations.

***Maximum Reactions for Simple Systems*** For two-anchor systems without intermediate restraints, the maximum instantaneous values of reaction forces and moments may be estimated from Eqs. (10-104) and (10-105).

1. *For extreme displacement conditions $R_m$.* The temperature for this computation is the design maximum or design minimum temperature as previously defined for reactions, whichever produces the larger reaction:

$$R_m = R\left(1 - \frac{2C}{3}\right)\frac{E_m}{E_a} \tag{10-104}$$

where $C$ = cold-spring factor varying from 0 for no cold spring to 1.0 for 100 percent cold spring. (The factor ⅔ is based on experience, which shows that specified cold spring cannot be fully ensured even with elaborate precautions.)
$E_a$ = modulus of elasticity at installation temperature, lbf/in$^2$ (MPa)
$E_m$ = modulus of elasticity at design maximum or design minimum temperature, lbf/in$^2$ (MPa)
$R$ = range of reaction forces or moments (derived from flexibility analysis) corresponding to the full displacement-stress range and based on reaction force, $E_a$, lbf or on moment in · lbf (N or N · mm)
$R_m$ = estimated instantaneous maximum reaction force or moment at design maximum or design minimum temperature, reaction force lbf or moment in · lbf (N or N · mm)

2. *For original condition $R_a$.* The temperature for this computation is the expected temperature at which the piping is to be assembled.

$$R_a = CR \quad \text{or} \quad C_1 R \quad \text{whichever is greater} \tag{10-105}$$

where nomenclature is as for Eq. (10-104) and

$C_1 = 1 - S_h E_a / S_E E_m$
= estimated self-spring or relaxation factor (use 0 if value of $C_1$ is negative)
$R_a$ = estimated instantaneous reaction force or moment at installation temperature, lbf or in · lbf (N or N · mm)
$S_E$ = computed displacement-stress range, lbf/in$^2$ (MPa); see Eq. (10-99)
$S_h$ = see Eq. (10-91)

***Maximum Reactions for Complex Systems*** For multianchor systems and for two-anchor systems with intermediate restraints, Eqs. (10-104) and (10-105) are not applicable. Each case must be studied to estimate the location, nature, and extent of local overstrain and its effect on stress distribution and reactions.

Acceptable comprehensive methods of analysis are analytical, model-test, and chart methods, which evaluate for the entire piping system under consideration the forces, moments, and stresses caused by bending and torsion from a simultaneous consideration of terminal and intermediate restraints to thermal expansion and include all external movements transmitted under thermal change to the piping by its terminal and

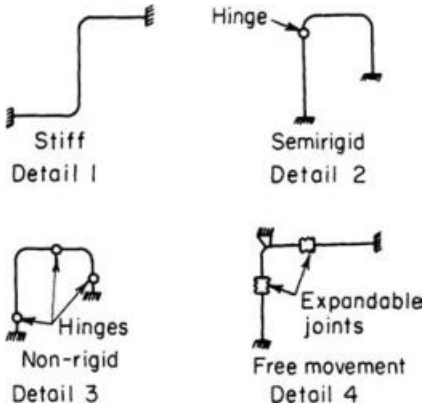

**FIG. 10-163** Flexibility classification for piping systems. (From Kellogg, *Design of Piping Systems,* Wiley, New York, 1965.)

intermediate attachments. Correction factors, as provided by the details of these rules, must be applied for the stress intensification of curved pipe and branch connections and may be applied for the increased flexibility of such component parts.

***Expansion Joints*** All the foregoing applies to "stiff piping systems," i.e., systems without expansion joints (see detail 1 of Fig. 10-163). When space limitations, process requirements, or other considerations result in configurations of insufficient flexibility, the capacity for deflection within allowable stress range limits may be increased successively by the use of one or more hinged bellows expansion joints, i.e., semirigid (detail 2) and nonrigid (detail 3) systems, and expansion effects essentially eliminated by a free-movement joint (detail 4) system. Expansion joints for semirigid and nonrigid systems are restrained against longitudinal and lateral movement by the hinges with the expansion element under bending movement only and are known as *rotation* or *hinged* joints (see Fig. 10-164). Semirigid systems are limited to one plane; nonrigid systems require a minimum of three joints for two-dimensional and five joints for three-dimensional expansion movement.

Joints similar to that shown in Fig. 10-164, except with two pairs of hinge pins equally spaced around a gimbal ring, achieve similar results with fewer joints.

Expansion joints for free-movement systems can be designed for axial or offset movement alone, or for combined axial and offset movements (see Fig. 10-165). For offset movement alone, the end load due to pressure and weight can be transferred across the joint by tie rods or structural members (see Fig. 10-166). For axial or combined movements, anchors must be provided to absorb the unbalanced pressure load and to force bellows to deflect.

Commercial bellows elements are usually light-gauge (of the order of 0.05 to 0.10 in thick) and are available in stainless and other alloy steels, copper, and other nonferrous materials. Multiply bellows, bellows with external reinforcing rings, and toroidal contour bellows are available for higher pressures. Since bellows elements are ordinarily rated for strain ranges that involve repetitive yielding, predictable performance is ensured only by adequate fabrication controls and knowledge of the potential fatigue performance of each design. The attendant cold work can affect

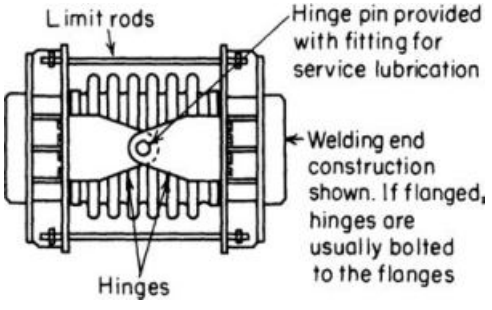

**FIG. 10-164** Hinged expansion joint. (From Kellogg, *Design of Piping Systems*, Wiley, New York, 1965.)

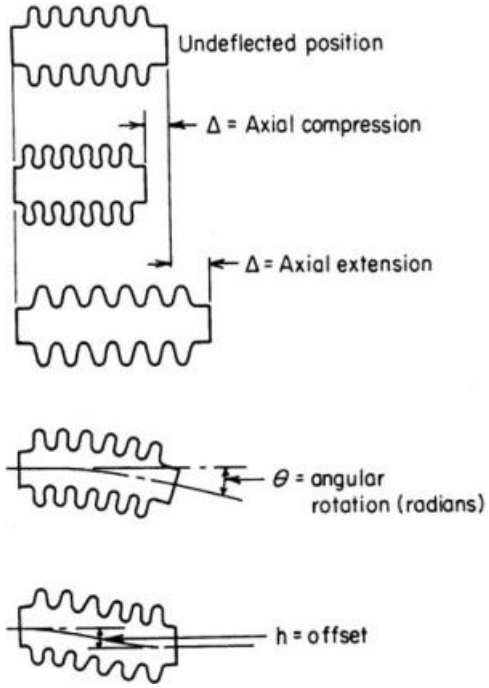

**FIG. 10-165** Action of expansion bellows under various movements. (From Kellogg, *Design of Piping Systems*, Wiley, New York, 1965.)

corrosion resistance and promote susceptibility to corrosion fatigue or stress corrosion; joints in a horizontal position cannot be drained and have frequently undergone pitting or cracking due to the presence of condensate during operation or off-stream. For low-pressure essentially nonhazardous service, nonmetallic bellows of fabric-reinforced rubber or special materials are sometimes used. For corrosive service PTFE bellows may be used.

Because of the inherently greater susceptibility of expansion bellows to failure from unexpected corrosion, failure of guides to control joint movements, etc., it is advisable to examine critically their design choice in comparison with a stiff system.

Slip-type expansion joints (Fig. 10-167) substitute packing (ring or plastic) for bellows. Their performance is sensitive to adequate design with respect to guiding to prevent binding and the adequacy of stuffing boxes and attendant packing, sealant, and lubrication. Anchors must be provided for the

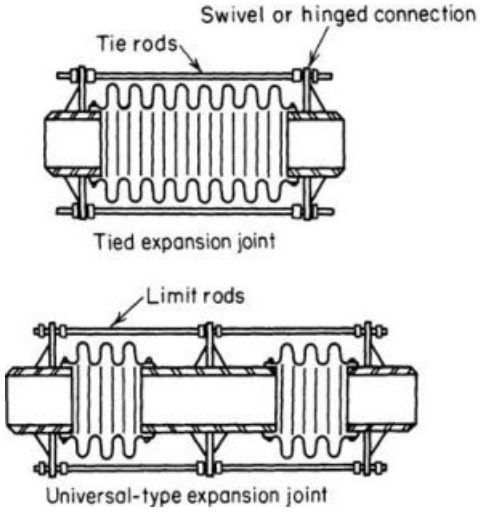

**FIG. 10-166** Constrained-bellows expansion joints. (From Kellogg, *Design of Piping Systems*, Wiley, New York, 1965.)

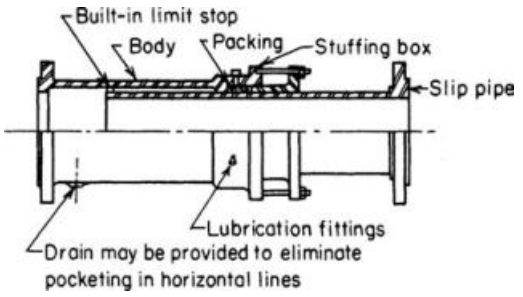

**FIG. 10-167** Slip-type expansion joint. (From Kellogg, *Design of Piping Systems*, Wiley, New York, 1965.)

unbalanced pressure force and for the friction forces to move the joint. The latter can be much higher than the elastic force required to deflect a bellows joint. Rotary packed joints, ball joints, and other special joints can absorb end load.

Corrugated pipe and corrugated and creased bends are also used to decrease stiffness.

**Pipe Supports** Loads transmitted by piping to attached equipment and supporting elements include weight, temperature- and pressure-induced effects, vibration, wind, earthquake, shock, and thermal expansion and contraction. The design of supports and restraints is based on concurrently acting loads (if it is assumed that wind and earthquake do not act simultaneously).

Resilient and constant-effort-type supports shall be designed for maximum loading conditions including test unless temporary supports are provided.

Though not specified in the code, supports for discharge piping from relief valves must be adequate to withstand the jet reaction produced by their discharge.

The code states further that pipe-supporting elements shall (1) avoid excessive interference with thermal expansion and contraction of pipe which is otherwise adequately flexible; (2) be such that they do not contribute to leakage at joints or excessive sag in piping, requiring drainage; (3) be designed to prevent overstress, resonance, or disengagement due to variation of load with temperature; also, so that combined longitudinal stresses in the piping shall not exceed the code allowable limits; (4) be such that a complete release of the piping load will be prevented in the event of spring failure or misalignment, weight transfer, or added load due to test during erection; (5) be of steel or wrought iron; (6) be of alloy steel or protected from temperature when the temperature limit for carbon steel may be exceeded; (7) not be cast iron except for roller bases, rollers, anchor bases, etc., under mainly compression loading; (8) not be malleable or nodular iron except for pipe clamps, beam clamps, hanger flanges, clips, bases, and swivel rings; (9) not be wood except for supports mainly in compression when the pipe temperature is at or below ambient; and (10) have threads for screw adjustment which shall conform to ASME B1.1.

A supporting element used as an anchor shall be designed to maintain an essentially fixed position.

To protect terminal equipment or other (weaker) portions of the system, restraints (such as anchors and guides) shall be provided where necessary to control movement or to direct expansion into those portions of the system that are adequate to absorb them. The design, arrangement, and location of restraints shall ensure that expansion-joint movements occur in the directions for which the joint is designed. In addition to the other thermal forces and moments, the effects of friction in other supports of the system shall be considered in the design of such anchors and guides.

***Anchors for Expansion Joints*** Anchors (such as those of the corrugated, omega, disk, or slip type) shall be designed to withstand the algebraic sum of the forces at the maximum pressure and temperature at which the joint is to be used. These forces are as follows:

1. Pressure thrust, which is the product of the effective thrust area and the maximum pressure to which the joint will be subjected during normal operation. (For slip joints the effective thrust area shall be computed by using the outside diameter of the pipe. For corrugated, omega, or disk-type joints, the effective thrust area shall be that area recommended by the joint manufacturer. If this information is unobtainable, the effective area shall be computed by using the maximum inside diameter of the expansion-joint bellows.)
2. The force required to compress or extend the joint in an amount equal to the calculated expansion movement.
3. The force required to overcome the static friction of the pipe in expanding or contracting on its supports, from installed to operating position. The length of pipe considered should be that located between the anchor and the expansion joint.

***Support Fixtures*** Hanger rods may be pipe straps, chains, bars, or threaded rods that permit free movement for thermal expansion or contraction. Sliding supports shall be designed for friction and bearing loads. Brackets shall be designed to withstand movements due to friction in addition to other loads. Spring-type supports shall be designed for weight load at the point of attachment, to prevent misalignment, buckling, or eccentric loading of springs, and provided with stops to prevent spring overtravel. Compensating-type spring hangers are recommended for high-temperature and critical-service piping to make the supporting force uniform with appreciable movement. Counterweight supports shall have stops to limit travel. Hydraulic supports shall be provided with safety devices and stops to support load in the event of loss of pressure. Vibration dampers or sway braces may be used to limit vibration amplitude.

The code requires that the safe load for threaded hanger rods be based on the root area of the threads. This, however, assumes concentric loading. When hanger rods move to a non-vertical position so that the load is transferred from the rod to the supporting structure via the edge of one flat of the nut on the rod, it is necessary to consider the root area to be reduced by one-third. If a clamp is connected to a vertical line to support its weight, then it is recommended that shear lugs be welded to the pipe, or that the clamp be located below a fitting or flange, to prevent slippage. Consideration shall be given to the localized stresses induced in the piping by the integral attachment. Typical pipe supports are shown in Fig. 10-168.

Much piping is supported from structures installed for other purposes. It is common practice to use beam formulas for tubular sections to determine stress, maximum deflection, and maximum slope of piping in *spans between supports*. When piping is supported from structures installed for that sole purpose and those structures rest on driven piles, detailed calculations are usually made to determine maximum permissible spans. Limits imposed on maximum slope to make the contents of the line drain to the lower end require calculations made on the weight per foot of the empty line. To avoid interference with other components, maximum deflection should be limited to 25.4 mm (1 in).

Pipe hangers are essentially frictionless but require taller pipe-support structures which cost more than structures on which pipe is laid. Devices that reduce friction between laid pipe subject to thermal movement and its supports are used to accomplish the following:

1. Reduce loads on anchors or on equipment acting as anchors.
2. Reduce the tendency of pipe acting as a column loaded by friction at supports to buckle sideways off supports.
3. Reduce nonvertical loads imposed by piping on its supports so as to minimize the cost of support foundations.
4. Reduce longitudinal stress in pipe.

Linear bearing surfaces made of fluorinated hydrocarbons or of graphite and also rollers are used for this purpose.

**Design Criteria: Nonmetallic Pipe** In using a nonmetallic material, designers must satisfy themselves as to the adequacy of the material and its manufacture, considering such factors as strength at design temperature, impact- and thermal-shock properties, toxicity, methods of making connections, and possible deterioration in service. Rating information, based usually on ASTM standards or specifications, is generally available from the manufacturers of these materials. Particular attention should be given to provisions for the thermal expansion of nonmetallic piping materials, which may be as much as 5 to 10 times that of steel (Table 10-47). Special consideration should be given to the strength of small pipe connections to piping and equipment and to the need for extra flexibility at the junction of metallic and nonmetallic systems.

Table 10-48 gives values for the modulus of elasticity for nonmetals; however, no specific stress-limiting criteria or methods of stress analysis are presented. Stress-strain behavior of most nonmetals differs considerably from that of metals and is less well defined for mathematic analysis. The piping system should be designed and laid out so that flexural stresses resulting from displacement due to expansion, contraction, and other movement are minimized. This concept requires special attention to supports, terminals, and other restraints.

***Displacement Strains*** The concepts of strain imposed by restraint of thermal expansion or contraction and by external movement described for metallic piping apply in principle to nonmetals. Nevertheless, the assumption that stresses throughout the piping system can be predicted from these strains because of fully elastic behavior of the piping materials is not generally valid for nonmetals.

In thermoplastics and some thermosetting resins, displacement strains are not likely to produce immediate failure of the piping, but may result in detrimental distortion. Especially in thermoplastics, progressive deformation may occur upon repeated thermal cycling or on prolonged exposure to elevated temperature.

In brittle nonmetallics (such as porcelain, glass, impregnated graphite) and some thermosetting resins, the materials show rigid behavior and develop high displacement stresses up to the point of sudden breakage due to overstrain.

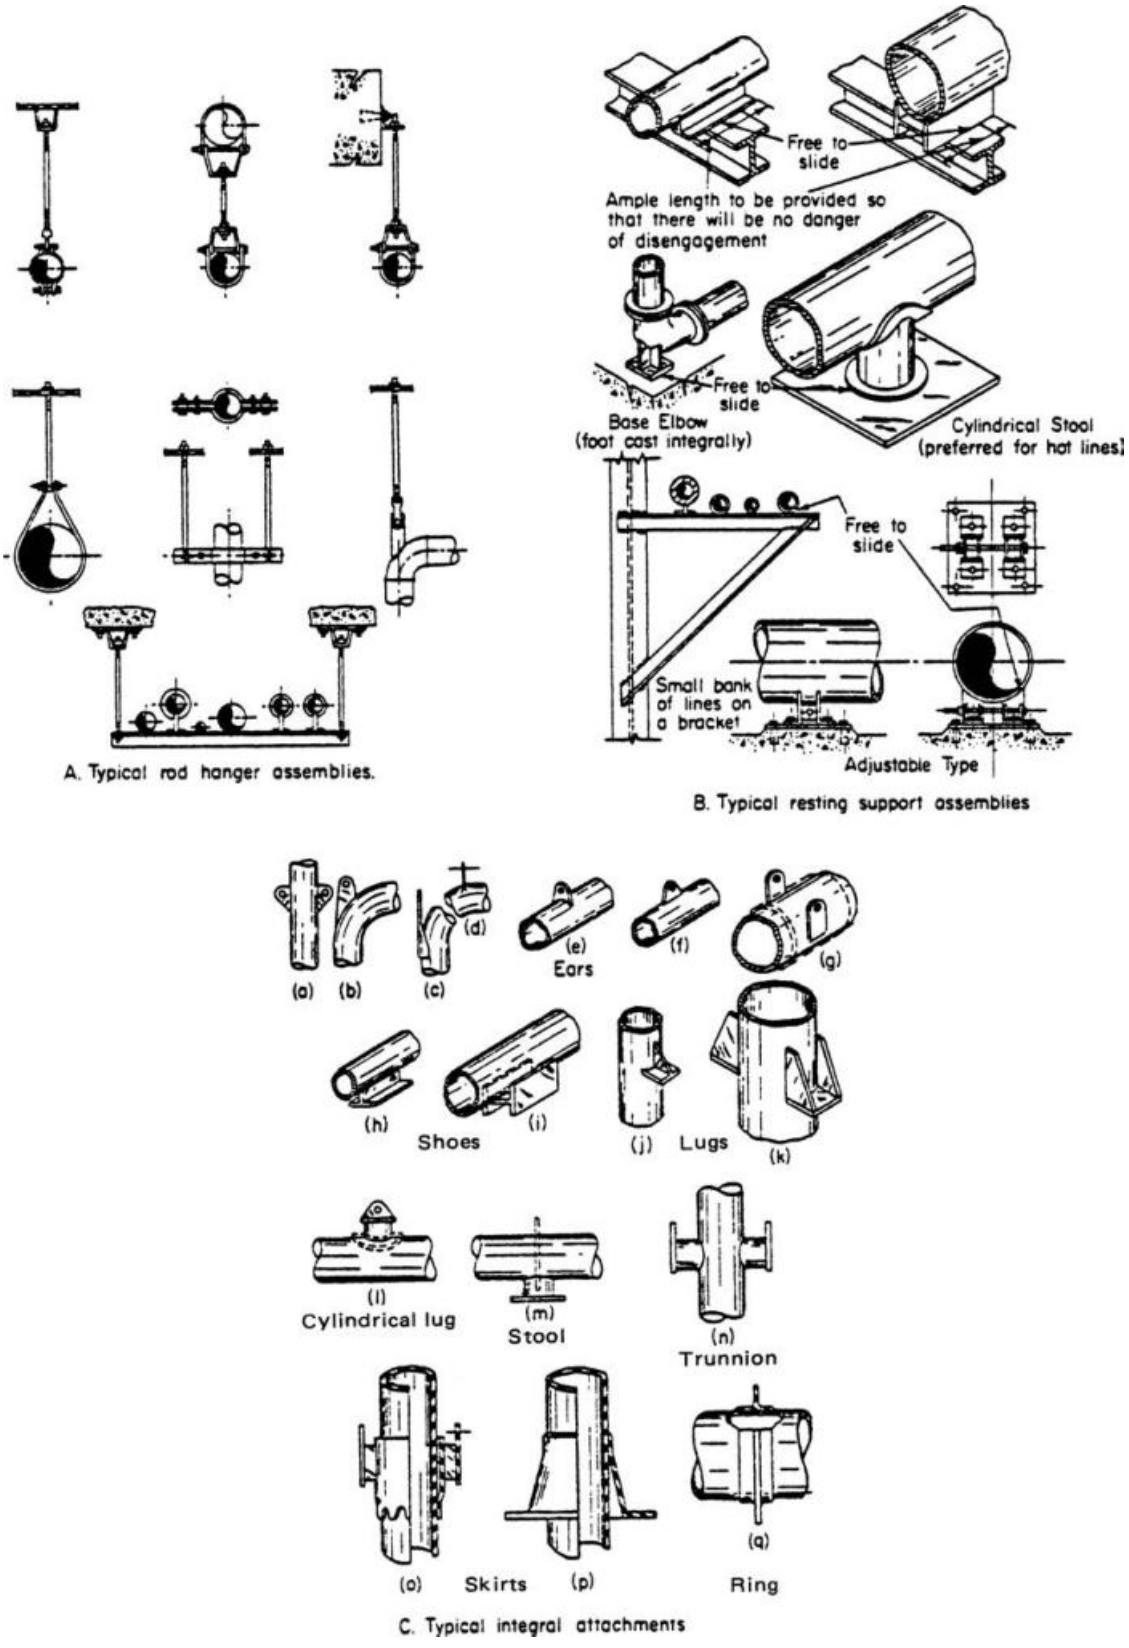

**FIG. 10-168** Typical pipe supports and attachments. (From Kellogg, *Design of Piping Systems,* Wiley, New York, 1965.)

GENERAL NOTES:

For Code references to this table, see para. A319.3.1, ASME B31.3-2014. Reprinted from ASME B31.3-2014 by permission of the American Society of Mechanical Engineers, New York. All rights reserved. These data are for use in the absence of more applicable data. It is the designer's responsibility to verify that materials are suitable for the intended service at the temperatures shown.

Individual compounds may vary from the values shown. Consult manufacturer for specific values for products.

***Elastic Behavior*** The assumption that displacement strains will produce proportional stress over a sufficiently wide range to justify an elastic-stress analysis often is not valid for nonmetals. In brittle nonmetallic piping, strains initially will produce relatively large elastic stresses. The total displacement strain must be kept small, however, since overstrain results in failure rather than plastic deformation. In plastic and resin nonmetallic piping, strains generally will produce stresses of the overstrained (plastic) type even at relatively low values of total displacement strain.

## FABRICATION, ASSEMBLY, AND ERECTION

**Welding, Brazing, or Soldering** Code requirements dealing with fabrication are more detailed for welding than for other methods of joining, since welding is the predominant method of construction and the method used for the most demanding applications. The code requirements for welding processes and operators are essentially the same as covered in the subsection on pressure vessels (i.e., qualification to Sec. IX of the ASME Boiler and Pressure Vessel Code) except that welding processes are not restricted, the material grouping (P number) must be in accordance with ASME B31.3 App. A-1 (A-1M Metric), and welding positions are related to pipe position. The code also permits one fabricator to accept welders or welding operators qualified by another employer without requalification when welding pipe by the same or equivalent procedure. The code may require that the welding procedure qualification include low-temperature toughness testing (see Table 10-49).

Filler metal is required to conform with the requirements of Sec. IX. Backing rings (of ferrous material), when used, shall be of weldable quality

GENERAL NOTE: For Code references to this table, see para. A319.3.2, ASME B31.3-2014. Reprinted from ASME B31.3-2014 by permission of the American Society of Mechanical Engineers, New York. All rights reserved. These data are for use in the absence of more applicable data. It is the designer's responsibility to verify that materials are suitable for the intended service at the temperatures shown.

NOTE:

(1) The modulus of elasticity data shown for thermoplastics are based on short-term tests. The manufacturer should be consulted to obtain values for use under long-term loading.

with sulfur limited to 0.05 percent. Backing rings of nonferrous and nonmetallic materials may be used provided they are proved satisfactory by procedure qualification tests and provided their use has been approved by the designer.

The code requires internal alignment within the dimensional limits specified in the welding procedure and the engineering design without specific dimensional limitations. Internal trimming is permitted for correcting internal misalignment provided such trimming does not result in a finished wall thickness before welding of less than required minimum wall thickness $t_m$. When necessary, weld metal may be deposited on the inside or outside of the component to provide alignment or sufficient material for trimming.

Table 10-51 is a summary of the code acceptance criteria (limits on imperfections) for welds. The defects referred to are illustrated in Fig. 10-169.

Brazing procedures, brazers, and brazing operators must be qualified in accordance with the requirements of Part QB, Sec. IX, ASME Code. Qualification is not required for Category D fluid service not exceeding 93°C (200°F), unless specified in the engineering design. The clearance between surfaces to be joined by brazing or soldering shall be no larger than is necessary to allow complete capillary distribution of the filler metal.

The only requirement for solderers is that they follow the procedure in ASTM B823–02, *Standard Practice for Making Capillary Joints by Soldering of Copper and Copper Alloy Tube and Fittings*.

**Bending and Forming** Pipe may be bent to any radius for which the bend-arc surface will be free of cracks and substantially free of buckles. The use of qualified bends that are creased or corrugated is permitted. Bending may be done by any hot or cold method that produces a product meeting code and service requirements, and that does not have an adverse effect on the essential characteristics of the material. Hot bending and hot forming must be done within a temperature range consistent with material characteristics, end use, and postoperation heat treatment. Postbend heat treatment may be required for bends in some materials; its necessity is dependent on the type of bending operation and the severity of the bend. Postbend heat treatment requirements are defined in the code.

Piping components may be formed by any suitable hot or cold pressing, rolling, forging, hammering, spinning, drawing, or other method. Thickness after forming shall not be less than required by design. Special rules cover the forming and pressure design verification of flared laps.

The development of fabrication facilities for bending pipe to the radius of commercial butt-welding long-radius elbows and forming flared metallic (Van Stone) laps on pipe is an important technique in reducing welded-piping costs. These techniques save both the cost of the ell or stub end and that of the welding operation required to attach the fitting to the pipe.

**Preheating and Heat Treatment** Preheating and postoperation heat treatment are used to avert or relieve the detrimental effects of the high temperature and severe thermal gradients inherent in the welding of metals. In addition, heat treatment may be needed to relieve residual stresses created during the bending or forming of metals. The code provisions shown in Tables 10-52 and 10-53 represent basic practices that are acceptable for most applications of welding, bending, and forming, but they are not necessarily suitable for all service conditions. The specification of more or less stringent preheating and heat-treating requirements is a function of those responsible for the engineering design.

Refer to the code for rules establishing the thickness to be used in determining PWHT (post weld heat treatment) requirements for configurations other than butt welds (e.g., fabricated branch connections and socket welds).

**Joining Nonmetallic Pipe** All joints should be made in accordance with procedures complying with the manufacturer's recommendations and code requirements. General welding and heat fusion procedures are described in ASTM D-2657. ASTM D2855 describes general solvent-cementing procedures.

Depending on size, thermoplastic piping can be joined with mechanical joints, solvent-cemented joints, hot-gas welding, or heat fusion procedures. Mechanical joints are frequently bell-and-spigot joints which employ an elastomer O-ring gasket. Joints of this type are generally not self-restrained against internal pressure thrust.

Thermosetting resin pipe can be joined with mechanical joints or adhesive-bonded joints. Mechanical joints are generally a variation of gasketed bell-and-spigot joints and may be either nonrestrained or self-restrained. Adhesive-bonded joints are typically bell-and-spigot or butt-and-strap. Butt-and-strap joints join piping components with multiple layers of resin-saturated glass reinforcement.

**Assembly and Erection** Flanged-joint faces shall be aligned to the design plane to within $\frac{1}{16}$ in/ft (0.5 percent) maximum measured across any diameter, and flange bolt holes shall be aligned to within 3.2-mm (⅛-in) maximum offset. Flanged joints involving flanges with widely differing mechanical properties shall be assembled with extra care, and tightening to a predetermined torque is recommended.

The use of flat washers under bolt heads and nuts is a code requirement when assembling nonmetallic flanges. It is preferred that the bolts extend completely through their nuts; however, a lack of complete thread engagement not exceeding one thread is permitted by the code. The assembly of cast-iron bell-and-spigot piping is covered in AWWA Standard C600.

Screwed joints that are intended to be seal-welded shall be made up dry without any thread compound.

When one is installing conductive nonmetallic piping and metallic pipe with nonmetallic linings, consideration should be given to the need to provide electrical continuity throughout the system and to grounding requirements. This is particularly critical in areas with potentially explosive atmospheres.

## EXAMINATION, INSPECTION, AND TESTING

This subsection provides a general synopsis of code requirements. It should not be viewed as comprehensive.

**Examination and Inspection** The code differentiates between examination and inspection. *Examination* applies to quality-control functions performed by personnel of the piping manufacturer, fabricator, or erector. *Inspection* applies to functions performed for the owner by the authorized inspector.

The authorized inspector shall be designated by the owner and shall be the owner, an employee of the owner, an employee of an engineering or scientific organization, or an employee of a recognized insurance or inspection company acting as the owner's agent. The inspector shall not represent or be an employee of the piping erector, the manufacturer, or the fabricator unless the owner is also the erector, the manufacturer, or the fabricator.

**TABLE 10-49 Requirements for Low-Temperature Toughness Tests for Metals***

These toughness requirements are in addition to tests required by the material specification.

| | Type of material | Column A<br>Design minimum temperature at or above min. temp. in Table A-1 of ASME B31.3-2014 or Table 10-50 | | Column B<br>Design minimum temperature below min. temp. in Table A-1 of ASME B31.3-2014 or Table 10-50 |
|---|---|---|---|---|
| Listed Materials | 1 Gray cast iron | A-1 No additional requirements | | B-1 No additional requirements |
| | 2 Malleable and ductile cast iron: carbon steel per Note (1) | A-2 No additional requirements | | B-2 Materials designated in Box 2 shall not be used. |
| | | (a) Base metal | (b) Weld metal and heat affected zone (HAZ) [Note (2)] | |
| | 3 Other carbon steels, low and intermediate alloy steels, high alloy ferritic steels, duplex stainless steels | A-3 (a) No additional requirements | A-3 (b) Weld metal deposits shall be impact tested per para. 323.3.† If design min. temp. < −29°C (−20°F), except as provided in Notes (3) and (5), and except as follows: for materials listed for Curves C and D of Table 10-50, where corresponding welding-consumables are qualified by impact testing at the design minimum temperature or lower in accordance with the applicable AWS specification, additional testing is not required. | B-3 Except as provided in Notes (3) and (5), heat treat base metal per applicable ASTM specification listed in para. 323.3.2†; then impact test base metal, weld deposits, and HAZ per para. 323.3‡ [see Note (2)]. When materials are used at design min. temp. below the assigned curve as permitted by Notes (2) and (3) of Table 10-50, weld deposits and HAZ shall be impact tested [see Note (2)]. |
| | 4 Austenitic stainless steels | A-4 (a) If:<br>(1) carbon content by analysis >0.1%; or<br>(2) material is not in solution heat treated condition; then, impact test per para. 323.3† for design min. temp. < −29°C (−20°F) except as provided in Notes (3) and (6) | A-4 (b) Weld metal deposits shall be impact tested per para 323.3.† If design min. temp. < −29°C (−20°F) except as provided in para. 323.2.2[b] and in Notes (3) and (6) | B-4 Base metal and weld metal deposits shall be impact tested per para. 323.3‡. See Notes (2),(3), and (6). |
| | 5 Austenitic ductile iron, ASTM A 571 | A-5 (a) No additional requirements | A-5 (b) Welding is not permitted | B-5 Base metal shall be impact tested per para 323.3.† Do not use < −196°C (−320°F). Welding is not permitted. |
| | 6 Aluminum, copper, nickel, and their alloys; unalloyed titanium | A-6 (a) No additional requirements | A-6 (b) No additional requirements unless filler metal composition is outside the range for base metal composition; then test per column B-6 | B-6 Designer shall be assured by suitable tests [see Note (4)] that base metal, weld deposits, and HAZ are suitable at the design min. temp. |
| Unlisted Materials | 7 An unlisted material shall conform to a published specification. Where composition, heat treatment, and product form are comparable to those of a listed material, requirements for the corresponding listed material shall be met. Other unlisted materials shall be qualified as required in the applicable section of column B. | | | |

NOTES:

(1) Carbon steels conforming to the following are subject to the limitations in Box B-2; plates per ASTM A 36, A 283, and A 570; pipe per ASTM A 134 when made from these plates; structural shapes in accordance with ASTM A992; and pipe per ASTM A 53 Type F and API 5L Gr. A25 butt weld.

(2) Impact tests that meet the requirements of Table 323.3.1,† which are performed as part of the weld procedure qualification, will satisfy all requirements of para. 323.2.2,‡ and need not be repeated for production welds.

(3) Impact testing is not required if the design minimum temperature is below −29°C (−20°F) but at or above −104°C (−155°F) and the Stress Ratio defined in Fig. 323.2.2B‡ does not exceed 0.3.

(4) Tests may include tensile elongation, sharp-notch tensile strength (to be compared with unnotched tensile strength), and/or other tests, conducted at or below design minimum temperature. See also para. 323.3.4.‡

(5) Impact tests are not required when the maximum obtainable Charpy specimen has a width along the notch of less than 2.5 mm (0.098 in). Under these conditions, the design minimum temperature shall not be less than the lower of −48°C (−55°F) or the minimum temperature for the material in Table A-1.

(6) Impact tests are not required when the maximum obtainable Charpy specimen has a width along the notch of less than 2.5 mm (0.098 in).

*Table 10-49 and notes have been extracted (with minor modifications) from *Process Piping,* ASME B31.3-2014, with permission of the publisher, the American Society of Mechanical Engineers, New York. All rights reserved.

†Refer to the referenced code paragraph for impact testing methods and acceptance.

‡Refer to the referenced code paragraph for comments regarding circumstances under which impact testing can be excluded.

The authorized inspector shall have a minimum of 10 years' experience in the design, fabrication, or inspection of industrial pressure piping. Each 20 percent of satisfactory work toward an engineering degree accredited by the Engineers' Council for Professional Development shall be considered equivalent to 1 year's experience, up to 5 years total.

It is the owner's responsibility, exercised through the authorized inspector, to verify that all required examinations and testing have been completed and to inspect the piping to the extent necessary to be satisfied that it conforms to all applicable requirements of the code and the engineering design. This verification may include certifications and records pertaining to materials, components, heat treatment, examination and testing, and qualifications of operators and procedures. The authorized inspector may delegate the performance of inspection to a qualified person.

Inspection does not relieve the manufacturer, the fabricator, or the erector of responsibility for providing materials, components, and skill in accordance with requirements of the code and the engineering design, performing all required examinations, and preparing records of examinations and tests for the inspector's use.

**Examination Methods** The code establishes the types of examinations for evaluating various types of imperfections (see Table 10-54).

Personnel performing examinations other than visual shall be qualified in accordance with applicable portions of SNT TC-1A, *Recommended Practice for Nondestructive Testing Personnel Qualification and Certification.* Procedures shall be qualified as required in Para. T-150, Art. 1, Sec. V of the ASME Code. Limitations on imperfections shall be in accordance with the engineering design but shall at least meet the requirements of the code

**TABLE 10-50 Tabular Values for Minimum Temperatures Without Impact Testing for Carbon Steel Materials***

| Nominal thickness [Note (6)] | | Design minimum temperature | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | | Curve A [Note (2)] | | Curve B [Note (3)] | | Curve C [Note (3)] | | Curve D | |
| mm | in | °C | °F | °C | °F | °C | °F | °C | °F |
| 6.4 | 0.25 | −9.4 | 15 | −28.9 | −20 | −48.3 | −55 | −48.3 | −55 |
| 7.9 | 0.3125 | −9.4 | 15 | −28.9 | −20 | −48.3 | −55 | −48.3 | −55 |

| 69.9 | 2.75 | 42.2 | 108 | 23.3 | 74 | 3.3 | 38 | −13.3 | 8 |
| 71.4 | 2.8125 | 42.2 | 108 | 23.9 | 75 | 3.9 | 39 | −13.3 | 8 |
| 73.0 | 2.875 | 42.8 | 109 | 24.4 | 76 | 4.4 | 40 | −12.8 | 9 |
| 74.6 | 2.9375 | 42.8 | 109 | 25.0 | 77 | 4.4 | 40 | −12.2 | 10 |
| 76.2 | 3.0 | 43.3 | 110 | 25.0 | 77 | 5.0 | 41 | −11.7 | 11 |

(see Tables 10-51 and 10-54) for the specific type of examination. Repairs shall be made as applicable.

***Visual Examination*** This consists of observation of the portion of components, joints, and other piping elements that are or can be exposed to view before, during, or after manufacture, fabrication, assembly, erection, inspection, or testing.

The examination includes verification of code and engineering design requirements for materials and components, dimensions, joint preparation, alignment, welding, bonding, brazing, bolting, threading and other joining methods, supports, assembly, and erection.

Visual examination shall be performed in accordance with Art. 9, Sec. V of the ASME Code.

***Magnetic-Particle Examination*** This examination shall be performed in accordance with Art. 7, Sec. V of the ASME Code.

***Liquid-Penetrant Examination*** This examination shall be performed in accordance with Art. 6, Sec. V of the ASME Code.

***Radiographic Examination*** The following definitions apply to radiography required by the code or by the engineering design:

1. *Random radiography* applies only to girth and miter groove welds. It is radiographic examination of the complete circumference of a specified percentage of the girth butt welds in a designated lot of piping.

2. Unless otherwise specified in engineering design, *100 percent radiography* applies only to girth welds, miter groove welds, and fabricated branch connections that utilize butt-type welds to join the header and the branch. The design engineer may, however, elect to designate other types of welds as requiring 100 percent radiography. By definition, 100 percent radiography requires radiographic examination of the complete length of all such welds in a designated lot of piping.

3. *Spot radiography* is the practice of making a single-exposure radiograph at a point within a specified extent of welding. Required coverage for a single-spot radiograph is as follows:

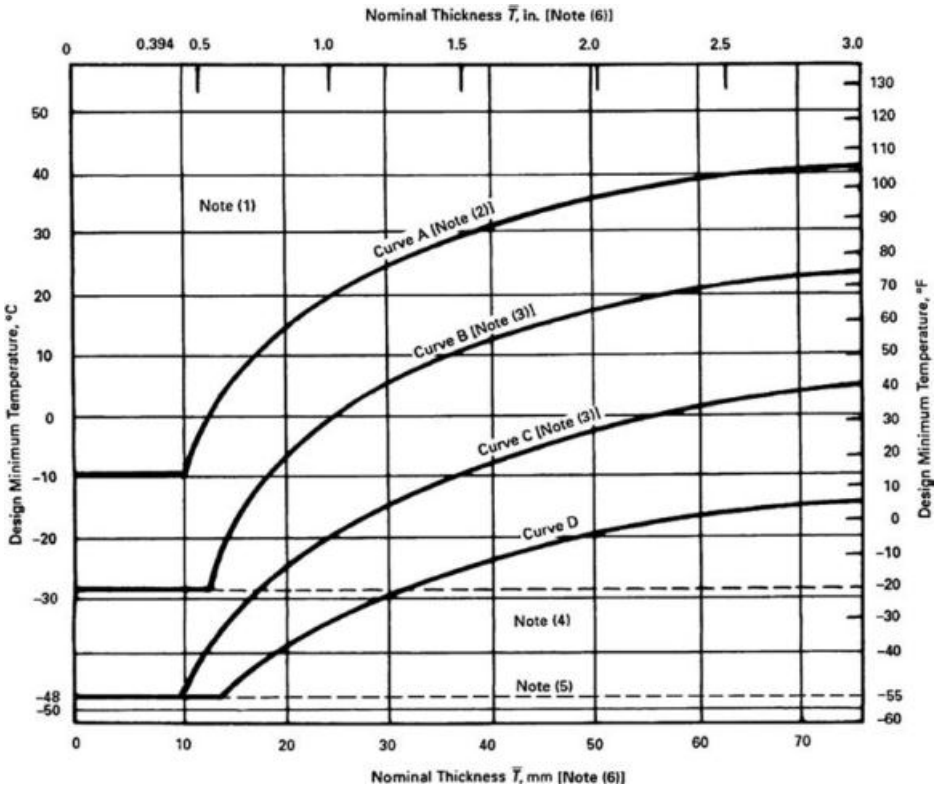
- For longitudinal welds, at least 150 mm (6 in) of weld length.
- For girth, miter, and branch welds in piping 2½ in NPS and smaller, a single elliptical exposure which encompasses the entire weld circumference, and in piping larger than 2½ in NPS, at least 25 percent of the inside circumference or 150 mm (6 in), whichever is less.

Radiography of components other than castings and of welds shall be in accordance with Art. 2, Sec. V of the ASME Code. Limitations on imperfections in components other than castings and welds shall be as stated in Table 10-51 for the degree of radiography involved.

***Ultrasonic Examination*** Ultrasonic examination of welds shall be in accordance with Art. 4, Sec. V of the ASME Code, except that the modifications stated in Para. 336.6.1 of the code shall be substituted for T434.2.1 and T434.3. Refer to the code for additional requirements.

**Type and Extent of Required Examination** The intent of examinations is to provide the examiner and the inspector with reasonable

**TABLE 10-50 Tabular Values for Minimum Temperatures Without Impact Testing for Carbon Steel Materials*** (*Continued*)



NOTES:

(1) Any carbon steel material may be used to a minimum temperature of –29°C (–20°F) for Category D Fluid Service.

(2) X Grades of API SL, and ASTM A 381 materials, may be used in accordance with Curve B if normalized or quenched and tempered.

(3) The following materials may be used in accordance with Curve D if normalized:

(*a*) ASTM A 516 Plate, all grades

(*b*) ASTM A 671 Pipe, Grades CE55, CE60, and all grades made with A 516 plate

(*c*) ASTM A 672 Pipe, Grades E55, E60, and all grades made with A 516 plate

(4) A welding procedure for the manufacture of pipe or components shall include impact testing of welds and HAZ for any design minimum temperature below –29°C (–20°F), except as provided in Table 10-49, A-3(b).

(5) Impact testing in accordance with para. 323.3† is required for any design minimum temperature below –48°C (–55°F), except as permitted by Note (3) in Table 10-49.‡

(6) For blind flanges and blanks, *T* shall be ¼ of the flange thickness.

*Table 10-50 and notes have been extracted (with minor modifications) from *Process Piping*, ASME B31.3-2014, with permission of the publisher, the American Society of Mechanical Engineers, New York. All rights reserved.

†Refer to the referenced code paragraph for impact testing methods and acceptance.

‡Refer to the referenced code paragraph for comments regarding circumstances under which impact testing can be excluded.

assurance that the requirements of the code and the engineering design have been met. For P-number 3, 4, and 5 materials, examination shall be performed after any heat treatment has been completed.

***Examination Normally Required**** Piping in normal fluid service shall be examined to the extent specified herein or to any greater extent specified in the engineering design. Acceptance criteria are as stated in the code for Normal Fluid Service unless more stringent requirements are specified.

1. *Visual examination.* At least the following shall be examined in accordance with code requirements:

*a.* Sufficient materials and components, selected at random, to satisfy the examiner that they conform to specifications and are free from defects.

*b.* At least 5 percent of fabrication. For welds, each welder's and welding operator's work shall be represented.

*c.* One hundred percent of fabrication for longitudinal welds, except those in components made in accordance with a listed specification. Longitudinal welds required to have a joint efficiency of 0.9 must be spot-radiographed to the extent of 300 mm (12 in) in each 30 m (100 ft) of weld for each welder or welding operator. Acceptance criteria shall comply with code radiography acceptance criteria for Normal Fluid Service.

*Extracted (with minor editing) from *Process Piping*, ASME B31.3-2014, paragraph 341, with permission of the publisher, the American Society of Mechanical Engineers, New York.

*d.* Random examination of the assembly of threaded, bolted, and other joints to satisfy the examiner that they conform to the applicable code requirements for erection and assembly. When pneumatic testing is to be performed, all threaded, bolted, and other mechanical joints shall be examined.

*e.* Random examination during erection of piping, including checking of alignment, supports, and cold spring.

*f.* Examination of erected piping for evidence of defects that would require repair or replacement, and for other evident deviations from the intent of the design.

2. *Other examination*

*a.* Not less than 5 percent of circumferential butt and miter groove welds shall be examined fully by random radiography or random ultrasonic examination in accordance with code requirements established for these methods. The welds to be examined shall be selected to ensure that the work product of each welder or welding operator doing the production welding is included. They shall also be selected to maximize coverage of intersections with longitudinal joints. When a circumferential weld with intersecting longitudinal weld(s) is examined, at least the adjacent 38 mm (1½ in) of each intersecting weld shall be examined. In-process examination in accordance with code requirements may be substituted for all or part of the radiographic or ultrasonic examination on a weld-for-weld basis if specified in the engineering design or specifically authorized by the Inspector.

*b.* Not less than 5 percent of all brazed joints shall be examined by in-process examination in accordance with the code definition of in-process

**TABLE 10-51 Acceptance Criteria for Welds—Visual and Radiographic Examination**

| Criteria (A to M) for Types of Welds and for Service Conditions [Note (1)] | | | | | | | | | | | Examination Methods | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Normal and Category M Fluid Service | | | Severe Cyclic Conditions | | | Category D Fluid Service | | | | | | |
| Type of Weld | | | Type of Weld | | | Type of Weld | | | | | | |
| Girth, Miter Groove & Branch Connection [Note (2)] | Longitudinal Groove [Note (3)] | Fillet [Note (4)] | Girth, Miter Groove & Branch Connection [Note (2)] | Longitudinal Groove [Note (3)] | Fillet [Note (4)] | Girth and Miter Groove | Longitudinal Groove [Note (3)] | Fillet [Note (4)] | Branch Connection [Note (2)] | Weld Imperfection | Visual | Radiography |
| A | A | A | A | A | A | A | A | A | A | Crack | ✓ | ✓ |
| A | A | A | A | A | A | C | A | N/A | A | Lack of fusion | ✓ | ✓ |
| B | A | N/A | A | A | N/A | C | A | N/A | A | Incomplete penetration | ✓ | ✓ |
| E | E | N/A | D | D | N/A | N/A | N/A | N/A | N/A | Rounded Indications | … | ✓ |
| G | G | N/A | F | F | N/A | N/A | N/A | N/A | N/A | Elongated indications | … | ✓ |
| H | A | H | A | A | A | I | A | H | H | Undercutting | ✓ | ✓ |
| A | A | A | A | A | A | A | A | A | A | Surface porosity or exposed slag inclusion [Note (5)] | ✓ | … |
| N/A | N/A | N/A | J | J | J | N/A | N/A | N/A | N/A | Surface finish | ✓ | … |
| K | K | N/A | K | K | N/A | K | K | N/A | K | Concave surface, concave root, or burn-through | ✓ | ✓ |
| L | L | L | L | L | L | M | M | M | M | Weld reinforcement or internal protrusion | ✓ | … |

examination, the joints to be examined being selected to ensure that the work of each brazer making the production joints is included.

3. *Certifications and records.* The examiner shall be assured, by examination of certifications, records, and other evidence, that the materials and components are of the specified grades and that they have received required heat treatment, examination, and testing. The examiner shall provide the Inspector with a certification that all the quality control requirements of the code and of the engineering design have been carried out.

***Examination—Category D Fluid Service**** Piping and piping elements for Category D fluid service as designated in the engineering design shall be visually examined in accordance with code requirements for visual examination to the extent necessary to satisfy the examiner that components, materials, and workmanship conform to the requirements of this code and the engineering design. Acceptance criteria shall be in accordance with code requirements and criteria in Table 10-51, for Category D fluid service, unless otherwise specified.

***Examination—Severe Cyclic Conditions**** Piping to be used under severe cyclic conditions shall be examined to the extent specified herein or to any greater extent specified in the engineering design. Acceptance criteria shall be in accordance with code requirements and criteria in Table 10-51, for severe cyclic conditions, unless otherwise specified.

1. *Visual examination.* The requirements for Normal Fluid Service apply with the following exceptions.

*a.* All fabrication shall be examined.

*b.* All threaded, bolted, and other joints shall be examined.

*c.* All piping erection shall be examined to verify dimensions and alignment. Supports, guides, and points of cold spring shall be checked to ensure that movement of the piping under all conditions of startup, operation, and shutdown will be accommodated without undue binding or unanticipated constraint.

2. *Other examination.* All circumferential butt and miter groove welds and all fabricated branch connection welds comparable to those recognized by the code (see Fig. 10-119) shall be examined by 100 percent radiography or 100 percent ultrasonic (if specified in engineering design) in accordance with code requirements. Socket welds and branch connection welds which are not radiographed shall be examined by magnetic-particle or liquid-penetrant methods in accordance with code requirements.

3. In-process examination in accordance with the code definition, supplemented by appropriate nondestructive examination, may be substituted for the examination required in 2 above on a weld-for-weld basis if specified in the engineering design or specifically authorized by the Inspector.

4. *Certification and records.* The requirements established by the code for Normal Fluid Service apply.

**Impact Testing** In specifying materials, it is critical that the low-temperature limits of materials and impact testing requirements of the applicable code edition be clearly understood. In the recent past, code criteria governing low-temperature limits and requirements for impact testing have undergone extensive revision. The code contains extensive criteria detailing when impact testing is required and describing how it is to be performed. Because of the potentially changing requirements and the complexity of the code requirements, this text does not attempt to provide a comprehensive treatment of this subject or a comprehensive presentation of the requirements of the current code edition. Some of the general guidelines are provided here; however, the designer should consult the code to clearly understand additional requirements and special circumstances under which impact testing may be omitted. These exclusions permitted by the code may be significant in selecting materials or establishing material requirements.

In general, materials conforming to ASTM specifications listed by the code may be used at temperatures down to the lowest temperature listed for that material in ASME B31.3 Table A-1, and A-1M. When welding or other operations are performed on these materials, additional low-temperature toughness tests (impact testing) may be required. Refer to Table 10-51 for a general summary of these requirements.

**Pressure Testing** Prior to initial operation, installed piping shall be pressure-tested to ensure tightness except as permitted for Category D fluid service described later. The pressure test shall be maintained for a sufficient time to determine the presence of any leaks but not less than 10 min.

If repairs or additions are made following the pressure tests, the affected piping shall be retested except that, in the case of minor repairs or additions, the owner may waive retest requirements when precautionary measures are taken to ensure sound construction.

*Extracted (with minor editing) from *Process Piping*, ASME B31.3-2014, paragraph 341, with permission of the publisher, the American Society of Mechanical Engineers, New York.

**TABLE 10-51 Acceptance Criteria for Welds—Visual and Radiographic Examination** (*Continued*)

Criterion Value Notes for Table 10-51

| Criterion | | |
|---|---|---|
| Symbol | Measure | Acceptable Value Limits [Note (6)] |
| A | Extent of imperfection | Zero (no evident imperfection) |
| B | Cumulative length of incomplete penetration | ≤38 mm (1.5 in.) in any 150 mm (6 in.) weld length or 25% of total weld length, whichever is less |
| C | Cumulative length of lack of fusion and incomplete penetration | ≤38 mm (1.5 in.) in any 150 mm (6 in.) weld length or 25% of total weld length, whichever is less |
| D | Size and distribution of rounded indications | See BPV Code, Section VIII, Division 1, Appendix 4 [Note (10)] |
| E | Size and distribution of rounded indications | For $\overline{T}_w \le 6$ mm (¼ in.), limit is same as D [Note (10)]<br>For $\overline{T}_w > 6$ mm (¼ in.), limit is 1.5 × D [Note (10)] |
| F | Elongated indications | |
| | Individual length | $\le \overline{T}_w/3$ |
| | Individual width | ≤2.5 mm (3⁄32 in.) and $\le \overline{T}_w/3$ |
| | Cumulative length | $\le \overline{T}_w$ in any 12 $\overline{T}_w$ weld length [Note (10)] |
| G | Elongated indications | |
| | Individual length | $\le 2\ \overline{T}_w$ |
| | Individual width | ≤3 mm (⅛ in.) and $\le \overline{T}_w/2$ |
| | Cumulative length | $\le 4\ \overline{T}_w$ in any 150 mm (6 in.) weld length [Note (10)] |
| H | Depth of undercut | ≤1 mm (1⁄32 in.) and $\le \overline{T}_w/4$ |
| | Cumulative length of internal and external undercut | ≤38 mm (1.5 in.) in any 150 mm (6 in.) weld length or 25% of total weld length, whichever is less |
| I | Depth of undercut | ≤1.5 mm (1⁄16 in.) and [$\le \overline{T}_w/4$ or 1 mm (1⁄32 in.)] |
| | Cumulative length of internal and external undercut | ≤38 mm (1.5 in.) in any 150 mm (6 in.) weld length or 25% of total weld length, whichever is less |
| J | Surface roughness | ≤12.5 μm (500 μin.) $R_a$ in accordance with ASME B46.1 |
| K | Depth of surface concavity, root concavity, or burn-through | Total joint thickness, incl. weld reinf., $\ge \overline{T}_w$ [Notes (7) and (11)] |
| L | Height of reinforcement or internal protrusion [Note (8)] in any plane through the weld shall be within limits of the applicable height value in the tabulation at right, except as provided in Note (9). Weld metal shall merge smoothly into the component surfaces. | For $\overline{T}_w$, mm (in.) / Height, mm (in.)<br>≤6 (¼) / ≤1.5 (1⁄16)<br>>6 (¼), ≤13 (½) / ≤3 (⅛)<br>>13 (½), ≤25 (1) / ≤4 (3⁄32)<br>>25 (1) / ≤5 (3⁄16) |
| M | Height of reinforcement or internal protrusion [Note (8)] as described in L. Note (9) does not apply. | Limit is twice the value applicable for L above |

GENERAL NOTES:

(a) Weld imperfections are evaluated by one or more of the types of examination methods given, as specified in paras. 341.4.1, 341.4.2, 341.4.3, and M341.4, or by the engineering design.

(b) "N/A" indicates the Code does not establish acceptance criteria or does not require evaluation of this kind of imperfection for this type of weld.

(c) Check (✓) indicates examination method generally used for evaluating this kind of weld imperfection.

(d) Ellipsis (. . .) indicates examination method not generally used for evaluating this kind of weld imperfection.

NOTES:

(1) Criteria given are for required examination. More stringent criteria may be specified in the engineering design. Other methods of examination may be specified by engineering design to supplement the examination required by the code. The extent of supplementary examination and any acceptance criteria differing from those specified by the code shall be specified by engineering design. Any examination method recognized by the code may be used to resolve doubtful indications. Acceptance criteria shall be those established by the code for the required examination.

(2) Longitudinal groove weld includes straight and spiral seam. Criteria are not intended to apply to welds made in accordance with component standards recognized by the code (ref. ASME.B31.3 Table A1 and Table 326.1); however, alternative leak test requirements dictate that all component welds be examined (see code for specific requirements).

(3) Fillet weld includes socket and seal welds, and attachment welds for slip-on flanges, branch reinforcement, and supports.

(4) Branch connection weld includes pressure containing welds in branches and fabricated laps.

(5) These imperfections are evaluated only for welds ≤5 mm (3⁄16 in) in nominal thickness.

(6) Where two limiting values are separated by *and* the lesser of the values determines acceptance. Where two sets of values are separated by *or* the larger value is acceptable. $\overline{T}_w$ is the nominal wall thickness of the thinner of two components joined by a butt weld.

(7) Tightly butted unfused root faces are unacceptable.

(8) For groove welds, height is the lesser of the measurements made from the surfaces of the adjacent components; both reinforcement and internal protrusion are permitted in a weld. For fillet welds, height is measured from the theoretical throat defined by the code; internal protrusion does not apply.

(9) For welds in aluminum alloy only, internal protrusion shall not exceed the following values:

(a) for thickness ≤2 mm (5⁄64 in): 1.5 mm (1⁄16 in)

(b) for thickness >2 mm and ≤6 mm (¼ in): 2.5 mm (3⁄32 in)

For external reinforcement and for greater thicknesses, see the tabulation for Symbol L.

*Table 10-51 and notes have been extracted (with minor modifications) from Section 341 of *Process Piping*, ASME B31.3–2004, with permission of the publisher, the American Society of Mechanical Engineers, New York. All rights reserved.

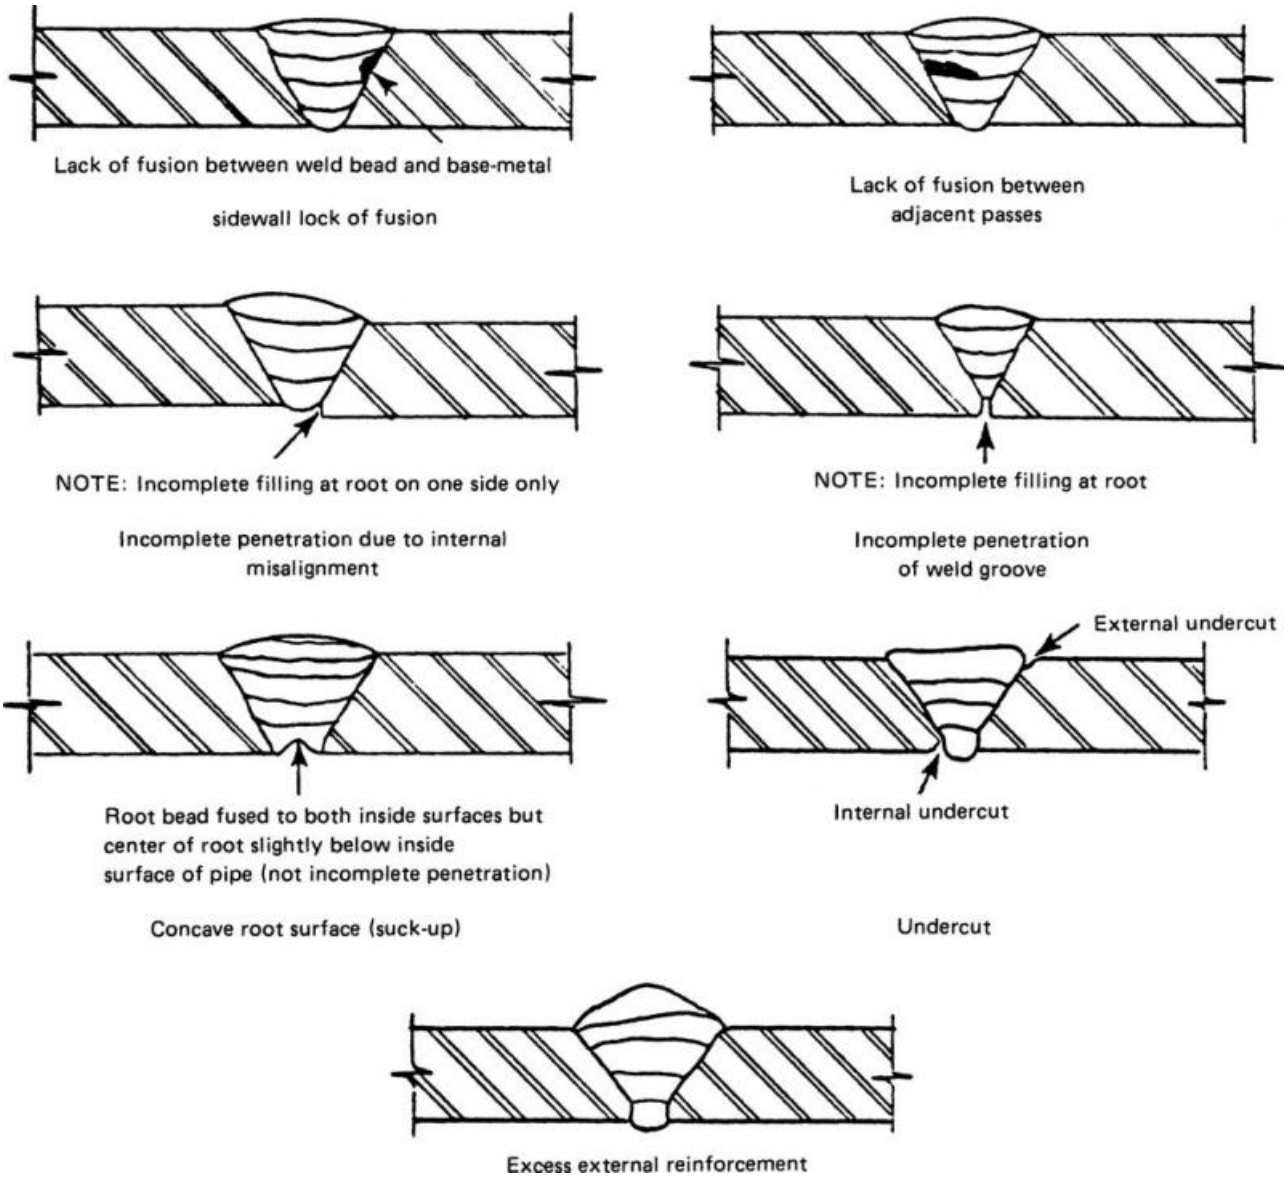


**FIG. 10-169** Typical weld imperfections. (*Extracted from Process Piping, ASME B31.3-2014, with permission of the publisher, the American Society of Mechanical Engineers, New York. All rights reserved.*)

When pressure tests are conducted at metal temperatures near the ductile-to-brittle transition temperature of the material, the possibility of brittle fracture shall be considered.

The test shall be hydrostatic, using water, with the following exceptions. If there is a possibility of damage due to freezing or if the operating fluid or piping material would be adversely affected by water, any other suitable nontoxic liquid may be used. If a flammable liquid is used, its flash point shall not be less than 50°C (120°F), and consideration shall be given to the test environment.

The hydrostatic-test pressure at any point in the system shall be as follows:

1. Not less than 1½ times the design pressure.
2. For a design temperature above the test temperature, the minimum test pressure shall be as calculated by the following formula:

$$P_T = 1.5PS_T/S \tag{10-106}$$

where $P_T$ = test hydrostatic gauge pressure, MPa (lbf/in$^2$)
$P$ = internal design pressure, MPa (lbf/in$^2$)
$S_T$ = allowable stress at test temperature, MPa (lbf/in$^2$)
$S$ = allowable stress at design temperature, MPa (lbf/in$^2$)

If the test pressure as so defined would produce a stress in excess of the yield strength at test temperature, the test pressure may be reduced to the maximum pressure that will not exceed the yield strength at test temperature. If the test liquid in the system is subject to thermal expansion, precautions shall be taken to avoid excessive pressure.

A preliminary air test at not more than 0.17 MPa (25 lbf/in$^2$) gauge pressure may be made prior to hydrostatic test in order to locate major leaks.

If hydrostatic testing is not considered practicable by the owner, a pneumatic test in accordance with the following procedure may be substituted, using air or another nonflammable gas.

If the piping is tested pneumatically, the test pressure shall be 110 percent of the design pressure. When pneumatically testing nonmetallic materials, ensure that the materials are suitable for compressed gas. Pneumatic testing involves a hazard due to the possible release of energy stored in compressed gas. Therefore, particular care must be taken to minimize the chance of brittle failure of metals and thermoplastics. The test temperature is important in this regard and must be considered when material is chosen in the original design. Any pneumatic test shall include a preliminary check at not more than 0.17 MPa (25 lbf/in$^2$) gauge pressure. The pressure shall be increased gradually in steps providing sufficient time to allow the piping to equalize strains during

GENERAL NOTE: The exemptions for mandatory PWHT are defined in ASME B31.1-2016, Table 331.1.3. Reprinted from ASME B31.1-2016 by permission of the American Society of Mechanical Engineers, New York. All rights reserved.
NOTES:
(1) The holding temperature range is further defined in para. 331.1.6(c), ASME B31.1-2016, and in Table 331.1.2.
(2) The control thickness is defined in para. 331.1.3.
(3) Cooling rate shall not be greater than 55°C (100°F) per hour in the range above 650°C (1200°F), after which the cooling rate shall be sufficiently rapid to prevent embrittlement.
(4) If PWHT is performed after welding, it shall be within the following temperature ranges for the specific alloy, followed by rapid cooling:
Alloys S31803 and S32205 — 1020°C to 1100°C (1870°F to 2010°F)
Alloy S32550 — 1040°C to 1120°C (1900°F to 2050°F)
Alloy S32750 — 1025°C to 1125°C (1880°F to 2060°F)
All others — 980°C to 1040°C (1800°F to 1900°F)
(5) Cooling rate shall be >165°C (300°F)/h to 315°C (600°F)/h.
(6) The minimum PWHT holding temperature may be 675°C (1250°F) for nominal material thicknesses [see para. 331.1.3(c)] ≤13 mm (½ in.).
(7) The Ni + Mn content of the filler metal shall not exceed 1.2% unless specified by the designer, in which case the maximum temperature to be reached during PWHT shall be the $A_1$ (lower transformation or lower critical temperature) of the filler metal, as determined by analysis and calculation or by test, but not exceeding 800°C (1470°F). If the 800°C (1470°F) limit was not exceeded but the $A_1$ of the filler metal was exceeded or if the composition of the filler metal is unknown, the weld must be removed and replaced. It shall then be rewelded with compliant filler metal and subjected to a compliant PWHT. If the 800°C (1470°F) limit was exceeded, the weld and the entire area affected by the PWHT will be removed and, if reused, shall be renormalized and tempered prior to reinstallation.
(8) Heat treat within 14 days after welding. Hold time shall be increased by 1.2 h for each 25 mm (1 in.) over 25 mm (1 in.) thickness.
Cool to 425°C (800°F) at a rate ≤280°C (500°F).

**TABLE 10-54 Types of Examination for Evaluating Imperfections***

| Type of imperfection | Type of examination | | | |

test and to check for leaks. Once test pressure has been achieved, the pressure shall be reduced to design pressure prior to examining for leakage.

At the owner's option, a piping system used only for Category D fluid service as defined in the subsection Classification of Fluid Service may be tested at the normal operating conditions of the system during or prior to initial operation by examining for leaks at every joint not previously tested. A preliminary check shall be made at not more than 0.17 MPa (25 lbf/in$^2$) gauge pressure when the contained fluid is a gas or a vapor. The pressure shall be increased gradually in steps providing sufficient time to allow the piping to equalize strains during testing and to check for leaks.

Tests alternative to those required by these provisions may be applied under certain conditions described in the code.

Piping required to have a sensitive leak test shall be tested by the gas and bubble formation testing method specified in Art. 10, App. I, Sec. V of the ASME Boiler and Pressure Vessel Code or by another method demonstrated to have equal or greater sensitivity. The sensitivity of the test shall be at least (100 Pa · mL)/s [($10^{-3}$ atm · mL)/s] under test conditions.

Records shall be kept of each piping installation during the testing.

## COST COMPARISON OF PIPING SYSTEMS

Piping may represent as much as 25 percent of the cost of a chemical-process plant. The installed cost of piping systems varies widely with the materials of construction and the complexity of the system. A study of piping costs shows that the most economical choice of material for a simple straight piping run may not be the most economical for a complex installation made up of many short runs involving numerous fittings and valves. The economics also depend heavily on the pipe size and fabrication techniques employed. Fabrication methods such as bending to standard long-radius-elbow dimensions and machine-flaring lap joints have a large effect on the cost of fabricating pipe from ductile materials suited to these techniques. Cost reductions of as high as 35 percent are quoted by some custom fabricators utilizing advanced techniques; however, the basis for pricing comparisons should be carefully reviewed.

Figure 10-170 is based on data extracted from a comparison of the installed cost of piping systems of various materials published by Dow Chemical Co. The chart shows the relative cost ratios for systems of various materials based on two installations, one consisting of 152 m (500 ft) of 2-in pipe in a complex piping arrangement and the other of 305 m (1000 ft) of 2-in pipe in a straight-run piping arrangement. Figure 10-170 is based on field-fabrication construction techniques using welding stubs, the method commonly used by contractors. A considerably different ranking would result from using other construction methods such as machine-formed lap joints and bends in place of welding elbows. Piping cost experience shows that it is difficult to generalize and reflect accurate piping cost comparisons. Although the prices for many of the metallurgies shown in Fig. 10-170 are very volatile even over short periods, Fig. 10-170 may still be used as a reasonable initial estimate of the relative cost of metallic materials. The cost of nonmetallic materials and lined metallic materials versus solid alloy materials should be carefully reviewed prior to material selection. For an accurate comparison the cost for each type of material must be estimated individually on the basis of the actual fabrication and installation methods that will be used, pipe sizes, and the conditions anticipated for the proposed installation.

## FORCES OF PIPING ON PROCESS MACHINERY AND PIPING VIBRATION

The reliability of process rotating machinery is affected by the quality of the process piping installation. Excessive external forces and moments upset casing alignment and can reduce clearance between motor and casing. Further, the bearings, seals, and coupling can be adversely affected, resulting in repeated failures that may be correctly diagnosed as misalignment, and may have excessive piping forces as the root causes. Most turbine and compressor manufacturers have prescribed specification or will follow NEMA standards for allowable nozzle loading. For most of the pumps, API or ANSI pump standards will be followed when evaluating the pump nozzle loads. Pipe support restraints need to be placed at the proper locations to protect the machinery nozzles during operation.

Prior to any machinery alignment procedure, it is imperative to check for machine pipe strain. This is accomplished by the placement of dial indicators on the shaft and then loosening the hold-down bolts. Movements of greater than 1 mil are considered indication of a pipe strain condition.

This is an important practical problem area, as piping vibration can cause considerable downtime or even pipe failure.

Pipe vibration is caused by

1. Internal flow (pulsation)
2. Plant machinery (such as compressors, pumps)

Pulsation can be problematic and difficult to predict. Pulsations are also dependent on acoustic resonance characteristics. For reciprocating equipment, such as reciprocating compressors and pumps, in some cases, an analog (digital) study needs to be performed to identify the deficiency in the piping and pipe support systems as well as to evaluate the performance of the machine during operation. The study will also provide recommendations on how to improve the machine and piping system's performance.

When a pulsation frequency coincides with a mechanical or acoustic resonance, severe vibration can result. A common cause for pulsation is the presence of flow control valves or pressure regulators. These often operate with high pressure drops (i.e., high flow velocities), which can result in the generation of severe pulsation. Flashing and cavitation can also contribute.

Modern-day piping design codes can model the vibration situation, and problems can thus be resolved in the design phases.

## HEAT TRACING OF PIPING SYSTEMS

Heat tracing is used to maintain pipes and the material that pipes contain at temperatures above the ambient temperature. Two common uses of heat tracing are to prevent water pipes from freezing and maintain fuel oil pipes at high enough temperatures that the viscosity of the fuel oil will allow easy pumping. Heat tracing is also used to prevent the condensation of a liquid from a gas and to prevent the solidification of a liquid commodity.

A heat-tracing system is often more expensive on an installed cost basis than the piping system it is protecting, and it will also have significant operating costs. A study of heat-tracing costs by a major chemical company showed installed costs of $31/ft to $142/ft and yearly operating costs of $1.40/ft to $16.66/ft. In addition to being a major cost, the heat-tracing system is an important component of the reliability of a piping system. A failure in the heat-tracing system will often render the piping system inoperable. For example, with a water freeze protection system, the piping system may be destroyed by the expansion of water as it freezes if the heat-tracing system fails.

The vast majority of heat-traced pipes are insulated to minimize heat loss to the environment. A heat input of 2 to 10 W/ft is generally required to prevent an insulated pipe from freezing. With high wind speeds, an uninsulated pipe could require well over 100 W/ft to prevent freezing. Such a high heat input would be very expensive.

Heat tracing for insulated pipes is generally only required for the period when the material in the pipe is not flowing. The heat loss of an insulated pipe is very small compared to the heat capacity of a flowing fluid. Unless the pipe is extremely long (several thousands of feet), the temperature drop of a flowing fluid will not be significant.

There are three major methods of avoiding heat tracing:

1. Change the ambient temperature around the pipe to a temperature that will avoid low-temperature problems. Burying water pipes below the frost line or running them through a heated building are the two most common examples of this method.
2. Empty a pipe after it is used. Arranging the piping such that it drains itself when not in use can be an effective method of avoiding the need for heat tracing. Some infrequently used lines can be pigged or blown out with compressed air. This technique is not recommended for commonly used lines due to the high labor requirement.
3. Arrange a process such that some lines have continuous flow; this can eliminate the need for tracing these lines. This technique is generally not recommended because a failure that causes a flow stoppage can lead to blocked or broken pipes.

Some combination of these techniques may be used to minimize the quantity of traced pipes. However, the majority of pipes containing fluids that must be kept above the minimum ambient temperature are generally going to require heat tracing.

**Types of Heat-Tracing Systems** Industrial heat-tracing systems are generally fluid systems or electrical systems. In fluid systems, a pipe or tube called the *tracer* is attached to the pipe being traced, and a warm fluid is

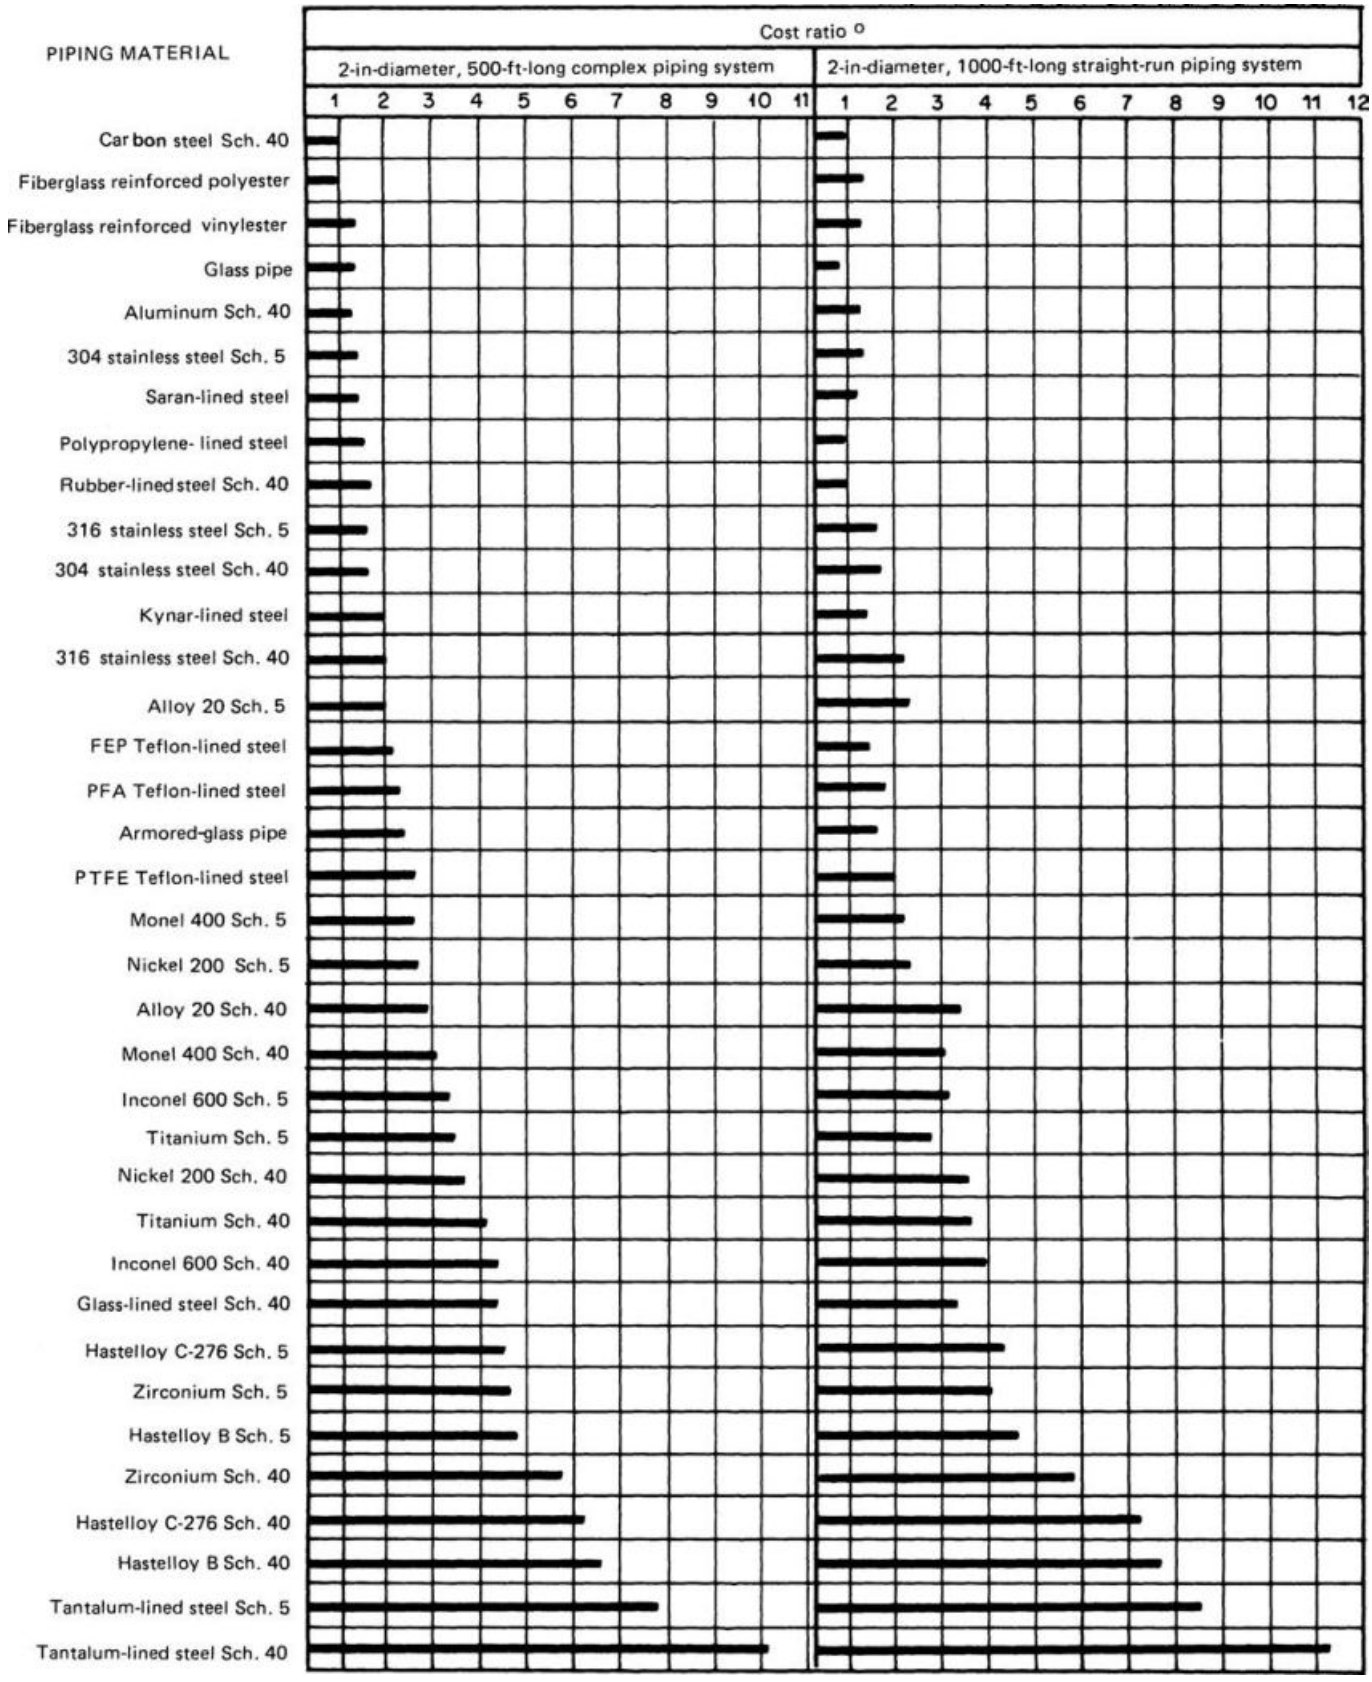

**FIG. 10-170** Cost rankings and cost ratios for various piping materials. This figure is based on field-fabrication construction techniques using welding stubs, as this is the method most often employed by contractors. A considerably different ranking would result from using other construction methods, such as machined-formed lap joints, for the alloy pipe. [o]Cost ratio = (cost of listed item)/(cost of Schedule 40 carbon-steel piping system, field-fabricated by using welding stubs). (*Extracted with permission from* Installed Cost of Corrosion Resistant Piping, *copyright 1977, Dow Chemical Co.*)

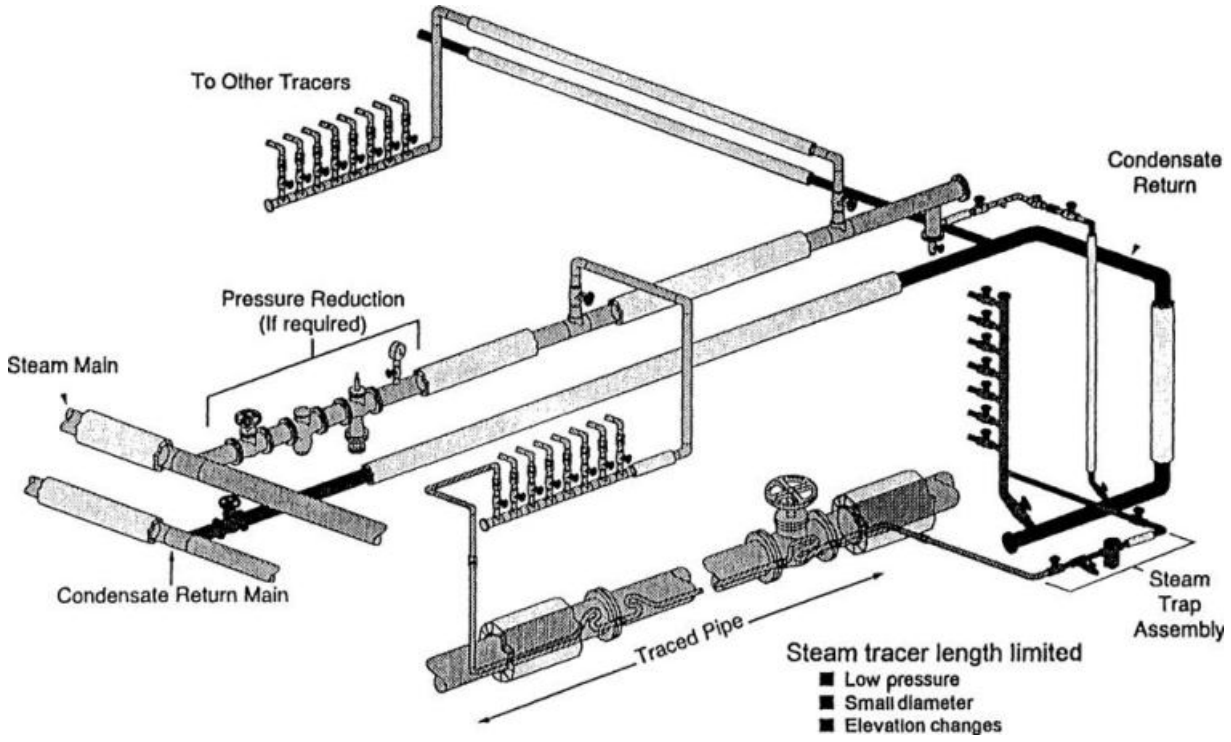

**FIG. 10-171** Steam tracing system.

put through it. The tracer is placed under the insulation. Steam is by far the most common fluid used in the tracer, although ethylene glycol and more exotic heat-transfer fluids are used. In electrical systems, an electrical heating cable is placed against the pipe under the insulation.

***Fluid Tracing Systems*** Steam tracing is the most common type of industrial pipe tracing. In 1960, over 95 percent of industrial tracing systems were steam-traced. By 1995, improvements in electric heating technology increased the electric share to 30 to 40 percent. Fluid systems other than steam are rather uncommon and account for less than 5 percent of tracing systems.

Half-inch copper tubing is commonly used for steam tracing. Three-eighths-inch tubing is also used, but the effective circuit length is then decreased from 150 ft to about 60 ft. In some corrosive environments, stainless steel tubing is used.

In addition to the tracer, a steam tracing system (Fig. 10-171) consists of steam supply lines to transport steam from the existing steam lines to the traced pipe, a steam trap to remove the condensate and hold back the steam, and in most cases a condensate return system to return the condensate to the existing condensate return system. In the past, a significant percentage of condensate from steam tracing was simply dumped to drains, but increased energy costs and environmental rules have caused almost all condensate from new steam tracing systems to be returned. This has significantly increased the initial cost of steam tracing systems.

Applications requiring accurate temperature control are generally limited to electric tracing. For example, chocolate lines cannot be exposed to steam temperatures, or the product will degrade; and if caustic soda is heated above 65°C (150°F), it becomes extremely corrosive to carbon-steel pipes.

For some applications, either steam or electricity is simply not available, and this makes the decision. It is rarely economic to install a steam boiler just for tracing. Steam tracing is generally considered only when a boiler already exists or is going to be installed for some other primary purpose. Additional electric capacity can be provided in most situations for reasonable costs. It is considerably more expensive to supply steam from a long distance than it is to provide electricity. Unless steam is available close to the pipes being traced, the automatic choice is usually electric tracing.

For most applications, particularly in processing plants, either steam tracing or electric tracing could be used, and the correct choice is dependent on the installed costs and the operating costs of the competing systems.

***Economics of Steam Tracing versus Electric Tracing*** The question of the economics of various tracing systems has been examined thoroughly. All these papers have concluded that electric tracing is generally less expensive to install and significantly less expensive to operate. Electric tracing has significant cost advantages in terms of installation because less labor is required than for steam tracing. However, it is clear that there are some special cases where steam tracing is more economical.

The two key variables in the decision to use steam tracing or electric tracing are the temperature at which the pipe must be maintained and the distance to the supply of steam and a source of electric power.

Table 10-55 shows the installed costs and operating costs for 400 ft of 4-in pipe, maintained at four different temperatures, with supply lengths of 100 ft for both electricity and steam and $25/h labor.

These are the major advantages of a steam tracing system:

1. *High heat output.* Due to its high temperature, a steam tracing system provides a large amount of heat to the pipe. There is a very high heat-transfer rate between the metallic tracer and a metallic pipe. Even with damage to the insulation system, there is very little chance of a low-temperature failure with a steam tracing system.
2. *High reliability.* Many things can go wrong with a steam tracing system, but very few of the potential problems lead to a heat-tracing failure. Steam traps fail, but they usually fail in the open position, allowing for a continuous flow of steam to the tracer. Other problems such as steam leaks that can cause wet insulation are generally prevented from becoming heat-tracing failures by the extremely high heat output of a steam tracer. Also, a tracing tube is capable of withstanding a large amount of mechanical abuse without failure.
3. *Safety.* While steam burns are fairly common, there are generally fewer safety concerns than with electric tracing.
4. *Common usage.* Steam tracing has been around for many years, and many operators are familiar with the system. Because of this familiarity, failures due to operator error are not very common.

These are the weaknesses of a steam tracing system:

1. *High installed costs.* The incremental piping required for the steam supply system and the condensate return system must be installed and insulated, and in the case of the supply system, additional steam traps are often required.

**TABLE 10-55 Steam versus Electric Tracing***

| Temperature maintained | TIC | | Ratio S/E | TOC | | Ratio S/E |
|---|---|---|---|---|---|---|
| | Steam | Electric | | Steam | Electric | |
| 50°F | 22,265 | 7,733 | 2.88 | 1,671 | 334 | 5.00 |
| 150°F | 22,265 | 13,113 | 1.70 | 4,356 | 1,892 | 2.30 |
| 250°F | 22,807 | 17,624 | 1.29 | 5,348 | 2,114 | 2.53 |
| 400°F | 26,924 | 14,056 | 1.92 | 6,724 | 3,942 | 1.71 |

*Specifications: 400 ft of 44-in pipe, $25/h labor, $0.07/kWh, $4.00/1000 lb steam, 100-ft supply lines. TIC = total installed cost; TOC = total operating costs.

The tracer itself is not expensive, but the labor required for installation is relatively high. Studies have shown that steam tracing systems typically cost from 50 to 150 percent more than a comparable electric tracing system.

2. *Energy inefficiency.* A steam tracing system's total energy use is often more than 20 times the actual energy requirement to keep the pipe at the desired temperature. The steam tracer itself puts out significantly greater energy than required. The steam traps use energy even when they are properly operating and waste large amounts of energy when they fail in the open position, which is the common failure mode. Steam leaks waste large amounts of energy, and both the steam supply system and the condensate return system use significant amounts of energy.

3. *Poor temperature control.* A steam tracing system offers very little temperature control capability. The steam is at a constant temperature (50 psig steam is 300°F) usually well above that desired for the pipe. The pipe will reach an equilibrium temperature somewhere between the steam temperature and the ambient temperature. However, the section of pipe against the steam tracer will effectively be at the steam temperature. This is a serious problem for temperature-sensitive fluids such as food products. It also represents a problem with fluids such as bases and acids, which are not damaged by high temperatures but often become extremely corrosive to piping systems at higher temperatures.

4. *High maintenance costs.* Leaks must be repaired and steam traps must be checked and replaced if they have failed. Numerous studies have shown that, due to the energy lost through leaks and failed steam traps, an extensive maintenance program is an excellent investment. Steam maintenance costs are so high that for low-temperature maintenance applications, total steam operating costs are sometimes greater than electric operating costs, even if no value is placed on the steam.

***Electric Tracing*** An electric tracing system (see Fig. 10-172) consists of an electric heater placed against the pipe under the thermal insulation, the supply of electricity to the tracer, and any control or monitoring system that may be used (optional). The supply of electricity to the tracer usually consists of an electrical panel and electrical conduit or cable trays. Depending on the size of the tracing system and the capacity of the existing electrical system, an additional transformer may be required.

***Advantages of Electric Tracing***

1. *Lower installed and operating costs.* Most studies have shown that electric tracing is less expensive to install and less expensive to operate. This is true for most applications. However, for some applications, the installed costs of steam tracing are equal to or less than those of electric tracing.

2. *Reliability.* In the past, electric heat tracing had a well-deserved reputation for poor reliability. However, since the introduction of self-regulating heaters in 1971, the reliability of electric heat tracing has improved dramatically. Self-regulating heaters cannot destroy themselves with their own heat output. This eliminates the most common failure mode of polymer-insulated constant-wattage heaters. Also, the technology used to manufacture mineral-insulated cables, high-temperature electric heat tracing, has improved significantly, and this has improved their reliability.

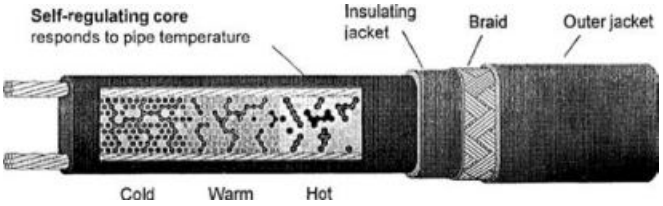

**FIG. 10-173** Self-regulating heating cable.

3. *Temperature control.* Even without a thermostat or any control system, an electric tracing system usually provides better temperature control than a steam tracing system. With thermostatic or electronic control, very accurate temperature control can be achieved.

4. *Safety.* The use of self-regulating heaters and ground leakage circuit breakers has answered the safety concerns of most engineers considering electric tracing. Self-regulating heaters eliminate the problems from high-temperature failures, and ground leakage circuit breakers minimize the danger of an electrical fault to ground, causing injury or death.

5. *Monitoring capability.* One question often asked about any heat-tracing system is, "How do I know it is working?" Electric tracing now has available almost any level of monitoring desired. The temperature at any point can be monitored with both high and low alarm capability. This capability has allowed many users to switch to electric tracing with a high degree of confidence.

6. *Energy efficiency.* Electric heat tracing can accurately provide the energy required for each application without the large additional energy use of a steam system. Unlike steam tracing systems, other parts of the system do not use significant amounts of energy.

***Disadvantages of Electric Tracing***

1. *Poor reputation.* In the past, electric tracing has been less than reliable. Due to past failures, some operating personnel are unwilling to take a chance on any electric tracing.

2. *Design requirements.* A slightly higher level of design expertise is required for electric tracing than for steam tracing.

3. *Lower power output.* Since electric tracing does not provide a large multiple of the required energy, it is less forgiving to problems such as damaged insulation or below design ambient temperatures. Most designers include a 10 to 20 percent safety factor in the heat loss calculation to cover these potential problems. Also, a somewhat higher than required design temperature is often specified to provide an additional safety margin. For example, many water systems are designed to maintain 50°F to prevent freezing.

***Types of Electric Tracing*** *Self-regulating electric tracing* (see Fig. 10-173) is by far the most popular type of electric tracing. The heating element in

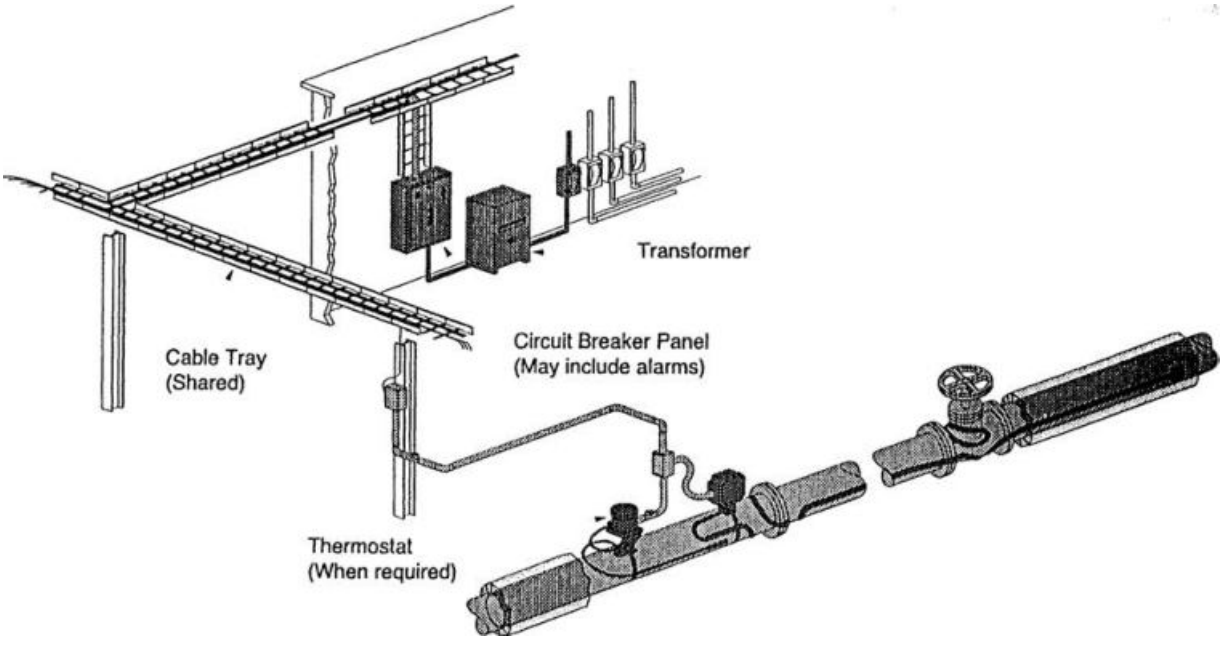

**FIG. 10-172** Electrical beat tracing system.

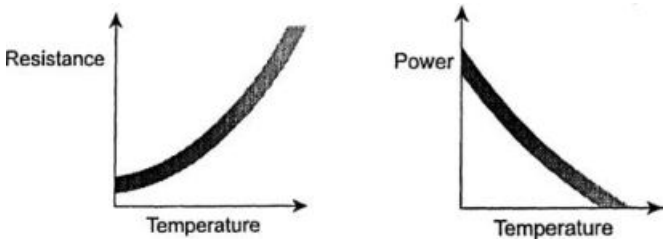

**FIG. 10-174** Self-regulation.

a self-regulating heater is a conductive polymer between the bus wires. This conductive polymer increases its resistance as its temperature increases. The increase in resistance with temperature causes the heater to lower its heat output at any point where its temperature increases (Fig. 10-174). This self-regulating effect eliminates the most common failure mode of constant-wattage electric heaters, which is destruction of the heater by its own heat output.

Because self-regulating heaters are parallel heaters, they may be cut to length at any point without changing their power output per unit of length. This makes them much easier to deal with in the field. They may be terminated, teed, or spliced in the field with hazardous-area-approved components.

***MI Cables*** Mineral insulated cables (Fig. 10-175) are the electric heat tracers of choice for high-temperature applications. High-temperature applications are generally considered to maintain temperatures above 250°F or exposure temperatures above 420°F where self-regulating heaters cannot be used. MI cable consists of one or two heating wires, magnesium oxide insulation (whence it gets its name) and an outer metal sheath. Today the metal sheath is generally Inconel. This eliminates both the corrosion problems with copper sheaths and the stress cracking problems with stainless steel.

MI cables can maintain temperatures up to 1200°F and withstand exposure up to 1500°F. The major disadvantage of MI cable is that it must be factory-fabricated to length. It is very difficult to terminate or splice the heater in the field. This means pipe measurements are necessary before the heaters are ordered. Also, any damage to an MI cable generally requires a complete new heater. It's not as easy to splice in a good section as with self-regulating heaters.

***Polymer-Insulated Constant-Wattage Electric Heaters*** These are slightly cheaper than self-regulating heaters, but they are generally being replaced with self-regulating heaters due to inferior reliability. These heaters tend to destroy themselves with their own heat output when they are overlapped at valves or flanges. Since overlapping self-regulating heaters is the standard installation technique, it is difficult to prevent this technique from being used on the similar-looking constant-wattage heaters.

**TABLE 10-56 Effect of Supply Lengths**

| Ratio of steam TIC to electric TIC maintained at 150°F | | | |
|---|---|---|---|
| | Electric supply length | | |
| Steam supply length, ft | 40 ft | 100 ft | 300 ft |
| 40 | 1.1 | 1.0 | 0.7 |
| 100 | 1.9 | 1.7 | 1.1 |
| 300 | 4.9 | 4.2 | 2.9 |

***SECT (Skin-Effect Current Tracing)*** This is a special type of electric tracing employing a tracing pipe, usually welded to the pipe being traced, that is used for extremely long lines. With SECT circuits, up to 10 mi can be powered from one power point. All SECT systems are specially designed by heat-tracing vendors.

***Impedance Tracing*** This uses the pipe being traced to carry the current and generate the heat. Less than 1 percent of electric heat-tracing systems use this method. Low voltages and special electrical isolation techniques are used. Impedance heating is useful when extremely high heat densities are required, such as when a pipe containing aluminum metal must be melted from room temperature on a regular basis. Most impedance systems are specially designed by heat-tracing vendors.

**Choosing the Best Tracing System** Some applications require either steam tracing or electric tracing regardless of the relative economics. For example, a large line that is regularly allowed to cool and needs to be quickly heated would require steam tracing because of its much higher heat output capability. In most heat-up applications, steam tracing is used with heat-transfer cement, and the heat output is increased by a factor of up to 10. This is much more heat than would be practical to provide with electric tracing. For example, a ½-in copper tube containing 50 psig steam with heat-transfer cement would provide over 1100 Btu/(h·ft) to a pipe at 50°F. This is over 300 W/ft or more than 15 times the output of a high-powered electric tracer.

Table 10-55 shows that electric tracing has a large advantage in terms of cost at low temperatures and smaller but still significant advantages at higher temperatures. Steam tracing does relatively better at higher temperatures because steam tracing supplies significantly more power than is necessary to maintain a pipe at low temperatures. Table 10-55 indicates that there is very little difference between the steam tracing system at 50°F and the system at 250°F. However, the electric system more than doubles in cost between these two temperatures because more heaters, higher-powered heaters, and higher-temperature heaters are required.

The effect of supply lengths on a 150°F system can be seen from Table 10-56. Steam supply pipe is much more expensive to run than electrical conduit. With each system having relatively short supply lines (40 ft each) the electric system has only a small cost advantage (10 percent, or a ratio of 1.1). This ratio is 2.1 at 50°F and 0.8 at 250°F. However, as the supply lengths increase, electric tracing has a large cost advantage.

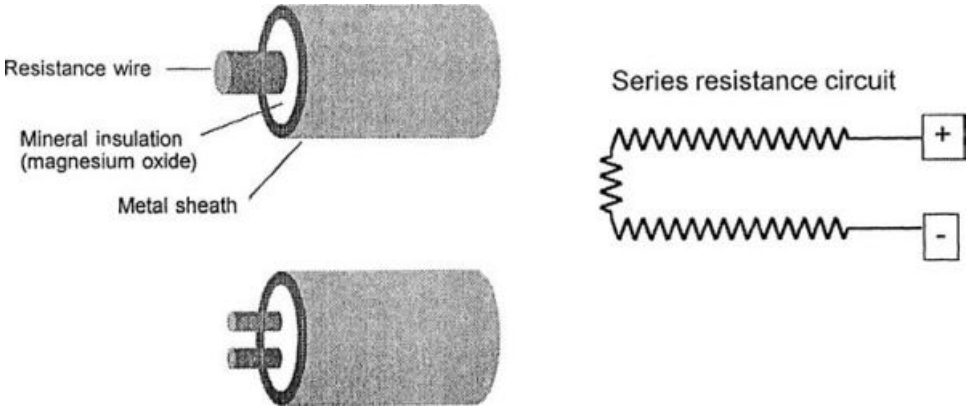

**FIG. 10-175** Mineral insulated cable (MI cable).

# STORAGE AND PROCESS VESSELS

## STORAGE OF LIQUIDS

**Atmospheric Tanks** The term *atmospheric tank* as used here applies to any tank that is designed to operate at pressures from atmospheric through 3.45 kPag (0.5 psig). It may be either open to the atmosphere or enclosed. Atmospheric tanks may be either shop-fabricated or field-erected. The most common application is storage of fuel for transportation and power generation. See Pressure Tanks and Pressure Vessels later in this subsection.

**Shop-Fabricated Storage Tanks** A shop-fabricated storage tank is a storage tank constructed at a tank manufacturer's plant and transported to a facility for installation. In general, tanks 190 $m^3$ (50,000 gal) and under can be shop-fabricated and shipped in one piece to an installation site. Shop-fabricated storage tanks may be either *underground storage tanks* (USTs) or *aboveground storage tanks* (ASTs).

**USTs versus ASTs** For decades, USTs were the standard means of storing petroleum and chemicals in quantities of 190 $m^3$ (50,000 gal) or less. However, during the 1990s, many industrial and commercial facilities shifted to ASTs for hazardous product storage. Reasons include the ability to visually monitor the storage tank as well as to avoid perceived risks and myriad regulations surrounding underground storage tanks. Nonetheless, AST installations are also subject to certain regulations and codes, particularly fire codes.

The choice of USTs or ASTs is driven by numerous factors. Local authorities having jurisdiction may allow only USTs. Limited real estate may also preclude the use of ASTs. In addition, ASTs are subject to minimum distance separations from one another and from buildings, property lines, and public ways. ASTs are visually monitorable, yet may be aesthetically undesirable. Other considerations are adequate protection from spills, vandalism, and vehicular damage. Additionally, central design elements regarding product transfer and system functionality must be taken into account.

USTs are subject to myriad EPA regulations and fire codes. Further, a commonly cited drawback is the potential for unseen leaks and subsequent environmental damage and cleanup. However, advances in technology have addressed these concerns. Corrosion protection and leak detection are now standard in all UST systems. Sophisticated tank and pipe secondary containment systems have been developed to meet the EPA's secondary containment mandate for underground storage of nonpetroleum chemicals. In-tank monitoring devices for tracking inventory, tank integrity testing equipment, statistical inventory reconciliation analysis, leak-free dry-disconnect pipe and hose joints for loading/unloading, and in-tank fill shutoff valves are just a few of the many pieces of equipment which have surfaced as marketplace solutions.

Properly designed and installed in accordance with industry standards, regulations, and codes, both UST and AST systems are reliable and safe. Because of space limitations and the prevalence of ASTs at plant sites, only ASTs will be discussed further.

**Aboveground Storage Tanks** Aboveground storage tanks are classified as either field-erected or shop-fabricated. The latter are typically 190 $m^3$ (50,000 gal) or less and may be shipped over the highway, while larger tanks are more economically erected in the field. Whereas field-erected tanks likely constitute the majority of total AST storage *capacity*, shop-fabricated ASTs constitute the majority of the total *number* of ASTs in existence today. Most of these shop-fabricated ASTs store hazardous liquids at atmospheric pressure and have 45-$m^3$ (12,000-gal) capacity or smaller.

Shop-fabricated ASTs can be designed and fabricated as pressure vessels, but are more typically vented to atmosphere. They are oriented for either horizontal or vertical installation and are made in either cylindrical or rectangular form. Tanks are often secondarily contained and may also include insulation for fire safety or temperature control. Compartmented ASTs are also available. Over 90 percent of the atmospheric tank applications store some sort of hydrocarbon. Within that, a majority are used to store motor fuels.

***Fire Codes*** Many chemicals are hazardous and may be subject to fire codes. All hydrocarbon tanks are classified as hazardous. Notably, with the increase in the use of ASTs at private fleet fueling facilities in the 1990s, fire codes were rapidly modified to address safety concerns. In the United States, two principal organizations publish fire codes for underground storage tanks, with each state adopting all or part of the respective codes.

The *National Fire Protection Association* (NFPA) has developed several principal codes pertaining to the storage of flammable and combustible liquids:

**NFPA 30,** *Flammable and Combustible Liquids Code* (2015)

**NFPA 30A,** *Code for Motor Fuel Dispensing Facilities and Repair Garages* (2015)

**NFPA 31,** *Standard for the Installation of Oil Burning Equipment* (2016)

The *International Code Council* (ICC) was formed by the consolidation of three formerly separate fire code organizations: International Conference of Building Officials (ICBO), which had published the Uniform Fire Code under its fire service arm, the International Fire Code Institute (IFCI); Building Officials and Code Administrators (BOCA), which had published the National Fire Prevention Code; and Southern Building Congress Code International (SBCCI), which had published the Standard Fire Prevention Code. When the three groups merged in 2000, in part to develop a common fire code, the individual codes became obsolete; however, they are noted above since references to them may periodically surface. The consolidated code is **IFC-2015,** *International Fire Code.*

The *Canadian Commission on Building and Fire Codes* (CCBFC) developed a recommended model code to permit adoption by various regional authorities. The National Research Council of Canada publishes the model code document *National Fire Code of Canada* (2010).

***Standards*** Third-party standards for AST fabrication have evolved over the past two decades, as have recommended practice guidelines for the installation and operations of AST systems. Standards developed by *Underwriters Laboratories* (UL) have been the most predominant of guidelines—in fact, ASTs are often categorized according to the UL standard that they meet, such as "a UL 142 tank."

Underwriters Laboratories Inc. standards for steel ASTs storing hazardous liquids include the following:

**UL 142,** *Steel Aboveground Tanks for Flammable and Combustible Liquids,* 9th ed., covers aboveground, steel atmospheric tanks for storage of noncorrosive, stable, and hazardous liquids that have a specific gravity not exceeding that of water. UL 142 applies to single-wall and double-wall horizontal carbon-steel and stainless steel tanks up to 190 $m^3$ (50,000 gal), with a maximum diameter of 3.66 m (12 ft) and a maximum length-to-diameter ratio of 8 to 1. A formula from *Roark's Formulas for Stress and Strain* has been incorporated within UL 58 to calculate minimum steel wall thicknesses. UL 142 also applies to vertical tanks up to 10.7 m (35 ft) in height. UL 142 has been the primary AST standard since its development in 1922.

Tanks covered by these standards can be fabricated in cylindrical or rectangular configurations. The standard covers secondary contained tanks, either of dual-wall construction or a tank in a steel or concrete dike or bund. It also provides listings for special AST construction, such as those used under generators for backup power. These tanks are fabricated, inspected, and tested for leakage before shipment from the factory as completely assembled vessels.

UL 142 provides details for steel type, wall thickness, compartments and bulkheads, manways, and other fittings and appurtenances. Issues relating to leakage, venting, and the ability of the tank to withstand the development of internal pressures encountered during operation and production leak testing are also addressed.

These requirements do not apply to large field-erected storage tanks covered by the *Standard for Welded Steel Tanks for Oil Storage*, **API 650,** or the *Specification for Field-Welded Tanks for Storage of Production Liquids*, **API 12D**; or the *Specification for Shop-Welded Tanks for Storage of Production Liquids*, **API 12F**.

**UL 2085,** *Protected Aboveground Tanks for Flammable and Combustible Liquids*, covers shop-fabricated, aboveground atmospheric protected tanks intended for storage of stable, hazardous liquids that have a specific gravity not greater than that of water and that are compatible with the material and construction of the tank.

The tank construction is intended to limit the heat transferred to the primary tank when the AST is exposed to a 2-h hydrocarbon pool fire of 1093°C (2000°F). The tank must be insulated to withstand the test without leakage and with an average maximum temperature rise on the primary tank not exceeding 127°C (260°F). Temperatures on the inside surface of the primary tank cannot exceed 204°C (400°F).

UL 2085 also provides criteria for resistance against vehicle impact, ballistic impact, and fire hose impact. These tanks are also provided with integral secondary containment intended to prevent any leakage from the primary tank.

**UL 2080,** *Fire Resistant Tanks for Flammable and Combustible Liquids,* is similar to UL 2085 tanks, except with an average maximum temperature rise on the primary tank limited to 427°C (800°F) during a 2-h pool fire. Temperatures on the inside surface of the primary tank cannot exceed 538°C (1000°F).

**UL 2244,** *Standard for Aboveground Flammable Liquid Tank Systems,* covers factory-fabricated, pre-engineered aboveground atmospheric tank systems intended for dispensing hazardous liquids, such as gasoline or diesel fuel, into motor vehicles, generators, or aircraft.

**UL 80,** *Steel Tanks for Oil-Burner Fuel,* covers the design and construction of welded, atmospheric steel tanks with a maximum capacity of 0.23 to 2.5 $m^3$ (60 to 660 gal) intended for unenclosed installation inside of buildings or for outside aboveground applications as permitted by the *Standard for Installation of Oil-Burning Equipment,* **NFPA 31,** primarily for the storage and supply of fuel oil for oil burners.

**UL 2245,** *Below-Grade Vaults for Flammable Liquid Storage Tanks,* covers below-grade vaults intended for the storage of hazardous liquids in an aboveground atmospheric tank. Below-grade vaults, constructed of a minimum of 150 mm (6 in) of reinforced concrete or other equivalent noncombustible material, are designed to contain one aboveground tank, which can be a compartment tank. Adjacent vaults may share a common wall. The lid of the vault may be at grade or below. Vaults provide a safe means to install hazardous tanks so that the system is accessible to the operator without unduly exposing the public.

Southwest Research Institute (SwRI) standards for steel ASTs storing hazardous liquids include the following:

**SwRI 93-01,** *Testing Requirements for Protected Aboveground Flammable Liquid/Fuel Storage Tanks,* includes tests to evaluate the performance of ASTs under fire, hose stream, ballistics, heavy vehicular impact, and different environments. This standard requires pool-fire resistance similar to that of UL 2085.

**SwRI 97-04,** *Standard for Fire Resistant Tanks,* includes tests to evaluate the performance of ASTs under fire and hose stream. This standard is similar to UL 2080 in that the construction is exposed to a 2-h hydrocarbon pool fire of 1093°C (2000°F). However, SwRI 97-04 is concerned only with the integrity of the tank after the 2-h test and is not concerned with the temperature inside the tank from heat transfer. As a result, UL 142 tanks have been tested to the SwRI standard and passed. Secondary containment with insulation is not necessarily an integral component of the system.

*Underwriters Laboratories of Canada* (ULC) publishes a number of standards for aboveground tanks and accessories. All the following pertain to the aboveground storage of hazardous liquids such as gasoline, fuel oil, or similar products with a relative density not greater than 1.0:

**ULC S601,** *Shop Fabricated Steel Aboveground Horizontal Tanks for Flammable and Combustible Liquids,* covers single- and double-wall cylindrical horizontal steel atmospheric tanks. These requirements do not cover tanks of capacities greater than 200 $m^3$ (52,800 gal).

**ULC S630,** *Shop Fabricated Steel Aboveground Vertical Tanks for Flammable and Combustible Liquids*, covers single- and double-wall cylindrical vertical steel atmospheric tanks.

**ULC S643,** *Shop Fabricated Steel Utility Tanks for Flammable and Combustible Liquids,* covers single- and double-wall cylindrical horizontal steel atmospheric tanks.

**ULC S653-94,** *Aboveground Steel Contained Tank Assemblies for Flammable and Combustible Liquids,* covers steel contained tank assemblies.

**ULC S655,** *Aboveground Protected Tank Assemblies for Flammable and Combustible Liquids,* covers shop-fabricated primary tanks that provided with secondary containment and protective encasement and are intended for stationary installation and use in accordance with

1. *National Fire Code of Canada*, Part 4
2. CAN/CSA-B139, *Installation Code for Oil Burning Equipment*
3. *The Environmental Code of Practice for Aboveground Storage Tank Systems Containing Petroleum Products*
4. The requirements of the authority having jurisdiction

**ULC/ORD C142.20,** *Secondary Containment for Aboveground Flammable and Combustible Liquid Storage Tanks,* covers secondary containments for aboveground primary tanks.

**ULC S602,** *Aboveground Steel Tanks for the Storage of Combustible Liquids Intended to Be Used as Heating and/or Generator Fuels,* covers the design and construction of tanks of the atmospheric-type, intended for installation inside or outside buildings. This standard covers single-wall tanks and tanks with secondary containment, having a maximum capacity of 2.5 $m^3$ (660 gal).

The *Petroleum Equipment Institute* (PEI) has developed a recommended practice for AST system installation: **PEI-RP200, RP 200,** *Recommended Practices for Installation of Aboveground Storage Systems for Motor Vehicle Fueling.*

The *American Petroleum Institute* (API) has developed a series of standards and specifications involving ASTs:

**API 12F,** *Shop Welded Tanks for Storage of Production Liquids*

**RP 12R1,** *Setting, Maintenance, Inspection, Operation, and Repair of Tanks in Production Service*

**RP 575,** *Inspection of Atmospheric and Low Pressure Storage Tanks*

**RP 579,** *Fitness-For-Service*

**API 650,** *Welded Tanks for Oil Storage*, now applies to welded aluminum alloy storage tanks as well as welded steel tanks.

**API 652,** *Lining of Aboveground Storage Tank Bottoms*

**API 653,** *Tank Inspection, Repair, Alteration, and Reconstruction*

**API 2350,** *Overfill Protection for Storage Tanks in Petroleum Facilities* (overfill is the primary cause of AST releases)

The *American Water Works Association* (AWWA) has many standards dealing with water handling and storage. A list of its publications is given in the *AWWA Handbook* (annually). AWWA D100, *Standard for Steel Tanks—Standpipes, Reservoirs, and Elevated Tanks for Water Storage*, contains rules for design and fabrication. Although AWWA tanks are intended for water, they could be used for the storage of other liquids.

The *Steel Tank Institute* (STI) publishes construction standards and recommended installation practices pertaining to ASTs fabricated to STI technologies. STI's recommended installation practices are notable for their applicability to similar respective technologies:

**SP001-06,** *Standard for Inspection of In-Service Shop Fabricated Aboveground Tanks for Storage of Combustible and Flammable Liquids*

**R912-00,** *Installation Instructions for Shop Fabricated Aboveground Storage Tanks for Flammable, Combustible Liquids*

**F921,** *Standard for Aboveground Tanks with Integral Secondary Containment*

*Standard for Fire Resistant Tanks (Flameshield)*

*Standard for Fireguard Thermally Insulated Aboveground Storage Tanks*

**F911,** *Standard for Diked Aboveground Storage Tanks*

The *National Association of Corrosion Engineers* (NACE International) has developed the following to protect the soil side of bottoms of on-grade carbon-steel storage tanks: **NACE RP0193-2001,** *Standard Recommended Practice—External Cathodic Protection of On-Grade Metallic Storage Tank Bottoms.*

***Environmental Regulations*** A key *U.S. Environmental Protection Agency* (U.S. EPA) requirement for certain aboveground storage facilities is the development and submittal of Spill Prevention Control and Countermeasure (SPCC) Plans within 40 CFR 112, the Oil Pollution Prevention regulation, which in turn is part of the *Clean Water Act* (CWA). SPCC Plans and Facility Response Plans pertain to facilities which may discharge oil into groundwater or storm runoff, which in turn may flow into navigable waters. Enacted in 1973, these requirements were principally used by owners of large, field-fabricated aboveground tanks predominant at that time, although the regulation applied to all bulk containers larger than 2.5 $m^3$ (660 gal) and included the requirement for a Professional Engineer to certify the spill plan.

In July 2002, the U.S. EPA issued a final rule amending 40 CFR 112 which included differentiation of shop-fabricated from field-fabricated ASTs. The rule also includes new subparts outlining the requirements for various classes of oil, revises the applicability of the regulation, amends the requirements for completing SPCC Plans, and makes other modifications.

The revised rule also states that all bulk storage container installations must provide a secondary means of containment for the entire capacity of the largest single container, with sufficient freeboard to contain precipitation, and that such containment must be sufficiently impervious to contain discharged oil. The U.S. EPA encourages the use of industry standards to comply with the rules. Many owners of shop-fabricated tanks have opted for double-wall tanks built to STI or UL standards as a means to comply with this requirement.

***State and Local Jurisdictions*** Due to the manner in which aboveground storage tank legislation was promulgated in 1972 for protection of surface waters from oil pollution, state environmental agencies did not receive similar jurisdiction as they did within the underground storage tank rules. Nonetheless, many state environmental agencies, state fire marshals, or Weights and Measures departments—including Minnesota, Florida, Wisconsin, Virginia, Oklahoma, Missouri, Maryland, Delaware, and Michigan—are presently regulating aboveground storage tanks through other means. Other regulations exist for hazardous chemicals and should be consulted for specific requirements.

***Aboveground Storage Tank Types and Options*** Most hydrocarbon storage applications use carbon steel as the most economical and available material that provides suitable strength and compatibility for the specific storage application. For vertical tanks installed on grade, corrosion protection can be given to exterior tank bottoms in contact with soil. The interior of the tank can incorporate special coatings and linings (e.g., polymer, glass, or other metals). Some chemical storage applications require the storage tank be made from a stainless steel or nickel alloy. *Fiberglass-reinforced plastic* (FRP), polyethylene, or polypropylene may be used for nonflammable storage in smaller sizes. Suppliers can be contacted to verify the appropriate material to be used.

As stated earlier, shop-fabricated ASTs are often categorized according to the standards to which the tanks are fabricated, e.g., a UL 142 or UL 2085 tank. That said, however, there are defined categories such as diked tanks, protected tanks, fire-resistant tanks, and insulated tanks. It is critical that the tank be specified for the given application, code requirements, and/or owner/operator preferences—and that the tank contractor and/or manufacturer be made aware of this.

Cylindrical or rectangular tanks storing flammable and combustible liquids (UL 142 ASTs) will normally comply with UL 142. The Seventh Edition published in 1993 was particularly notable, as it incorporated secondary containment designs (diking or steel secondary containment tanks) and rectangular tank designs. The latest edition is the Ninth Edition (2006).

Rectangular tanks became a desirable option for small tanks, typically less than 7.6 $m^3$ (2000 gal), as operators liked the accessibility of the flat top to perform operations and maintenance, without the need for special ladders or catwalks.

*Post-tensioned concrete* is frequently used for tanks to about 57,000 $m^3$ ($15 \times 10^6$ gal), usually containing water. Their design is treated in detail by Creasy (*Pre-stressed Concrete Cylindrical Tanks,* Wiley, New York, 1961). For the most economical design of large open tanks at ground levels, he recommends limiting vertical height to 6 m (20 ft). Seepage can be a problem if unlined concrete is used with some liquids (e.g., gasoline).

*Elevated tanks* can supply a large flow when required, but pump capacities need be only for average flow. Thus, they may save on pump and piping investment. They also provide flow after pump failure, an important consideration for fire systems.

*Open tanks* may be used to store materials that will not be harmed by water, weather, or atmospheric pollution. Otherwise, a roof, either fixed or floating, is required. *Fixed roofs* are usually either domed or coned. Large tanks have coned roofs with intermediate supports. Since negligible pressure is involved, snow and wind are the principal design loads. Local building codes often give required values.

Fixed-roof atmospheric tanks require *vents* to prevent pressure changes which would otherwise result from temperature changes and withdrawal or addition of liquid. **API Standard 2000,** *Venting Atmospheric and Low Pressure Storage Tanks,* gives practical rules for conservative vent design. The principles of this standard can be applied to fluids other than petroleum products. Excessive losses of volatile liquids, particularly those with flash points below 38°C (100°F), may result from the use of open vents on fixed-roof tanks. Sometimes vents are connected to a manifold and lead to a vent tank, or the vapor may be removed by a *vapor recovery unit* (VRU).

An effective way of preventing vent loss is to use one of the many types of *variable-volume tanks.* These are built under **API Standard 650**. They may have floating roofs of the double-deck or the single-deck type. There are lifter-roof types in which the roof either has a skirt moving up and down in an annular liquid seal or is connected to the tank shell by a flexible membrane. A fabric expansion chamber housed in a compartment on top of the tank roof also permits variation in volume.

*Floating roofs* must have a seal between the roof and the tank shell. If not protected by a fixed roof, they must have drains for the removal of water, and the tank shell must have a "wind girder" to avoid distortion. An industry has developed to retrofit existing tanks with floating roofs. Many details on the various types of tank roofs are given in manufacturers' literature. Figure 10-176 shows roof types. These roofs cause less condensation buildup and are highly recommended.

***Fire-Rated or Insulated ASTs: Protected and Fire-Resistant*** These ASTs have received much attention within the fire regulatory community, particularly for motor fuel storage and dispensing applications and generator base tanks. National model codes have been revised to allow this type of storage aboveground.

An insulated tank can be a protected tank, built to third-party standards UL 2085 and/or SwRI 93-01, or a fire-resistant tank built to UL 2080 or SwRI 97-04. Protected tanks were developed in line with NFPA requirements and terminology, while fire-resistant ASTs were developed in line with Uniform Fire Code (now International Fire Code) requirements and terminology. Both protected tanks and fire-resistant tanks must pass a 1093°C (2000°F), 2-h fire test.

The insulation properties of many fire-rated ASTs marketed today are typically provided by concrete; i.e., the primary steel tank is surrounded by concrete. Due to the weight of concrete, this design is normally limited to small tanks. Another popular AST technology meeting all applicable code requirements for insulated tanks and fabricated to UL 2085 is a tank that utilizes a lightweight monolithic thermal insulation in between two walls of steel to minimize heat transfer from the outer tank to the inner tank and to make tank handling easier.

A *secondary containment AST* to prevent contamination of our environment has become a necessity for all hazardous liquid storage, regardless of its chemical nature, in order to minimize liability and protect neighboring property. A number of different regulations exist, but the regulations with the greatest impact are fire codes and the U.S. EPA SPCC rules for oil storage.

In 1991, the Spill Prevention Control and Countermeasure (SPCC) rule proposed a revision to require secondary containment that was impermeable for at least 72 h following a release. The 2003 promulgated EPA SPCC rule no longer mandates a 72-h containment requirement, instead opting to require means to contain releases until they can be detected and removed. Nonetheless, the need for impermeable containment continues to position steel as a material of choice for shop-fabricated tanks. However, release prevention barriers made from plastic or concrete can also meet U.S. EPA requirements when periodically inspected for integrity.

***Diked ASTs*** Fire codes dictate that hazardous liquid tanks have spill control in the form of dike, remote impounding, or small secondary containment tanks. The dike must contain the content of the largest tank to prevent hazardous liquids from endangering the public and property. Traditional bulk storage systems include multiple tanks within a concrete or earthen dike wall.

From a shop-fabricated tank manufacturer's perspective, a diked AST generally refers to a steel tank within a factory-fabricated steel box, or dike. An example of a diked AST is the STI F911 standard, providing an open-topped steel rectangular dike and floor as support and secondary containment of a UL 142 steel tank. The dike will contain 110 percent of the tank capacity; as rainwater may already have collected in the dike, the additional 10 percent acts as freeboard should a catastrophic failure dump a full tank's contents into a dike. Many fabricators offer steel dikes with shields to prevent rainwater from collecting.

A *double-wall AST* of steel fulfills the same function as a diked AST with a rain shield. Double-wall designs consist of a steel wrap over a horizontal or vertical steel storage tank. The steel wrap provides an intimate, secondary containment over the primary tank. One such design is the Steel Tank Institute's F921 standard, based upon UL 142–listed construction for the primary tank, outer containment, associated tank supports, or skids.

*Venting* of ASTs is critical, since they are exposed to greater ambient temperature fluctuations than are USTs. Properly designed and sized venting, both normal (atmospheric) and emergency, is required. Normal vents permit the flow of air or inert gas into and out of the tank. The vent line must be large enough to accommodate the maximum filling or withdrawal rates without exceeding the allowable stress for the tank.

Fire codes' recommended installation procedures also detail specifics on pressure/vacuum venting devices and vent line flame arresters. For example, codes mandate different ventilation requirements for Class I-A liquids versus Class I-B or I-C liquids. Tank vent piping is generally not connected to a manifold unless required for special purposes, such as pollution control or vapor recovery. As always, local codes must be followed.

Emergency venting prevents an explosion during a fire or another emergency. All third-party laboratory standards except UL 80 include emergency relief provisions, since these tanks are designed for atmospheric pressure conditions.

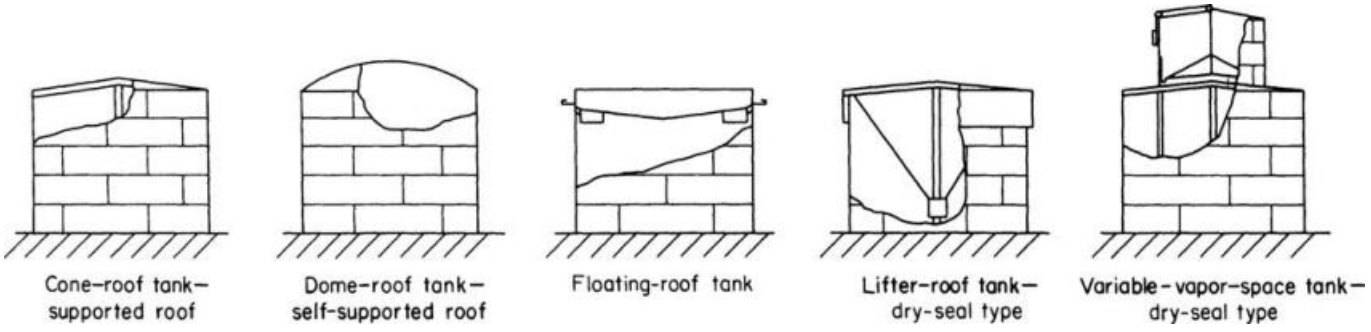

**FIG. 10-176** Some types of atmospheric storage tanks.

*Separation distances* are also important. Aboveground storage tanks must be separated from buildings, property lines, fuel dispensers, and delivery trucks in accordance with the level of safety the tank design provides, depending on whether they are constructed of traditional steel or are vault/fire-resistant.

For most chemical storage tanks, codes such as NFPA 30 and IFC give specific separation distances. For motor vehicle fueling applications, the codes are more stringent on separation requirements due to a greater exposure of the public to the hazards. Hence codes such as NFPA 30A establish variable separation distances depending on whether the facility is private or public.

Separation distance requirements may dictate whether a tank buyer purchases a traditional steel UL 142 tank, a fire-resistant tank, or a tank in a vault. For example, NFPA 30, NFPA 30A, and the IFC codes allow UL 2085 tanks to be installed closer to buildings and property lines, thereby reducing the real estate necessary to meet fire codes.

Under NFPA 30A, dispensers may be installed directly over vaults or upon fire-resistant tanks at fleet-type installations, whereas a 7.6- to 15.2-m (25- to 50-ft) separation distance is required at retail-type service station installations. The IFC only allows gasoline and diesel to be dispensed from ASTs, designed with a 2-h fire rating. Non-2-h fire-rated UL 142 tanks dispensing diesel can be installed if permitted by local codes.

***Maintenance and Operations*** Water in any storage system can cause myriad problems from product quality to corrosion caused by trace contaminants and microbial action. Subsequently, any operations and maintenance program must include a proactive program of monitoring for and removal of water. Other operations and maintenance procedures include periodic integrity testing and corrosion control for vertical tank bottoms. Additional guidance is available from organizations such as API, Petroleum Equipment Institute (PEI), ASTM International, *National Oilheat Research Alliance* (NORA), and STI. Also see the STI document *Keeping Water Out of Your Storage System* (http://www.steeltank.com/library/pubs/waterinfueltanks.pdf).

Integrity testing and visual inspection requirements are discussed in the SPCC requirements, Subpart B, Para. 112.8c(6). Chemical tanks storing toluene and benzene are subject to the rule in addition to traditional fuels. But a good inspection program is recommended regardless of applicable regulations. Both visual inspection and another testing technique are required. Comparison records must be kept, and frequent inspections must be made of the outside of the tank and system components for signs of deterioration, discharge, or accumulation of oil inside diked areas.

For inspection of large field-erected tanks, API 653, *Tank Inspection, Repair, Alteration, and Reconstruction*, is referenced by the U.S. EPA. A certified inspector must inspect tanks. U.S. EPA references the Steel Tank Institute Standard SP001-06, *Standard for Inspection of In-Service Shop Fabricated Aboveground Tanks for Storage of Combustible and Flammable Liquids,* as an industry standard that may assist an owner or operator with the integrity testing and inspection of shop-fabricated tanks. The STI SP001-06 standard includes inspection techniques for all types of shop-fabricated tanks—horizontal cylindrical, vertical, and rectangular. SP001-06 also addresses tanks that rest directly on the ground or on release prevention barriers, tanks that are elevated on supports, and tanks that are either single- or double-wall using a risk-based approach.

**Pressurized Tanks** Vertical cylindrical tanks constructed with domed or coned roofs, which operate at pressures above several hundred pascals (a few pounds per square foot) but which are still relatively close to atmospheric pressure, can be built according to API Standard 650. The pressure force acting against the roof is transmitted to the shell, which may have sufficient weight to resist it. If not, the uplift will act on the tank bottom. The strength of the bottom, however, is limited, and if it is not sufficient, an anchor ring or a heavy foundation must be used. In the larger sizes, uplift forces limit this style of tank to very low pressures.

As the size or the pressure goes up, curvature on all surfaces becomes necessary. Tanks in this category, up to and including a pressure of 103.4 kPag (15 psig), can be built according to API Standard 620. Shapes used are spheres, ellipsoids, toroidal structures, and circular cylinders with torispherical, ellipsoidal, or hemispherical heads. The ASME Boiler and Pressure Vessel Code, Sec. VIII-1 (2015), although not required below 15 psig (103.4 kPag), is also useful for designing such tanks.

Tanks that could be subjected to vacuum should be provided with vacuum-breaking valves or be designed for vacuum (external pressure). The BPVC contains design procedures.

**Calculation of Tank Volume** A tank may be a single geometric element, such as a cylinder, a sphere, or an ellipsoid. It may also have a compound form, such as a cylinder with hemispherical ends or a combination of a toroid and a sphere. To determine the volume, each geometric element usually must be calculated separately. Calculations for a full tank are usually simple, but calculations for partially filled tanks may be complicated.

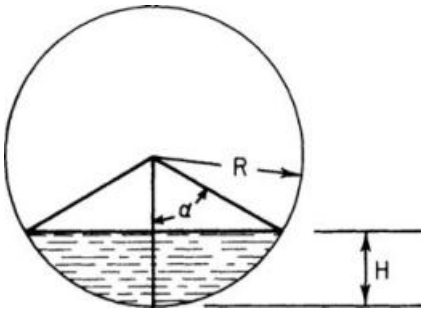

**FIG. 10-177** Calculation of partially filled horizontal tanks. $H$ = depth of liquid; $R$ = radius; $D$ = diameter; $L$ = length; $\alpha$ = half of the included angle; and $\cos\alpha = 1 - H/R = 1 - 2H/D$.

To calculate the volume of a *partially filled horizontal cylinder,* refer to Fig. 10-177. Calculate the angle $\alpha$ in degrees. Any units of length can be used, but they must be the same for *H, R,* and *L.* The liquid volume

$$V = LR^2\left(\frac{\alpha}{57.30} - \sin\alpha\,\cos\alpha\right) \tag{10-107}$$

This formula may be used for any depth of liquid between zero and the full tank, provided the algebraic signs are observed. If $H$ is greater than $R$, then $\sin\alpha\cos\alpha$ will be negative and thus will add numerically to $\alpha/57.30$. Table 10-57 gives liquid volume, for a partially filled horizontal cylinder, as a fraction of the total volume, for the dimensionless ratio $H/D$ or $H/2R$.

The *volumes of heads* must be calculated separately and added to the volume of the cylindrical portion of the tank. The four types of heads most frequently used are the standard dished head,* torispherical or ASME head, ellipsoidal head, and hemispherical head. Dimensions and volumes for all four types are given in *Lukens Spun Heads,* Lukens Inc., Coatesville, Pennsylvania. Approximate volumes can also be calculated by the formulas in Table 10-58. Consistent units must be used in these formulas.

A partially filled horizontal tank requires the determination of the partial volume of the heads. The Lukens catalog gives approximate volumes for partially filled (axis horizontal) standard ASME and ellipsoidal heads. A formula for *partially filled heads* (excluding conical), by Doolittle [*Ind. Eng. Chem.* **21:** 322–323 (1928)], is

$$V = 0.215H^2(3R - H) \tag{10-108}$$

where in consistent units $V$ = volume, $R$ = radius, and $H$ = depth of liquid. Doolittle made some simplifying assumptions that affect the volume given

* The standard dished head does not comply with the ASME BPVC.

*Use consistent units.

by the equation, but the equation is satisfactory for determining the volume as a fraction of the entire head. This fraction, calculated by Doolittle's formula, is given in Table 10-59 as a function of $H/D_i$ ($H$ is the depth of liquid, and $D_i$ is the inside diameter). Table 10-59 can be used for standard dished, torispherical, ellipsoidal, and hemispherical heads with an error of less than 2 percent of the volume of the entire head. The error is zero when $H/D_i = 0$, 0.5, and 1.0. Table 10-59 cannot be used for conical heads.

When a tank volume cannot be calculated or when greater precision is required, *calibration* may be necessary. This is done by draining (or filling) the tank and measuring the volume of liquid. The measurement may be made by weighing, by a calibrated fluid meter or by repeatedly filling small measuring tanks which have been calibrated by weight.

**Container Materials and Safety** Storage tanks are made of almost any structural material. Steel and reinforced concrete are most widely used. Plastics and glass-reinforced plastics are used for tanks up to about 230 $m^3$ (60,000 gal). Resistance to corrosion, light weight, and lower cost are their advantages. Plastic and glass coatings are also applied to steel tanks. Aluminum and other nonferrous metals are used when their special properties are required. When expensive metals such as tantalum are required, they may be applied as tank linings or as clad metals.

Some grades of steel listed by API and AWWA Standards are of lower quality than is customarily used for pressure vessels. The stresses allowed by these standards are also higher than those allowed by the ASME Pressure Vessel Code. Small tanks containing nontoxic substances are not particularly hazardous and can tolerate a reduced factor of safety. Tanks containing highly toxic substances and very large tanks containing any substance can be hazardous. The designer must consider the magnitude of the hazard. The possibility of brittle behavior of ferrous metal should be taken into account in specifying materials (see subsection Safety in Design).

Volume 1 of National Fire Codes (NFPA, Quincy, Massachusetts) contains recommendations (NFPA 30) for venting, drainage, and dike construction of tanks for *flammable liquids.*

*Based on Eq. (10-108).

***Container Insulation*** Tanks containing materials above atmospheric temperature may require insulation to reduce the loss of heat. Almost any of the commonly used insulating materials can be employed. Calcium silicate, glass fiber, mineral wool, cellular glass, and plastic foams are among those used. Tanks exposed to weather must have jackets or protective coatings, usually asphalt, to keep water out of the insulation.

Tanks with contents at lower than atmospheric temperature may require insulation to minimize heat absorption. The insulation must have a vapor barrier on the outside to prevent condensation of moisture from reducing its effectiveness. The insulation techniques presently used for refrigerated systems can be applied (see subsection Low-Temperature and Cryogenic Storage).

***Tank Supports*** Large vertical atmospheric steel tanks may be built on a base of about 150 cm (6 in) of sand, gravel, or crushed stone if the subsoil has adequate bearing capacity. It can be level or slightly coned, depending on the shape of the tank bottom. The porous base provides drainage in case of leaks. A few feet beyond the tank perimeter the surface should drop about 1 m (3 ft) to ensure proper drainage of the subsoil. API Standard 650, App. B, and API Standard 620, App. C, give recommendations for tank foundations.

The bearing pressure of the tank and contents must not exceed the *bearing capacity* of the soil. Local building codes usually specify allowable soil loading. These are some approximate bearing capacities:

| | kPa | psf |
|---|---|---|
| Soft clay (can be crumbled between fingers) | 100 | 2,000 |
| Dry fine sand | 200 | 4,000 |
| Dry fine sand with clay | 300 | 6,000 |
| Coarse sand | 300 | 6,000 |
| Dry hard clay (requires a pick to dig it) | 350 | 7,000 |
| Gravel | 400 | 8,000 |
| Rock | 1000–4000 | 20,000–80,000 |

For high, heavy tanks, a foundation ring may be needed. Prestressed concrete tanks are sufficiently heavy to require foundation rings. Foundations must extend below the frost line. Some tanks that are not flat-bottomed may also be supported by soil if it is suitably graded and drained. When soil does not have adequate bearing strength, it may be excavated and backfilled with a suitable soil, or piles capped with a concrete mat may be required.

Spheres, spheroids, and toroids use steel or concrete saddles or are supported by columns. Some may rest directly on soil. Horizontal cylindrical tanks should have two rather than multiple saddles to avoid indeterminate load distribution. Small horizontal tanks are sometimes supported by legs. Most tanks must be designed to resist the reactions of the saddles or legs, and they may require reinforcing. Neglect of this can cause collapse. Tanks without stiffeners usually need to make contact with the saddles on at least 2.1 rad (120°) of their circumference. An elevated steel tank may have either a circle of steel columns or a large central steel standpipe. Concrete tanks usually have concrete columns. Tanks are often supported by buildings.

**Pond and Underground Storage** Low-cost liquid materials, if they will not be damaged by rain or atmospheric pollution, may be stored in *ponds.* A pond may be excavated or formed by damming a ravine. To prevent

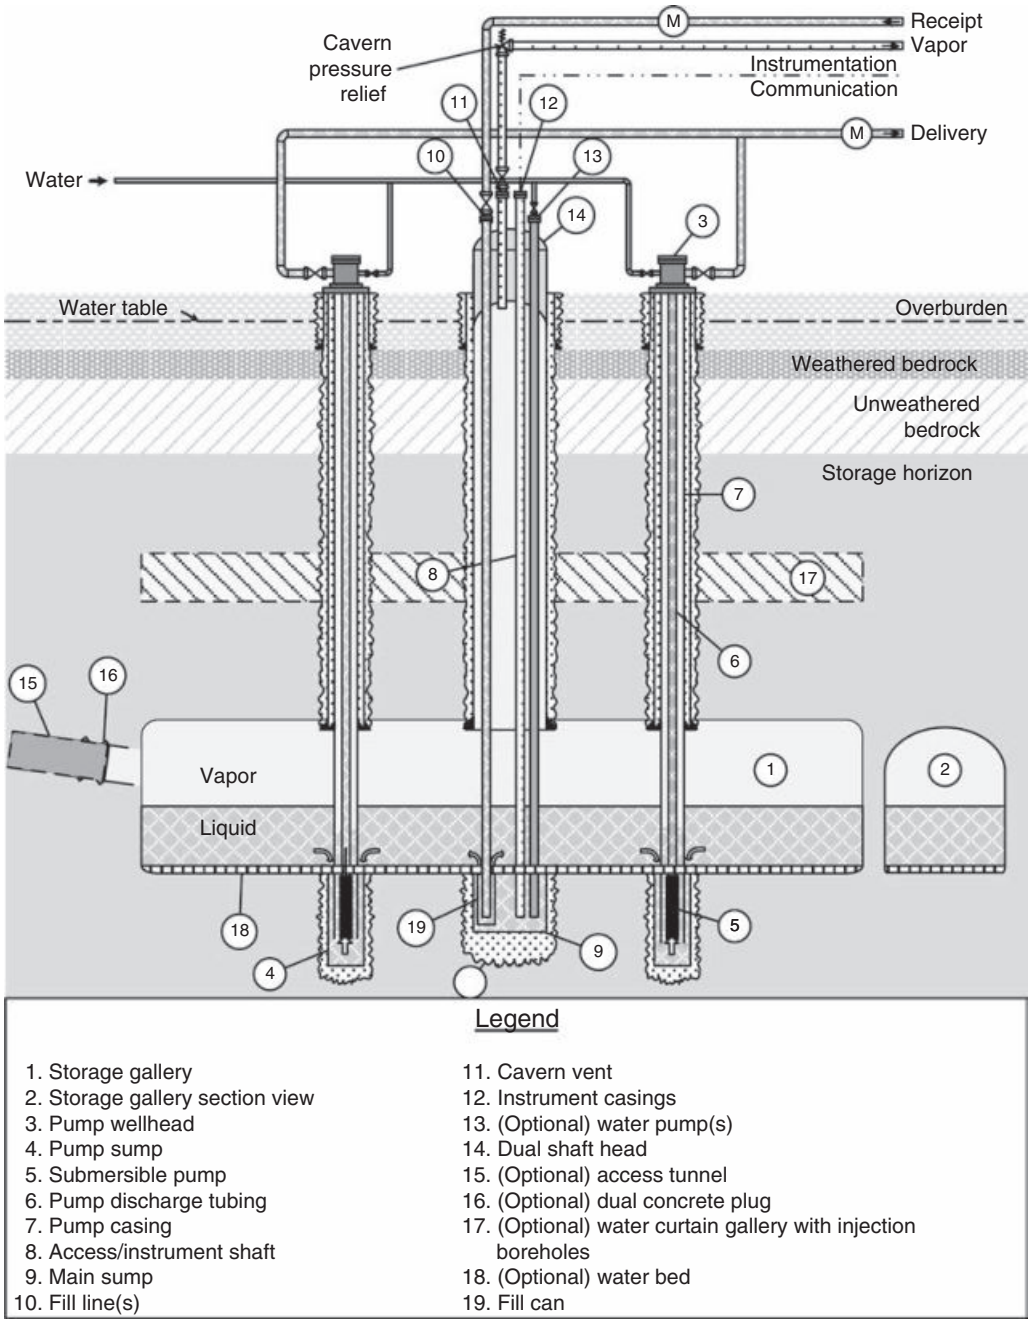

**FIG. 10-178** Mined cavern.

loss by seepage, the soil which will be submerged may require treatment to make it sufficiently impervious. This can also be accomplished by lining the pond with concrete, polymeric membrane, or another barrier. Detection and mitigation of seepage is especially necessary if the pond contains material that could contaminate present or future water supplies.

**Underground Cavern Storage** Large volumes of liquids and gases are often stored below ground in artificial caverns as an economical alternative to aboveground tanks and other modes of storage. The stored fluids must tolerate water, brine, and other contaminants that are usually present to some degree in the cavern. The liquids that are most commonly stored are *natural gas liquids* (NGLs), LPG, crude oil, and refined petroleum products. Gases commonly stored are natural gas and hydrogen. If fluids are suitable for cavern storage, this method may be less expensive, safer, and more secure than other storage modes.

There are two types of caverns used for storing liquids. *Hard rock* (mined) caverns are constructed by mining rock formations such as shale, granite, limestone, and many other types of rock. *Solution-mined* caverns are constructed by dissolution processes, i.e., solution mining or leaching a mineral deposit, most often salt (sodium chloride). The salt deposit may take the form of a massive salt dome or thinner layers of bedded salt that are stratified between layers of rock. Hard rock and solution-mined caverns have been constructed in the United States and many other parts of the world.

***Mined Caverns*** Caverns mined in hard rock are generally situated 100 to 150 m (325 to 500 ft) below ground level. These caverns are constructed by excavating rock with conventional drill-and-blast mining methods. The excavated cavern consists of a grouping of interconnecting tunnels or storage "galleries." Mined caverns have been constructed for volumes ranging from as little as 3200 to 800,000 $m^3$ [20,000 to 5 million API barrels* (bbl)]. Figure 10-178 illustrates a typical mined cavern for liquid storage.

*One API barrel = 42 U.S. gal = 5.6146 $ft^3$ = 0.159 $m^3$.

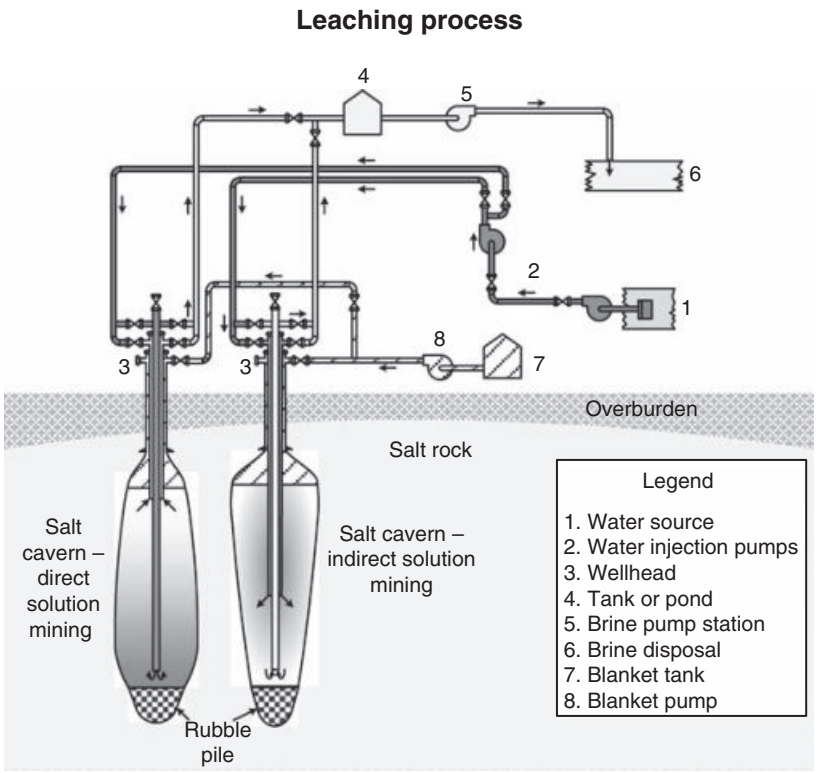

**FIG. 10-179** Cavern leaching process.

Hard rock caverns are designed so that the internal storage pressure at all times is less than the hydrostatic head of the water contained in the surrounding rock matrix. Thus, the depth of a cavern determines its maximum allowable operating pressure. Groundwater that continuously seeps into hard rock caverns in permeable formations is periodically pumped out of the cavern. The maximum operating pressure of the cavern is established after a thorough geological and hydrogeological evaluation is made of the rock formation and the completed cavern is pressure-tested.

***Salt Caverns*** Salt caverns are constructed in both *domal salt*, more commonly referred to as "salt domes," and *bedded salt*, which consists of a body of salt sandwiched between layers of rock. The greatest total volume of underground liquid storage in the United States is stored in salt dome caverns. A salt dome is a large body, mostly consisting of sodium chloride, which over geologic time moved upward thousands of feet from extensive halite deposits deep below the earth's crust. There are numerous salt domes in the United States and other parts of the world [see Harben, P. W., and R. L. Bates, "Industrial Minerals Geology and World Deposits," *Metal Bulletin Plc*, UK, pp. 229–234 (1990)]. An individual salt dome may exceed 1 mi in diameter and contain many storage caverns. The depth to the top of a salt dome may range from a few hundred to several thousand feet, although depths to about 460 m (1500 ft) are commercially viable for cavern development. The extent of many salt domes allows for caverns of many different sizes and depths to be developed. The extensive nature of salt domes has allowed the development of caverns as large as $5.7 \times 10^6$ m$^3$ (36 million bbl) (U.S. DOE Bryan Mound Strategic Petroleum Reserve) and larger; however, cavern volumes of 159,000 to $1.59 \times 10^6$ m$^3$ (1 to 10 million bbl) are more common for liquid storage.

The benefits of salt are its high compressive strength of 13.8 to 27.6 MPa (2000 to 4000 psi), its impermeability to hydrocarbon liquids and gases, and its non–chemically reactive (inert) nature. Due to the impervious nature of salt, the maximum allowed storage pressure gradient in this type of cavern is greater than that of a mined cavern. A typical storage pressure gradient for liquids is about 18 kPa/m of depth (0.80 psi/ft) to the bottom of the well casing. Actual maximum and minimum allowable operating pressure gradients are determined from geologic evaluations and rock mechanics studies. Typical depths to the top of a salt cavern may range from 500 to 4000 ft (about 150 to 1200 m). Therefore, the maximum storage pressure (2760 to 32,060 kPag, or 400 to 3200 psig) usually exceeds the vapor pressure of all commonly stored hydrocarbon liquids. Higher-vapor-pressure products such as ethylene or ethane cannot be stored in relatively shallow caverns.

Salt caverns are developed by solution mining, a process (leaching) in which water is injected to dissolve the salt. Approximately 7 to 10 units of freshwater are required to leach 1 unit of cavern volume. Figure 10-179 illustrates the leaching process for two caverns. Modern salt dome caverns are shaped as relatively tall, slender cylinders. The leaching process produces nearly saturated brine from the cavern. Brine may be disposed into nearby disposal wells or offshore disposal fields, or it may be supplied to nearby plants as a feedstock for manufacturing of caustic (NaOH) and chlorine ($Cl_2$). The final portion of the produced brine is retained and stored in artificial surface ponds or tanks to be used to displace the stored liquid from the cavern.

Salt caverns are usually developed using a single well, although some employ two or more wells. The well consists of a series of concentric casings that protect the water table and layers of rock and sediments (overburden) that lie above the salt dome. The innermost well casing is referred to as the last cemented or well "production" casing and is cemented in place, sealing the cavern and protecting the surrounding geology. Once the last cemented casing is in place, a bore hole is drilled from the bottom of the well, through the salt to the design cavern depth. For single-well leaching, two concentric tubing strings are then suspended in the well. A liquid, such as diesel or propane, or a gas, such as nitrogen, is then injected through the outer annular space and into the top of the cavern to act as a "blanket" to prevent undesired leaching of the top of the cavern. Water is then injected into one of the suspended tubing strings, and brine is withdrawn from the other. During the leaching process, the water is injected initially for 30 to 60 days into the innermost tubing and into the inner annulus for the remaining time. The tubing strings are periodically raised upward to control the cavern shape. A typical salt dome cavern may require 9 to 30 months of leaching time, whereas smaller, bedded salt caverns may be developed in a shorter time frame.

***Brine-Compensated Storage*** As the stored product is pumped into the cavern, brine is displaced into an aboveground brine storage reservoir. To withdraw the product from the cavern, brine is pumped back into the cavern, displacing the stored liquid. This method of product transfer is termed *brine-compensated,* and caverns that operate in this fashion remain liquid-filled at all times. Figure 10-180 illustrates brine-compensated storage operations.

***Uncompensated Storage*** Hard rock caverns and a few bedded salt caverns do not use brine for product displacement. This type of storage operation is referred to as *pump out* or *uncompensated* storage operations. When the cavern is partially empty of liquid, the void space is filled with the vapor that is in equilibrium with the stored liquid. When liquid is introduced into the

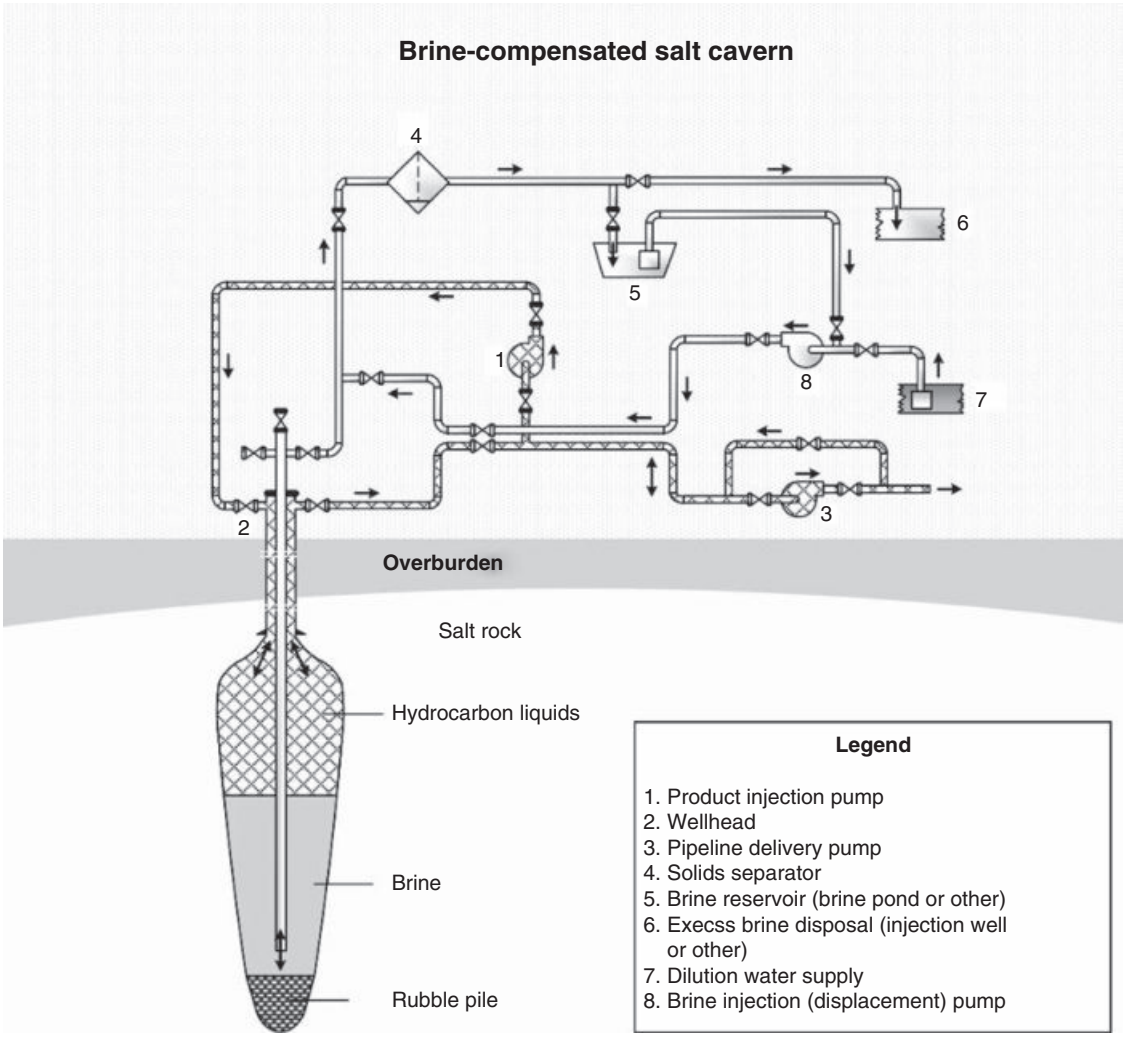

**FIG. 10-180** Brine-compensated storage.

cavern, it compresses and condenses this saturated vapor phase. In some cases, vapor may be vented to the surface where it may be refrigerated, liquefied, and recycled to the cavern.

Submersible pumps or vertical line shaft pumps are used for withdrawing the stored liquid. Vertical line shaft pumps are suited for depths of no more than several hundred feet. Figure 10-178 illustrates an example of uncompensated storage operations.

Underground chambers are also constructed in frozen earth (see subsection Low-Temperature and Cryogenic Storage). Underground tunnel or tank storage is often the most practical way of storing hazardous or radioactive materials, such as proposed at Yucca Mountain, Nevada. A cover of 30 m (100 ft) of rock or dense earth can exert a pressure of about 690 kPa (100 lbf/in$^2$).

The storage of natural gas in depleted aquifers and petroleum reservoirs is another mode of underground storage. This type of storage requires that a number of wells be drilled into the underground storage zone at different locations and depths determined from geologic analysis.

## STORAGE OF GASES

**Gas Holders** Gas is sometimes stored in expandable gas holders of either the liquid-seal or dry-seal type. The liquid-seal holder is a familiar sight. It has a cylindrical container, closed at the top, and varies its volume by moving it up and down in an annular water-filled seal tank. The seal tank may be staged in several lifts (as many as five). Seal tanks have been built in sizes up to 280,000 m$^3$ ($9.9 \times 10^6$ ft$^3$). The dry-seal holder has a rigid top attached to the sidewalls by a flexible fabric diaphragm which permits it to move up and down. It does not involve the weight and foundation costs of the liquid-seal holder. Additional information on gas holders can be found in *Gas Engineers Handbook*, Industrial Press, New York, 1966.

**Solution of Gases in Liquids** Certain gases will dissolve readily in liquids. In some cases in which the quantities are not large, this may be a practical storage procedure. Examples of gases that can be handled in this way are ammonia in water, acetylene in acetone, and hydrogen chloride in water. Whether this method is used depends mainly on whether the end use requires the anhydrous or the liquid state. Pressure may be either atmospheric or elevated. The solution of acetylene in acetone is also a safety feature because of the instability of acetylene.

**Storage in Pressure Vessels, Bottles, and Pipelines** The distinction between pressure vessels, bottles, and pipes is arbitrary. They can all be used for storing gases under pressure. A storage pressure vessel is usually a permanent installation. Storing a gas under pressure not only reduces its volume but also in many cases liquefies it at ambient temperature. Some gases in this category are carbon dioxide, several petroleum gases, chlorine, ammonia, sulfur dioxide, and some types of Freon or Suva. Pressure tanks are frequently installed underground.

Liquefied petroleum gas (LPG) is the subject of API Standard 2510, *The Design and Construction of Liquefied Petroleum Gas Installations at Marine and Pipeline Terminals, Natural Gas Processing Plants, Refineries, and Tank Farms*. This standard in turn refers to:

1. National Fire Protection Association (NFPA) Standard 58, *Standard for the Storage and Handling of Liquefied Petroleum Gases*
2. NFPA Standard 59, *Standard for the Storage and Handling of Liquefied Petroleum Gases at Utility Gas Plants*
3. NFPA Standard 59A, *Standard for the Production, Storage, and Handling of Liquefied Natural Gas (LNG)*

The API Standard gives considerable information on the construction and safety features of such installations. It also recommends minimum distances from property lines. The user may wish to obtain added safety by increasing these distances.

The term *bottle* is usually applied to a pressure vessel that is small enough to be conveniently portable. Bottles range from about 57 L (2 $ft^3$) down to $CO_2$ capsules of about 16.4 mL (1 $in^3$). Bottles are convenient for small quantities of many gases, including air, hydrogen, nitrogen, oxygen, argon, acetylene, Freon, and petroleum gas. Some are one-time-use disposable containers.

***Pipelines*** A pipeline is not ordinarily a storage device. Sections of pipe have been connected in series and in parallel, buried underground, and used for storage. This avoids the necessity of providing foundations, and the earth protects the pipe from extremes of temperature. The economics of such an installation would be doubtful if it were designed to the same stresses as a pressure vessel. Storage is also obtained by increasing the pressure in operating pipelines and thus having a similar impact as a tank.

***Low-Temperature and Cryogenic Storage*** This type is used for gases that liquefy under pressure at atmospheric temperature. In cryogenic storage the gas is at, or near to, atmospheric pressure and remains liquid because of low temperature. A system may also operate with a combination of pressure and reduced temperature. The term *cryogenic* usually refers to temperatures below −101°C (−150°F). Some gases, however, liquefy between −101°C and ambient temperatures. The principle is the same, but cryogenic temperatures create different problems with insulation and construction materials.

The liquefied gas must be maintained at or below its boiling point. Refrigeration can be used, but the usual practice is to cool by evaporation. The quantity of liquid evaporated is minimized by insulation. The vapor may be vented to the atmosphere (this may be prohibited due to emissions limitations), it may be compressed and reliquefied, or it may be consumed as fuel.

At very low temperatures with liquid air and similar substances, the tank may have double walls with the interspace evacuated. The well-known Dewar flask is an example. Large tanks and even pipelines are now built this way. An alternative is to use double walls without vacuum but with an insulating material in the interspace. Perlite and plastic foams are two insulating materials employed in this way. Sometimes both insulation and vacuum are used.

**Materials** Materials for liquefied-gas containers must be suitable for the temperatures, and they must not become embrittled. Some carbon steels can be used down to −59°C (−75°F), and low-alloy steels to −101°C (−150°F) and sometimes −129°C (−200°F). Below these temperatures austenitic stainless steel (AISI 300 series) and aluminum are the principal materials. (See discussion of brittle fracture on p. 10-139.)

Low temperatures involve problems of *differential thermal expansion.* With the outer wall at ambient temperature and the inner wall at the liquid boiling point, relative movement must be accommodated. Proprietary systems accomplish this. The Gaz Transport of France reduces dimensional change by using a thin inner liner of Invar. Another patented French system accommodates this change by means of the flexibility of thin metal which is creased. The creases run in two directions, and the form of the crossings of the creases is a feature of the system.

Low-temperature tanks may be installed in-ground to take advantage of the insulating value of the earth. Frozen-earth storage is also used. The frozen earth forms the tank. Some installations using this technique have been unsuccessful because of excessive heat absorption.

**Cavern Storage** Gases are also stored below ground in salt caverns. The most common type of gas stored in caverns is natural gas, although hydrogen and air have also been stored. Hydrogen storage requires special consideration in selecting metallurgy for the wellhead and the wellbore casings. Air is stored for the purpose of providing compressed air energy for peak shaving power plants. Two such plants are in operation, one in the United States (McIntosh, Alabama), the other in Huntorf, Germany. A discussion of the Alabama plant is presented in *History of First U.S. Compressed Air Energy Storage (CAES) Plant*, vol. 1, *Early CAES Development*, Electric Power Research Institute (EPRI), Palo Alto, Calif., 1992.

Since salt caverns contain brine and other contaminants, the type of gas to be stored should not be sensitive to the presence of contaminants. If the gas is determined suitable for cavern storage, then cavern storage may not offer only economic benefits and enhanced safety and security; salt caverns also offer relatively high rates of deliverability compared to reservoir and aquifer storage fields. Solution-mined gas storage caverns in salt formations operate as *uncompensated* storage—no fluid is injected into the well to displace the compressed gas.

Surface gas handling facilities for storage caverns typically include custody transfer measurement for receipt and delivery, gas compressors, and gas dehydration equipment. When compressors are required for cavern injection and/or withdrawal, banks of positive-displacement-type compressors are commonly used, since this compressor type is well suited for handling the highly variable compression ratios and flow rates associated with cavern injection and withdrawal operations. Cavern withdrawal operations typically involve single- or dual-stage pressure reduction stations and full or partial gas dehydration. Large pressure throttling requirements often require heating the gas upon withdrawal and immediately before throttling, and injection of methanol or other liquid desiccant may be necessary to help control hydrate formation.

An in-depth discussion of natural gas storage in underground caverns may be found in *Gas Engineering and Operating Practices, Supply,* Book S-1, Part 1, *Underground Storage of Natural Gas,* and Part 2, Chap. 2, "Leached Caverns," American Gas Association, Arlington, Va., 1990.

## COST OF STORAGE FACILITIES

Contractors' bids offer the most reliable information on cost. Order-of-magnitude costs, however, may be required for preliminary studies. One way of estimating them is to obtain cost information from similar facilities and scale it to the proposed installation. Costs of steel storage tanks and vessels have been found to vary approximately as the 0.6 to 0.7 power of their weight [see Happel, *Chemical Process Economics,* Wiley, 1958, p. 267; also Williams, *Chem. Eng.* **54**(12): 124 (1947)]. All estimates based on the costs of existing equipment must be corrected for changes in the price index from the date when the equipment was built. Considerable uncertainty is involved in adjusting data more than a few years old.

Based on a survey in 1994 for storage tanks, the prices for field-erected tanks are for multiple-tank installations erected by the contractor on foundations provided by the owner. Some cost information on tanks is given in various references cited in Sec. 9. Cost data vary considerably from one reference to another. (See Figs. 10-181 to 10-183.)

Prestressed (post-tensioned) concrete tanks cost about 20 percent more than steel tanks of the same capacity. Once installed, however, concrete tanks require very little maintenance. A true comparison with steel would therefore require evaluating the maintenance cost of both types.

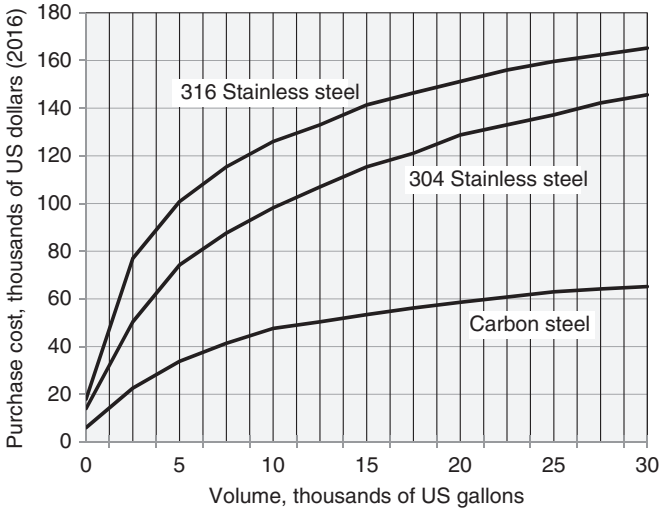

**FIG. 10-181** Cost of shop-fabricated tanks in mid-1980 with ¼-in walls. Multiplying factors on carbon-steel costs for other materials are: carbon steel, 1.0; rubber-lined carbon steel, 1.5; aluminum, 1.6; glass-lined carbon steel, 4.5; and fiber-reinforced plastic, 0.75 to 1.5. Multiplying factors on type 316 stainless-steel costs for other materials are: 316 stainless steel, 1.0; Monel, 2.0; Inconel, 2.0; nickel, 2.0; titanium, 3.2; and Hastelloy C, 3.8. Multiplying factors for wall thicknesses different from ¼ in are:

| Thickness, in | Carbon Steel | 304 Stainless Steel | 316 Stainless Steel |
|---|---|---|---|
| ½ | 1.4 | 1.8 | 1.8 |
| ¾ | 2.1 | 2.5 | 2.6 |
| 1 | 2.7 | 3.3 | 3.5 |

To convert gallons to cubic meters, multiply by $3.785 \times 10^{-3}$.

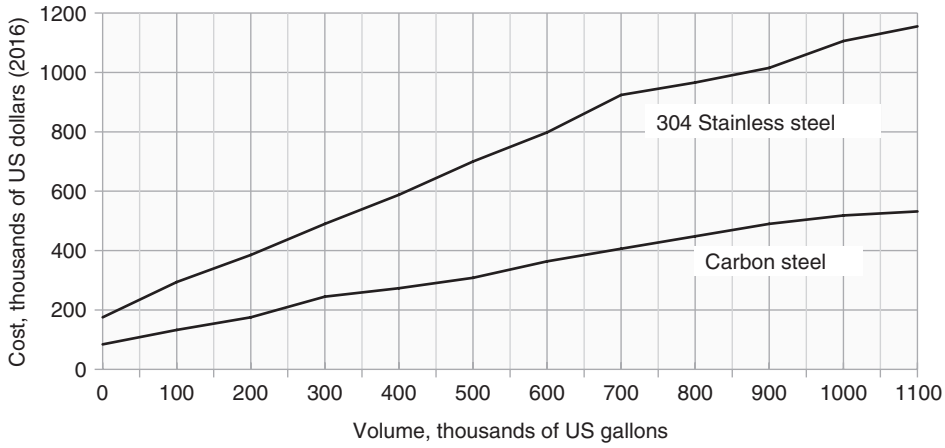

**FIG. 10-182** Cost (±30 percent) of field-erected, domed, flat-bottom API 650 tanks, October 2016, includes concrete foundation and typical nozzles, ladders, and platforms. 1 gal = 0.003785 $m^3$.

## BULK TRANSPORT OF FLUIDS

Transportation is often an important part of product cost. Bulk transportation may provide significant savings. When there is a choice between two or more forms of transportation, the competition may result in rate reduction. Transportation is subject to considerable regulation, which will be discussed in some detail under specific headings.

**Pipelines** For quantities of fluid that an economic investigation indicates are sufficiently large and continuous to justify the investment, pipelines are one of the lowest-cost means of transportation. They have been built up to 1.22 m (48 in) or more in diameter and about 3200 km (2000 mi) in length for oil, gas, and other products. Water is usually not transported more than 160 to 320 km (100 to 200 mi), but the conduits may be much greater than 1.22 m (48 in) in diameter. Open canals are also used for water transportation.

Petroleum pipelines before 1969 were built to ASA (now ASME) Standard B31.4 for liquids and Standard B31.8 for gas. These standards were seldom mandatory because few states adopted them. The U.S. Department of Transportation (DOT), which now has responsibility for pipeline regulation, issued Title 49, Part 192—Transportation of Natural Gas and Other Gas by Pipeline: Minimum Safety Standards, and Part 195—Transportation of Liquids by Pipeline. These contain considerable material from B31.4 and B31.8. They allow generally higher stresses than the ASME Boiler and Pressure Vessel Code would allow for steels of comparable strength. The enforcement of their regulations is presently left to the states and is therefore somewhat uncertain.

Pipeline pumping stations usually range from 16 to 160 km (10 to 100 mi) apart, with maximum pressures up to 6900 kPa (1000 $lbf/in^2$) and velocities up to 3 m/s (10 ft/s) for liquid. Gas pipelines have higher velocities and may have greater spacing of stations.

**Tanks** Tank cars (single and multiple tanks), tank trucks, portable tanks, drums, barrels, carboys, and cans are used to transport fluids. Interstate transportation is regulated by the DOT. There are other regulating agencies—state, local, and private. Railroads make rules determining what they will accept, some states require compliance with DOT specifications on intrastate movements, and tunnel authorities as well as fire chiefs apply restrictions. Water shipments involve regulations of the U.S. Coast Guard. The American Bureau of Shipping sets rules for design and construction which are recognized by insurance underwriters.

The most pertinent *DOT regulations* (*Code of Federal Regulations,* Title 18, Parts 171–179 and 397) were published by R. M. Graziano (then agent and attorney for carriers and freight forwarders) in his tariff titled *Hazardous Materials Regulations of the Department of Transportation* (1978). New tariffs identified by number are issued at intervals, and interim revisions are sent out. Agents change at intervals.

Graziano's tariff lists many regulated (dangerous) commodities (Part 172, DOT regulations) for transportation. This includes those that are poisonous, flammable, oxidizing, corrosive, explosive, radioactive, and compressed gases. Part 178 covers specifications for all types of containers from carboys to large portable tanks and tank trucks. Part 179 deals with tank-car construction.

| Thickness, in | Carbon steel | 304 Stainless steel | 316 Stainless steel |
|---|---|---|---|
| ½ | 1.4 | 1.8 | 1.8 |
| ¾ | 2.1 | 2.5 | 2.6 |
| 1 | 2.7 | 3.3 | 3.5 |

To convert gallons to cubic meters, multiply by $3.786 \times 10^{-3}$.

The Association of American Railroads (AAR) publication *Specifications for Tank Cars* covers many requirements beyond the DOT regulations.

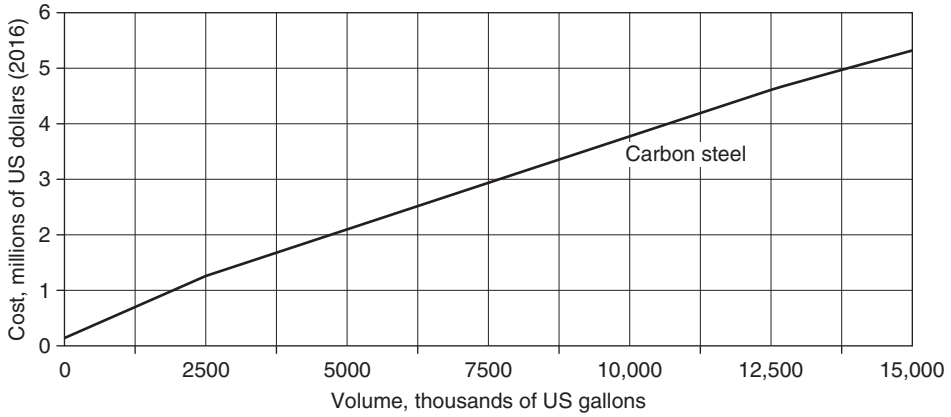

**FIG. 10-183** Cost (±30 percent) of field-erected, floating roof tanks, October 2016, includes concrete foundation and typical nozzles, ladders, and platforms. 1 gal = 0.003785 $m^3$.

Some additional details are given later. Because of frequent changes, it is always necessary to check the latest rules. The *shipper,* not the carrier, has the ultimate responsibility for shipping in the correct container.

**Tank Cars** These range in size from about 7.6 to 182 $m^3$ (2000 to 48,000 gal), and a car may be single-unit or multiunit. The DOT now limits them to 130 $m^3$ (34,500 gal) and 120,000 kg (263,000 lb) gross weight. Large cars usually result in lower investment per cubic meter and take lower shipping rates. Cars may be insulated to reduce heating or cooling of the contents. Certain liquefied gases may be carried in insulated cars; temperatures are maintained by evaporation (see subsection Low-Temperature and Cryogenic Storage). Cars may be heated by steam coils or by electricity. Some products are loaded hot, solidify in transport, and are melted for removal. Some low-temperature cargoes must be unloaded within a given time (usually 30 days) to prevent pressure buildup.

Tank cars are classified as pressure or general-purpose. Pressure cars have relief-valve settings of 517 kPa (75 $lbf/in^2$) and above. Those designated as general-purpose cars are, nevertheless, pressure vessels and may have relief valves or rupture disks. The DOT specification code number indicates the type of car. For instance, 105A500W indicates a pressure car with a test pressure of 3447 kPa (500 $lbf/in^2$) and a relief-valve setting of 2585 kPa (375 $lbf/in^2$). In most cases, loading and unloading valves, safety valves, and vent valves must be in a dome or an enclosure.

Companies shipping dangerous materials sometimes build tank cars with metal thicker than required by the specifications in order to reduce the possibility of leakage during a wreck or fire. The punching of couplers or rail ends into heads of tanks is a hazard.

Older tank cars have a center sill or beam running the entire length of the car. Most modern cars have no continuous sill, only short stub sills at each end. Cars with full sills have tanks anchored longitudinally at the center of the sill. The anchor is designed to be weaker than either the tank shell or the doubler plate between anchor and shell. Cars with stub sills have similar safeguards. Anchors and other parts are designed to meet AAR requirements.

The impact forces on car couplers put high stresses on sills, anchors, and doublers. This may start fatigue cracks in the shell, particularly at the corners of welded doubler plates. With brittle steel in cold weather, such cracks sometimes cause complete rupture of the tank. Large end radii on the doublers and tougher steels will reduce this hazard. Inspection of older cars can reveal cracks prior to failure.

A difference between tank cars and most pressure vessels is that tank cars are designed in terms of the theoretical ultimate or bursting strength of the tank. The test pressure is usually 40 percent of the bursting pressure (sometimes less). The safety valves are set at 75 percent of the test pressure. Thus, the maximum operating pressure is usually 30 percent of the bursting pressure. This gives a nominal factor of safety of 3.3, compared with 3.5 for Division 1 of the ASME Boiler and Pressure Vessel Code.

The DOT rules require that pressure cars have relief valves designed to limit pressure to 82.5 percent (with certain exceptions) of test pressure (110 percent of maximum operating pressure) when exposed to fire. Appendix A of AAR Specifications deals with the flow capacity of relief devices. The formulas apply to cars in the upright position with the device discharging vapor. They may not protect the car adequately when it is overturned and the device is discharging liquid.

Appendix B of AAR Specifications deals with the certification of facilities. Fabrication, repairing, testing, and specialty work on tank cars must be done in certified facilities. The AAR certifies shops to build cars of certain materials, to do test work on cars, or to make certain repairs and alterations.

**Tank Trucks** These trucks may have single, compartmented, or multiple tanks. Many of their requirements are similar to those for tank cars, except that thinner shells are permitted in most cases. Trucks for nonhazardous materials are subject to few regulations other than the normal highway laws governing all motor vehicles. But trucks carrying hazardous materials must comply with DOT regulations, Parts 173, 177, 178, and 397. Maximum weight, axle loading, and length are governed by state highway regulations. Many states have limits in the vicinity of 31,750 kg (70,000 lb) total weight, 14,500 kg (32,000 lb) for tandem axles, and 18.3 m (60 ft) or less overall length. Some allow tandem trailers.

Truck cargo tanks ( for dangerous materials) are built under Part 173 and Subpart J of Part 178, DOT regulations. This includes Specifications MC-306, MC-307, MC-312, and MC-331. MC-331 is required for compressed gas. Subpart J requires tanks for pressures above 345 kPa (50 $lbf/in^2$) in one case and 103 kPa (15 $lbf/in^2$) in another to be built according to the ASME Boiler and Pressure Vessel Code. A particular issue of the code is specified.

Because of the demands of highway service, the DOT specifications have a number of requirements in addition to the ASME Code. These include design for impact forces and rollover protection for fittings.

*Portable tanks, drums, or bottles* are shipped by rail, ship, air, or truck. Portable tanks containing hazardous materials must conform to DOT regulations, Parts 173 and 178, Subpart H.

Some tanks are designed to be shipped by trailer and transferred to railcars or ships (see following discussion).

**Marine Transportation** Seagoing *tankers* are for high tonnage. The traditional tanker uses the ship structure as a tank. It is subdivided into a number of tanks by means of transverse bulkheads and a centerline bulkhead. More than one product can be carried. An elaborate piping system connects the tanks to a pumping plant which can discharge or transfer the cargo. Harbor and docking facilities appear to be the only limit to tanker size. The largest crude oil tanker size to date is about 560,000 deadweight tons. In the United States, tankers are built to specifications of the American Bureau of Shipping and the U.S. Coast Guard.

Low-temperature liquefied gases are shipped in special ships with insulation between the hull and an inner tank. The largest LNG carrier's capacity is about 145,000 $m^3$. Poisonous materials are shipped in separate tanks built into the ship. This prevents tank leakage from contaminating harbors. Separate tanks are also used to transport pressurized gases.

Barges are used on inland waterways. Popular sizes are up to 16 m (52½ ft) wide by 76 m (250 ft) long, with 2.6-m (8½-ft) to 4.3-m (14-ft) draft. Cargo requirements and waterway limitations determine the design. Use of barges of uniform size facilitates rafting them together.

*Portable tanks* may be stowed in the holds of conventional cargo ships or special container ships, or they may be fastened on deck.

*Container ships* have guides in the hold and on deck which hold boxlike containers or tanks. The tank is latched to a trailer chassis and hauled to shipside. A movable gantry, sometimes permanently installed on the ship, hoists the tank from the trailer and lowers it into the guides on the ship. This system achieves large savings in labor, but its application is sometimes limited by lack of agreement between ship operators and unions.

Portable tanks for regulated commodities in marine transportation must be designed and built under Coast Guard regulations (see discussion under Pressure Vessels).

**Materials of Construction for Bulk Transport** Because of the more severe service, construction materials for transportation usually are more restricted than for storage. Most large pipelines are constructed of steel conforming to API Specification 5L or 5LX. Most tanks (cars, etc.) are built of pressure-vessel steels or AAR specification steels, with a few made of aluminum or stainless steel. Carbon-steel tanks may be lined with rubber, plastic, nickel, glass, or other materials. In many cases this is practical and cheaper than using a stainless-steel tank. Other materials for tank construction may be proposed and used if approved by the appropriate authorities (AAR and DOT).

## PRESSURE VESSELS

This discussion of pressure vessels is intended as an overview of the codes most frequently used for the design and construction of pressure vessels. Chemical engineers who design or specify pressure vessels should determine the federal and local laws relevant to the problem and then refer to the most recent issue of the pertinent code or standard before proceeding. Laws, codes, and standards are frequently changed.

A *pressure vessel* is a closed container of limited length (in contrast to the indefinite length of piping). Its smallest dimension is considerably larger than the connecting piping, and it is subject to pressures above 7 or 14 kPa (1 or 2 $lbf/in^2$). It is distinguished from a boiler, which in most cases is used to generate steam for use external to itself.

**Code Administration** The American Society of Mechanical Engineers has written the ASME Boiler and Pressure Vessel Code (BPVC), which contains rules for the design, fabrication, and inspection of boilers and pressure vessels. The ASME Code is an American National Standard. Most states in the United States and all Canadian provinces have passed legislation which makes the ASME Code or certain parts of it their legal requirement. Only a few jurisdictions have adopted the code for all vessels. The others apply it to certain types of vessels or to boilers. States employ inspectors (usually under a chief boiler inspector) to enforce code provisions. The authorities also depend a great deal on insurance company inspectors to see that boilers and pressure vessels are maintained in a safe condition.

The ASME Code is written by a large committee and many subcommittees, composed of engineers appointed by the ASME. The Code Committee meets regularly to review the code and consider requests for its revision, interpretation, or extension. *Interpretation* and *extension* are accomplished through "code cases." The decisions are published in *Mechanical Engineering.* Code cases are also mailed to those who subscribe to the service. A typical code case might be the approval of the use of a metal which is not presently on the list of approved code materials. Inquiries relative to code cases should be addressed to the secretary of the ASME Boiler and Pressure Vessel Committee, American Society of Mechanical Engineers, New York.

A new edition of the code is issued every 3 years. Between editions, alterations are handled by issuing semiannual addenda, which may be purchased by subscription. The ASME considers any issue of the code to be adequate

and safe, but some government authorities specify certain issues of the code as their legal requirement.

***Inspection Authority*** The National Board of Boiler and Pressure Vessel Inspectors is composed of the chief inspectors of states and municipalities in the United States and Canadian provinces who have made any part of the Boiler and Pressure Vessel Code a legal requirement. This board promotes uniform enforcement of boiler and pressure-vessel rules. One of the board's important activities is to provide examinations for, and commissioning of, inspectors. Inspectors so qualified and employed by an insurance company, state, municipality, or Canadian province may inspect a pressure vessel and permit it to be stamped ASME—NB (National Board). An inspector employed by a vessel user may authorize the use of only the ASME stamp. The ASME Code Committee authorizes fabricators to use the various ASME stamps. The stamps, however, may be applied to a vessel only with the approval of the inspector.

The ASME Boiler and Pressure Vessel Code consists of eleven sections as follows:

I. Power Boilers
II. Materials
  *a.* Ferrous
  *b.* Nonferrous
  *c.* Welding rods, electrodes, and filler metals
  *d.* Properties
III. Rules for Construction of Nuclear Power Plant Components
IV. Heating Boilers
V. Nondestructive Examination
VI. Rules for Care and Operation of Heating Boilers
VII. Guidelines for the Care of Power Boilers
VIII. Pressure Vessels
IX. Welding and Brazing Qualifications
X. Fiber-Reinforced Plastic Pressure Vessels
XI. Rules for In-service Inspection of Nuclear Power Plant Components

Pressure vessels (as distinguished from boilers) are involved with Secs. II, III, V, VIII, IX, X, and XI. Section VIII, Division 1, is the Pressure Vessel Code as it existed in the past (and will continue). Division 1 was brought out as a means of permitting higher design stresses while ensuring at least as great a degree of safety as in Division 1. These two divisions plus Secs. III and X will be discussed briefly here. They refer to Secs. II and IX.

**ASME Code Section VIII, Division 1** Most pressure vessels used in the process industry in the United States are designed and constructed in accordance with Sec. VIII, Division 1 (see Fig. 10-184). This division is divided into three subsections followed by appendices.

***Introduction*** The Introduction contains the scope of the division and defines the responsibilities of the user, the manufacturer, and the inspector. The scope defines pressure vessels as containers for the containment of pressure. It specifically excludes vessels having an internal pressure not exceeding 103 kPa (15 lbf/in$^2$) and further states that the rules are applicable for pressures not exceeding 20,670 kPa (3000 lbf/in$^2$). For higher pressures it is usually necessary to deviate from the rules in this division.

The scope covers many other less basic exclusions, and inasmuch as the scope is occasionally revised, except for the most obvious cases, it is prudent to review the current issue before specifying or designing pressure vessels to this division. Any vessel that meets all the requirements of this division may be stamped with the code *U* symbol even though exempted from such stamping.

***Subsection A*** This subsection contains the general requirements applicable to all materials and methods of construction. Design temperature and pressure are defined here, and the loadings to be considered in design are specified. For stress failure and yielding, this section of the code uses the maximum-stress theory of failure as its criterion.

This subsection refers to the tables elsewhere in the division in which the maximum allowable tensile stress values are tabulated. The basis for the establishment of these allowable stresses is defined in detail in App. P; however, as the safety factors used were very important in establishing the various rules of this division, note that the safety factors for internal-pressure loads are 3.5 on ultimate strength and 1.6 or 1.5 on yield strength, depending on the material. For external-pressure loads on cylindrical shells, the safety factors are 3 for both elastic buckling and plastic collapse. For other shapes subject to external pressure and for longitudinal shell compression, the safety factors are 3.5 for both elastic buckling and plastic collapse. Longitudinal compressive stress in cylindrical elements is limited in this subsection by the lower of either stress failure or buckling failure.

Internal-pressure design rules and formulas are given for cylindrical and spherical shells and for ellipsoidal, torispherical (often called ASME heads), hemispherical, and conical heads. The formulas given assume membrane-stress failure, although the rules for heads include consideration for buckling failure in the transition area from cylinder to head (knuckle area).

Longitudinal joints in cylinders are more highly stressed than circumferential joints, and the code takes this fact into account. When forming heads, there is usually some thinning from the original plate thickness in the knuckle area, and it is prudent to specify the minimum allowable thickness at this point.

Unstayed flat heads and covers can be designed by very specific rules and formulas given in this subsection. The stresses caused by pressure on these members are bending stresses, and the formulas include an allowance for additional edge moments induced when the head, cover, or blind flange is attached by bolts. Rules are provided for quick-opening closures because of the risk of incomplete attachment or opening while the vessel is pressurized. Rules for braced and stayed surfaces are also provided.

External-pressure failure of shells can result from overstress at one extreme or from elastic instability at the other or at some intermediate loading. The code provides the solution for most shells by using a number of charts. One chart is used for cylinders where the shell diameter-to-thickness ratio and the length-to-diameter ratio are the variables. The rest of the charts depict curves relating the geometry of cylinders and spheres to allowable stress by curves which are determined from the modulus of elasticity, tangent modulus, and yield strength at temperatures for various materials or classes of materials. The text of this subsection explains how the allowable stress is determined from the charts for cylinders, spheres, and hemispherical, ellipsoidal, torispherical, and conical heads.

Frequently cost savings for cylindrical shells can result from reducing the effective length-to-diameter ratio and thereby reducing shell thickness. This can be accomplished by adding circumferential stiffeners to the shell. Rules are included for designing and locating the stiffeners.

Openings are always required in pressure-vessel shells and heads. Stress intensification is created by the existence of a hole in an otherwise symmetric section. The code compensates for this by an area-replacement method. It takes a cross section through the opening, and it measures the area of the metal of the required shell that is removed and replaces it in the cross section by additional material (shell wall, nozzle wall, reinforcing plate, or weld) within certain distances of the opening centerline. These rules and formulas for calculation are included in Subsection A.

When a cylindrical shell is drilled for the insertion of multiple tubes, the shell is significantly weakened and the code provides rules for tube-hole patterns and the reduction in strength that must be accommodated.

Fabrication tolerances are covered in this subsection. The tolerances permitted for shells for external pressure are much closer than those for internal pressure because the stability of the structure is dependent on the symmetry. Other paragraphs cover repair of defects during fabrication, material identification, heat treatment, and impact testing.

Inspection and testing requirements are covered in detail. Most vessels are required to be hydrostatically tested (generally with water) at 1.3 times the maximum allowable working pressure. Some enameled (glass-lined) vessels are permitted to be hydrostatically tested at lower pressures. Pneumatic tests are permitted and are carried to at least 1.25 times the maximum allowable working pressure, and there is provision for proof testing when the strength of the vessel or any of its parts cannot be computed with satisfactory assurance of accuracy. Pneumatic or proof tests are rarely conducted because release of the stored energy of compression of the test gas can cause an explosion upon failure of the vessel under test.

Pressure-relief device requirements are defined in Subsection A. Set point and maximum pressure during relief are defined according to the service, the cause of overpressure, and the number of relief devices. Safety, safety relief, relief valves, rupture disk, rupture pin, and rules on tolerances for the relieving point are given.

Testing, certification, and installation rules for relieving devices are extensive. Every chemical engineer responsible for the design or operation of process units should become very familiar with these rules. The pressure-relief device paragraphs are the only parts of Sec. VIII, Division 1, that are concerned with the installation and ongoing operation of the facility; all other rules apply only to the design and manufacture of the vessel.

***Subsection B*** This subsection contains rules pertaining to the methods of fabrication of pressure vessels. Part UW is applicable to welded vessels. Service restrictions are defined. Lethal service is for *lethal substances*, defined as poisonous gases or liquids of such a nature that a very small amount of the gas or the vapor of the liquid mixed or unmixed with air is dangerous to life when inhaled. It is stated that it is the user's responsibility to advise the designer or manufacturer if the service is lethal. All vessels in lethal service shall have all butt-welded joints fully radiographed, and when practical, joints shall be butt-welded. All vessels fabricated of carbon steel or low-alloy steel shall be postweld-heat-treated.

*Low-temperature service* is defined as being below −29°C (−20°F), and impact testing of many materials is required. The code is restrictive in the type of welding permitted.

**FIG. 10-184** (*Continued*)

Unfired steam boilers with design pressures exceeding 345 kPa (50 lbf/in$^2$) have restrictive rules on welded-joint design, and all butt joints require full radiography.

Pressure vessels subject to direct firing have special requirements relative to welded-joint design and postweld heat treatment.

This subsection includes rules governing welded-joint designs and the degree of radiography, with efficiencies for welded joints specified as functions of the quality of joint. These efficiencies are used in the formulas in Subsection A for determining vessel thicknesses.

Details are provided for head-to-shell welds, tube sheet-to-shell welds, and nozzle-to-shell welds. Acceptable forms of welded stay-bolts and plug and slot welds for staying plates are given here.

Rules for the welded fabrication of pressure vessels cover welding processes, manufacturer's record keeping on welding procedures, welder qualification, cleaning, fit-up alignment tolerances, and repair of weld defects. Procedures for postweld heat treatment are detailed. Checking the procedures and welders and radiographic and ultrasonic examination of welded joints are covered.

Requirements for vessels fabricated by forging in Part UF include unique design requirements with particular concern for stress risers, fabrication, heat treatment, repair of defects, and inspection. Vessels fabricated by brazing are covered in Part UB. Brazed vessels cannot be used in lethal service, for unfired steam boilers, or for direct firing. Permitted brazing processes and testing of brazed joints for strength are covered. Fabrication and inspection rules are also included.

***Subsection C*** This subsection contains requirements pertaining to classes of materials. Carbon steels and low-alloy steels are governed by Part UCS, nonferrous materials by Part UNF, high-alloy steels by Part UHA, and steels with tensile properties enhanced by heat treatment by Part UHT. Each of these parts includes tables of maximum allowable stress values for all code materials for a range of metal temperatures. These stress values include appropriate safety factors. Rules governing the application, fabrication, and heat treatment of the vessels are included in each part.

Part UHT also contains more stringent details for nozzle welding that are required for some of these high-strength materials. Part UCI has rules for cast-iron construction, Part UCL has rules for welded vessels of clad plate as lined vessels, and Part UCD has rules for ductile-iron pressure vessels.

A relatively recent addition to the code is Part ULW, which contains requirements for vessels fabricated by layered construction. This type of construction is most frequently used for high pressures, usually in excess of 13,800 kPa (2000 lbf/in$^2$).

There are several methods of layering in common use: (1) thick layers shrunk together; (2) thin layers, each wrapped over the other and the longitudinal seam welded by using the prior layer as backup; and (3) thin layers spirally wrapped. The code rules are written for either thick or thin layers. Rules and details are provided for all the usual welded joints and nozzle reinforcement. Supports for layered vessels require special consideration, in that only the outer layer could contribute to the support. For lethal service, only the inner shell and inner heads need comply with the requirements in Subsection B. Inasmuch as radiography would not be practical for inspection of many of the welds, extensive use is made of magnetic-particle and ultrasonic inspection. When radiography is required, the code warns the inspector that indications sufficient for rejection in single-wall vessels may be acceptable. Vent holes are specified through each layer down to the inner shell to prevent buildup of pressure between layers in the event of leakage at the inner shell.

***Mandatory Appendices*** These include a section on supplementary design formulas for shells not covered in Subsection A. Formulas are given for thick shells, heads, and dished covers. Another appendix gives very specific rules, formulas, and charts for the design of bolted-flange connections. The nature of these rules is such that they are readily computer-programmable, and most flanges now are computer-designed. One appendix includes only the charts used for calculating shells for external pressure discussed previously. Jacketed vessels are covered in a separate appendix in which very specific rules are given, particularly for the attachment of the jacket to the inner shell. Other appendices cover inspection and quality control.

***Nonmandatory Appendices*** These cover a number of subjects, primarily suggested good practices and other aids in understanding the code and in designing with the code. Several current nonmandatory appendixes will probably become mandatory.

Figure 10-184 illustrates a pressure vessel with the applicable code paragraphs noted for the various elements. Additional important paragraphs are referenced at the bottom of the figure.

**ASME BPVC Section VIII, Division 2** Paragraph AG-100e of Division 2 states:

> In relation to the rules of Division 1 of Section VIII, these rules of Division 2 are more restrictive in the choice of materials which may be used but permit higher design stress intensity values to be employed in the range of temperatures over which the design stress intensity value is controlled by the ultimate strength or the yield strength; more precise design procedures are required and some common design details are prohibited; permissible fabrication procedures are specifically delineated and more complete testing and inspection are required.

Most Division 2 vessels fabricated to date have been large or intended for high pressure and, therefore, expensive when the material and labor savings resulting from smaller safety factors have been greater than the additional engineering, administrative, and inspection costs.

The organization of Division 2 differs from that of Division 1.

***Part AG*** This part gives the scope of the division, establishes its jurisdiction, and sets forth the responsibilities of the user and the manufacturer. Of particular importance is the fact that no upper limitation in pressure is specified and that a user's design specification is required. The user or the user's agent shall provide requirements for intended operating conditions in such detail as to constitute an adequate basis for selecting materials and designing, fabricating, and inspecting the vessel. The user's design specification shall include the method of supporting the vessel and any requirement for a fatigue analysis. If a fatigue analysis is required, the user must provide information in sufficient detail that an analysis for cyclic operation can be made.

***Part AM*** This part lists permitted individual construction materials, applicable specifications, special requirements, design stress intensity values, and other property information. Of particular importance are the ultrasonic test and toughness requirements. Among the properties for which data are included are thermal conductivity and diffusivity, coefficient of thermal expansion, modulus of elasticity, and yield strength. The design stress intensity values include a safety factor of 3 on ultimate strength at temperature or 1.5 on yield strength at temperature.

***Part AD*** This part contains requirements for the design of vessels. The rules of Division 2 are based on the maximum-shear theory of failure for stress failure and yielding. Higher stresses are permitted when wind or earthquake loads are considered. Any rules for determining the need for fatigue analysis are given here.

Rules for the design of shells of revolution under internal pressure differ from the Division 1 rules, particularly the rules for formed heads when plastic deformation in the knuckle area is the failure criterion. Shells of revolution for external pressure are determined on the same criterion, including safety factors, as in Division 1. Reinforcement for openings uses the same area-replacement method as Division 1; however, in many cases the reinforcement metal must be closer to the opening centerline.

The rest of the rules in Part AD for flat heads, bolted and studded connections, quick-actuating closures, and layered vessels essentially duplicate Division 1. The rules for support skirts are more definitive in Division 2.

***Part AF*** This part contains requirements governing the fabrication of vessels and vessel parts.

***Part AR*** This part contains rules for pressure-relieving devices.

***Part AI*** This part contains requirements controlling inspection of the vessel.

***Part AT*** This part contains testing requirements and procedures.

***Part AS*** This part covers requirements for stamping and certifying the vessel and vessel parts.

***Appendices*** Appendix 1 defines the basis used for defining stress intensity values. Appendix 2 contains external-pressure charts, and App. 3 has the rules for bolted-flange connections; these two are exact duplicates of the equivalent appendices in Division 1.

Appendix 4 gives definitions and rules for stress analysis for shells, flat and formed heads, and tube sheets, layered vessels, and nozzles including discontinuity stresses. Of particular importance are Table 4-120.1, Classification of Stresses for Some Typical Cases, and Fig. 4-130.1, Stress Categories and Limits of Stress Intensity. These are very useful in that they clarify a number of paragraphs and simplify stress analysis.

Appendix 5 contains rules and data for stress analysis for cyclic operation. Except in short-cycle batch processes, pressure vessels are usually subject to few cycles in their projected lifetime, and the endurance-limit data used in the machinery industries are not applicable. Curves are given for a broad spectrum of materials, covering a range from 10 to 1 million cycles with allowable stress values as high as 650,000 lbf/in$^2$. This low-cycle fatigue has been developed from strain-fatigue work in which stress values are obtained by multiplying the strains by the modulus of elasticity. Stresses of this magnitude cannot occur, but strains do. The curves given have a factor of safety of 2 on stress or 20 on cycles.

Appendix 6 contains the requirements of experimental stress analysis, Appendix 8 has acceptance standards for radiographic examination, Appendix 9 covers nondestructive examination, Appendix 10 gives rules for capacity conversions for safety valves, and App. 18 details quality control system requirements.

The remaining appendices are nonmandatory but useful to engineers working with the code.

***General Considerations*** Most pressure vessels for the chemical-process industry will continue to be designed and built to the rules of BPVC, Section VIII, Division 1. While the rules of Section VIII, Division 2, will frequently provide thinner elements, the cost of the engineering analysis, stress analysis and higher-quality construction, material control, and inspection required by these rules frequently exceeds the savings from the use of thinner walls.

**Additional ASME Code Considerations**

***ASME BPVC Section III: Nuclear Power Plant Components*** This section of the code includes vessels, storage tanks, and concrete containment vessels as well as other nonvessel items.

***ASME BPVC Section X: Fiberglass–Reinforced-Plastic Pressure Vessels*** This section is limited to four types of vessels: bag-molded and centrifugally cast, each limited to 1000 kPa (150 lbf/in$^2$); filament-wound with cut filaments limited to 10,000 kPa (1500 lbf/in$^2$); and filament-wound with uncut filaments limited to 21,000 kPa (3000 lbf/in$^2$). Operating temperatures are limited to the range from +66°C (150°F) to −54°C (−65°F). Low modulus of elasticity and other property differences between metal and plastic required that many of the procedures in Section X be different from those in the sections governing metal vessels. The requirement that at least one vessel of a particular design and fabrication shall be tested to destruction has prevented this section from being widely used. The results from the combined fatigue and burst test must give the design pressure a safety factor of 6 to the burst pressure.

***Safety in Design*** Designing a pressure vessel in accordance with the code, under most circumstances, will provide adequate safety. In the code's own words, however, the rules "cover minimum construction requirements for the design, fabrication, inspection, and certification of pressure vessels." The significant word is *minimum*. The *ultimate responsibility* for safety rests with the user and the designer. They must decide whether anything beyond code requirements is necessary. The code cannot foresee and provide for all the unusual conditions to which a pressure vessel might be exposed. If it tried to do so, the majority of pressure vessels would be unnecessarily restricted. Some of the conditions that a vessel might encounter are unusually low temperatures, unusual thermal stresses, stress ratcheting caused by thermal cycling, vibration of tall vessels excited by von Karman vortices caused by wind, very high pressures, runaway chemical reactions, repeated local overheating, explosions, exposure to fire, exposure to materials that rapidly attack the metal, containment of extremely toxic materials, and very large sizes of vessels. Large vessels, although they may contain nonhazardous materials, by their very size, could create a serious hazard if they burst. The failure of the Boston molasses tank in 1919 killed 12 people. For pressure vessels which are outside code jurisdiction, there are sometimes special hazards in very high-strength materials and plastics. There may be many others which the designers should recognize if they encounter them.

*Metal fatigue,* when it is present, is a serious hazard. BPVC Section VIII, Division 1, mentions rapidly fluctuating pressures. Division 2 and Section III do require a fatigue analysis. In extreme cases, vessel contents may affect the fatigue strength (endurance limit) of the material. This is *corrosion fatigue*. Although most ASME Code materials are not particularly sensitive to corrosion fatigue, even they may suffer an endurance limit loss of 50 percent in some environments. High-strength heat-treated steels, on the other hand, are very sensitive to corrosion fatigue. It is not unusual to find some of these which lose 75 percent of their endurance in corrosive environments. In fact, in corrosion fatigue many steels do not have an endurance limit. The curve of stress versus cycles to failure (*S/N* curve) continues to slope downward regardless of the number of cycles.

*Brittle fracture* is probably the most insidious type of pressure-vessel failure. Without brittle fracture, a pressure vessel could be pressurized approximately to its ultimate strength before failure. With brittle behavior some vessels have failed well below their design pressures (which are about 25 percent of the theoretical bursting pressures). To reduce the possibility of brittle behavior, Division 2 and Section III require impact tests.

The subject of brittle fracture has been understood only since about 1950, and knowledge of some of its aspects is still inadequate. A notched or cracked plate of pressure-vessel steel, stressed at 66°C (150°F), would elongate and absorb considerable energy before breaking. It would have a ductile or plastic fracture. As the temperature is lowered, a point is reached at which the plate would fail in a brittle manner with a flat fracture surface and almost no elongation. The transition from ductile to brittle fracture actually takes place over a temperature range, but a point in this range is selected as the *transition temperature.* One of the ways of determining this temperature is the Charpy impact test (see ASTM Specification E-23). After the transition temperature has been determined by laboratory impact tests, it must be correlated with service experience on full-size plates. The literature on brittle fracture contains information on the relation of impact tests to service experience on some carbon steels.

A more precise but more elaborate method of dealing with the ductile-brittle transition is the *fracture-analysis diagram.* This uses a transition known as the *nil-ductility temperature* (NDT), which is determined by the drop-weight test (ASTM Standard E208) or the drop-weight tear test (ASTM Standard E436). The application of this diagram is explained in two papers by Pellini and Puzak [*Trans. Am. Soc. Mech. Eng.* 429 (October 1964); *Welding Res. Counc. Bull.* 88, 1963].

BPVC Section VIII, Division 1, is lax with respect to brittle fracture. It allows the use of many steels down to −29°C (−20°F) without a check on toughness. Occasional brittle failures show that some vessels are operating below the nil-ductility temperature, i.e., the lower limit of ductility. Division 2 has solved this problem by requiring impact tests in certain cases. Tougher grades of steel, such as the SA516 steels (in preference to SA515 steel), are available for a small price premium. Stress relief, steel made to fine-grain practice, and normalizing all reduce the hazard of brittle fracture.

*Nondestructive testing* of both the plate and the finished vessel is important to safety. In the analysis of fracture hazards, it is important to know the size of the flaws that may be present in the completed vessel. The four most widely used methods of examination are radiographic, magnetic-particle, liquid-penetrant, and ultrasonic.

*Radiographic examination* is either by *x-rays* or by *gamma radiation.* The former has greater penetrating power, but the latter is more portable. Few x-ray machines can penetrate beyond 300-mm (12-in) thickness.

*Ultrasonic techniques* use vibrations with a frequency between 0.5 and 20 MHz transmitted to the metal by a transducer. The instrument sends out a series of pulses. These show on a cathode-ray screen as they are sent out and again when they return after being reflected from the opposite side of the member. If there is a crack or an inclusion along the way, it will reflect part of the beam. The initial pulse and its reflection from the back of the member are separated on the screen by a distance which represents the thickness. The reflection from a flaw will fall between these signals and indicate its magnitude and position. Ultrasonic examination can be used for almost any thickness of material from a fraction of an inch to several feet. Its use is dependent on the shape of the body because irregular surfaces may give confusing reflections. Ultrasonic transducers can transmit pulses normal to the surface or at an angle. Transducers transmitting pulses that are oblique to the surface can solve a number of special inspection problems.

*Magnetic-particle examination* is used only on magnetic materials. Magnetic flux is passed through the part in a path parallel to the surface. Fine magnetic particles, when dusted over the surface, will concentrate near the edges of a crack. The sensitivity of magnetic-particle examination is proportional to the sine of the angle between the direction of the magnetic flux and the direction of the crack. To be sure of picking up all cracks, it is necessary to probe the area in two directions.

*Liquid-penetrant examination* involves wetting the surface with a fluid that penetrates open cracks. After the excess liquid has been wiped off, the surface is coated with a material which will reveal any liquid that has penetrated the cracks. In some systems a colored dye will seep out of cracks and stain whitewash. Another system uses a penetrant that becomes fluorescent under ultraviolet light.

Each of these four popular methods has its advantages. Frequently, best results are obtained by using more than one method. Magnetic particles or liquid penetrants are effective on surface cracks. Radiography and ultrasonic examination are necessary for subsurface flaws. *No known method of nondestructive testing can guarantee the absence of flaws.* There are other less widely used methods of examination. Among these are eddy current, electrical resistance, acoustics, and thermal testing. *Nondestructive Testing Handbook* [Robert C. McMaster (ed.), Ronald, New York, 1959] gives information on many testing techniques.

The *eddy-current technique* involves an alternating-current coil along and close to the surface being examined. The electrical impedance of the coil is affected by flaws in the structure or changes in composition. Commercially, the principal use of eddy-current testing is for the examination of tubing. It could, however, be used for testing other things.

The *electrical resistance method* involves passing an electric current through the structure and exploring the surface with voltage probes. Flaws, cracks, or inclusions will cause a disturbance in the voltage gradient on the surface. Railroads have used this method for many years to locate transverse cracks in rails.

The *hydrostatic test* is, in one sense, a method of examination of a vessel. It can reveal gross flaws, inadequate design, and flange leaks. Many believe that a hydrostatic test guarantees the safety of a vessel. This is not necessarily so. A vessel that has passed a hydrostatic test is probably safer than one that has not been tested. It can, however, still fail in service, even on the next application of pressure. Care in material selection, examination, and fabrication does more to guarantee vessel integrity than the hydrostatic test.

The ASME Codes recommend that hydrostatic tests be run at a temperature that is usually above the nil-ductility temperature of the material.

This is, in effect, a pressure-temperature treatment of the vessel. When tested in the relatively ductile condition above the nil-ductility temperature, the material will yield at the tips of cracks and flaws and at points of high residual weld stress. This procedure will actually reduce the residual stresses and cause a redistribution at crack tips. The vessel will then be in a safer condition for subsequent operation. This procedure is sometimes referred to as *notch nullification.*

It is possible to design a hydrostatic test in such a way that it probably will be a proof test of the vessel. This usually requires, among other things, that the test be run at a temperature as low as and preferably lower than the minimum operating temperature of the vessel. Proof tests of this type are run on vessels built of ultrahigh-strength steel to operate at cryogenic temperatures.

**Other Regulations and Standards** Pressure vessels may come under many types of regulation, depending on where they are and what they contain. Although many states have adopted the ASME Boiler and Pressure Vessel Code, either in total or in part, any state or municipality may enact its own requirements. The federal government regulates some pressure vessels through the Department of Transportation, which includes the Coast Guard. If pressure vessels are shipped into foreign countries, they may face additional regulations.

Pressure vessels carried aboard United States–registered ships must conform to rules of the *U.S. Coast Guard.* Subchapter F of Title 46, *Code of Federal Regulations,* covers marine engineering. Of this, Parts 50 through 61 and 98 include pressure vessels. Many of the rules are similar to those in the ASME Code, but there are differences.

The *American Bureau of Shipping* (ABS) has rules that insurance underwriters require for the design and construction of pressure vessels which are a permanent part of a ship. Pressure cargo tanks may be permanently attached and come under these rules. Such tanks supported at several points are independent of the ship's structure and are distinguished from integral cargo tanks such as those in a tanker. ABS has pressure-vessel rules in two of its publications. Most of them are in *Rules for Building and Classing Steel Vessels.*

**Standards of Tubular Exchanger Manufacturers Association (TEMA)** These standards give recommendations for the construction of tubular heat exchangers. Although TEMA is not a regulatory body and there is no legal requirement for the use of its standards, they are widely accepted as a good basis for design. By specifying TEMA standards, one can obtain adequate equipment without having to write detailed specifications for each piece. TEMA gives formulas for the thickness of tube sheets. Such formulas are not in ASME Codes. (See further discussion of TEMA in Sec. 11.)

**Vessels with Unusual Construction** High pressures create design problems. ASME BPVC Section VIII, Division 1, applies to vessels rated for pressures up to 20,670 kPa (3000 lbf/in$^2$). Division 2 is unlimited. At high pressures, special designs not necessarily in accordance with the code are sometimes used. At such pressures, a vessel designed for ordinary low-carbon-steel plate, particularly in large diameters, would become too thick for practical fabrication by ordinary methods. The alternatives are to make the vessel of high-strength plate, use a solid forging, or use multilayer construction.

*High-strength steels* with tensile strengths over 1380 MPa (200,000 lbf/in$^2$) are limited largely to applications for which weight is very important. Welding procedures are carefully controlled, and preheat is used. These materials are brittle at almost any temperature, and vessels must be designed to prevent brittle fracture. Flat spots and variations in curvature are avoided. Openings and changes in shape require appropriate design. The maximum permissible size of flaws is determined by fracture mechanics, and the method of examination must ensure as much as possible that larger flaws are not present. All methods of nondestructive testing may be used. Such vessels require the most sophisticated techniques in design, fabrication, and operation.

*Solid forgings* are frequently used in construction for pressure vessels above 20,670 kPa (3000 lbf/in$^2$) and even lower. Almost any shell thickness can be obtained, but most of them range between 50 and 300 mm (2 and 12 in). The ASME Code lists forging materials with tensile strengths from 414 to 930 MPa ( from 60,000 to 135,000 lbf/in$^2$). Brittle fracture is a possibility, and the hazard increases with thickness. Furthermore, some forging alloys have nil-ductility temperatures as high as 121°C (250°F). A forged vessel should have an NDT at least 17°C (30°F) below the design temperature. In operation, it should be slowly and uniformly heated at least to the NDT before it is subjected to pressure. During construction, nondestructive testing should be used to detect dangerous cracks or flaws. Section VIII of the ASME Code, particularly Division 2, gives design and testing techniques.

As the size of a forged vessel increases, the sizes of ingot and handling equipment become larger. The cost may increase faster than the weight. The problems of getting sound material and avoiding brittle fracture also become more difficult. Some of these problems are avoided by use of *multilayer construction.* In this type of vessel, the heads and flanges are made of forgings, and the cylindrical portion is built up by a series of layers of thin material. The thickness of these layers may be between 3 and 50 mm (⅛ and 2 in), depending on the type of construction. There is an inner lining which may be different from the outer layers.

Although there are multilayer vessels as small as 380-mm (15-in) inside diameter and 2400 mm (8 ft) long, their principal advantage applies to the larger sizes. When properly made, a multilayer vessel is probably safer than a vessel with a solid wall. The layers of thin material are tougher and less susceptible to brittle fracture, have lower probability of defects, and have the statistical advantage of a number of small elements instead of a single large one. The heads, flanges, and welds, of course, have the same hazards as other thick members. Proper attention is necessary to avoid cracks in these members.

There are several assembly techniques. One technique frequently used is to form successive layers in half cylinders and butt-weld them over the previous layers. In doing this, the welds are staggered so that they do not fall together. This type of construction usually uses plates from 6 to 12 mm (¼ to ½ in) thick. Another method is to weld each layer separately to form a cylinder and then shrink it over the previous layers. Layers up to about 50-mm (2-in) thickness are assembled in this way. A third method of fabrication is to wind the layers as a continuous sheet. This technique is used in Japan. The Wickel construction, fabricated in Germany, uses helical winding of interlocking metal strip. Each method has its advantages and disadvantages, and the choice will depend on circumstances.

Because of the possibility of voids between layers, it is preferable not to use multilayer vessels in applications where they will be subjected to fatigue. Inward thermal gradients (inside temperature lower than outside temperature) are also undesirable.

Articles on these vessels have been written by Fratcher [*Pet. Refiner* **34**(11): 137 (1954)] and by Strelzoff, Pan, and Miller [*Chem. Eng.* **75**(21): 143–150 (1968)].

*Vessels for high-temperature service* may be beyond the temperature limits of the stress tables in the ASME Codes. BPVC Section VIII, Division 1, makes provision for construction of pressure vessels up to 650°C (1200°F) for carbon and low-alloy steel and up to 815°C (1500°F) for stainless steels (300 series). If a vessel is required for temperatures above these values and above 103 kPa (15 lbf/in$^2$), it would be necessary, in a code state, to get permission from the state authorities to build it as a special project. Above 815°C (1500°F), even the 300 series stainless steels are weak, and creep rates increase rapidly. If the metal that resists the pressure operates at these temperatures, the vessel pressure and size will be limited. The vessel must also be expendable because its life will be short. Long exposure to high temperature may cause the metal to deteriorate and become brittle. Sometimes, however, economics favor this type of operation.

One way to circumvent the problem of low metal strength is to use a metal inner liner surrounded by insulating material, which in turn is confined by a pressure vessel. The liner, in some cases, may have perforations that will allow pressure to pass through the insulation and act on the outer shell, which is kept cool to obtain normal strength. The liner has no pressure differential acting on it and, therefore, does not need much strength. Ceramic linings are also useful for high-temperature work.

*Lined vessels* are used for many applications. Any type of lining can be used in an ASME Code vessel, provided it is compatible with the metal of the vessel and the contents. Glass, rubber, plastics, rare metals, and ceramics are a few types. The lining may be installed separately, or if a metal is used, it may be in the form of clad plate. The cladding on plate can sometimes be considered as a stress-carrying part of the vessel.

A *ceramic lining* when used with high temperature acts as an insulator so that the steel outer shell is at a moderate temperature while the temperature at the inside of the lining may be very high. Ceramic linings may be of unstressed brick, or prestressed brick, or cast in place. Cast ceramic linings or unstressed brick may develop cracks and is used when the contents of the vessel will not damage the outer shell. They are usually designed so that the high temperature at the inside will expand them sufficiently to make them tight in the outer (and cooler) shell. This, however, is not usually sufficient to prevent some penetration by the product.

Prestressed-brick linings can be used to protect the outer shell. In this case, the bricks are installed with a special thermosetting-resin mortar. After lining, the vessel is subjected to internal pressure and heat. This expands the steel vessel shell, and the mortar expands to take up the space. The pressure and temperature must be at least as high as the maximum that will be encountered in service. After the mortar has set, reduction of pressure and temperature will allow the vessel to contract, putting the brick in compression. The upper temperature limit for this construction is about 190°C (375°F). The installation of such linings is highly specialized work done by a few companies. Great care is usually exercised in operation to protect the

vessel from exposure to asymmetrical temperature gradients. Side nozzles and other unsymmetrical designs are avoided insofar as possible.

*Concrete pressure vessels* may be used in applications that require large sizes. Such vessels, if made of steel, would be too large and heavy to ship. Through the use of post-tensioned (prestressed) concrete, the vessel is fabricated on site. In this construction, the reinforcing steel is placed in tubes or plastic covers, which are cast into the concrete. Tension is applied to the steel after the concrete has acquired most of its strength.

Concrete nuclear reactor vessels, of the order of magnitude of 15-m (50-ft) inside diameter and length, have inner linings of steel which confine the pressure. After fabrication of the liner, the tubes for the cables or wires are put in place and the concrete is poured. High-strength reinforcing steel is used. Because there are thousands of reinforcing tendons in the concrete vessel, there is a statistical factor of safety. The failure of 1 or even 10 tendons would have little effect on the overall structure.

*Plastic pressure vessels* have the *advantages of chemical resistance* and light weight. Above 103 kPa (15 lbf/in$^2$), with certain exceptions, they must be designed according to ASME BPVC Section X (see Storage of Gases) and are confined to the three types of approved code construction. Below 103 kPa (15 lbf/in$^2$), any construction may be used. Even in this pressure range, however, the code should be used for guidance. Solid plastics, because of low strength and creep, can be used only for the lowest pressures and sizes. A stress of a few hundred pounds-force per square inch is the maximum for most plastics. To obtain higher strength, the filled plastics or filament-wound vessels, specified by the code, must be used. Solid-plastic parts, however, are often employed inside a steel shell, particularly for heat exchangers.

*Graphite and ceramic vessels* are used fully armored; that is, they are enclosed within metal pressure vessels. These materials are also used for boxlike vessels with backing plates on the sides. The plates are drawn together by tie bolts, thus putting the material in compression so that it can withstand low pressure.

**ASME Code Developments** ASME BPVC Section VIII (2015) has been reorganized into three classes. Class 1 is for low-pressure vessels employing spot radiography. Class 2 is for vessels requiring full radiography. Class 3 is for vessels experiencing fatigue. Material stress levels similar to those of competing vessel codes from Europe and Asia are included.

**Vessel Codes Other than ASME** Different design and construction rules are used in other countries. Chemical engineers concerned with pressure vessels outside the United States must become familiar with local pressure-vessel laws and regulations. *Boilers and Pressure Vessels,* an international survey of design and approval requirements published by the British Standards Institution, Maylands Avenue, Hemel Hempstead, Hertfordshire, England, in 1975, gives pertinent information for 76 political jurisdictions.

The British Code (British Standards) and the German Code (*A. D. Merkblätter*) in addition to the ASME Code are most commonly permitted, although Netherlands, Sweden, and France also have codes. The major difference between the codes lies in factors of safety and in whether ultimate strength is considered. BPVC, Section VIII, Division 1, vessels are generally heavier than vessels built to the other codes; however, the differences in allowable stress for a given material are less in the higher-temperature (creep) range.

Engineers and metallurgists have developed alloys to comply economically with individual codes. In Germany, where design stress is determined from yield strength and creep-rupture strength and no allowance is made for ultimate strength, steels that have a very high yield strength/ultimate strength ratio are used.

Other differences between codes include different bases for the design of reinforcement for openings and the design of flanges and heads. Some codes include rules for the design of heat-exchanger tube sheets, while others (ASME Code) do not. The Dutch Code (*Grondslagen*) includes very specific rules for calculation of wind loads, while the ASME Code leaves this entirely to the designer.

There are also significant differences in construction and inspection rules. Unless engineers make a detailed study of the individual codes and keep current, they will be well advised to make use of responsible experts for any of the codes.

**Vessel Design and Construction** The ASME Code lists a number of loads that must be considered in designing a pressure vessel. Among them are impact, weight of the vessel under operating and test conditions, superimposed loads from other equipment and piping, wind and earthquake loads, temperature-gradient stresses, and localized loadings from internal and external supports. In general, the code gives no values for these loads or methods for determining them, and no formulas are given for determining the stresses from these loads. Engineers must be knowledgeable in mechanics and strength of materials to solve these problems.

Some of the problems are treated by Brownell and Young, *Process Equipment Design,* Wiley, New York, 1959. ASME papers treat others, and a number of books published by the ASME are collections of papers on pressure-vessel design: *Pressure Vessels and Piping Design: Collected Papers, 1927–1959; Pressure Vessels and Piping Design and Analysis,* four volumes; and *International Conference: Pressure Vessel Technology,* published annually.

Throughout the year the Welding Research Council publishes bulletins which are final reports from projects sponsored by the council, important papers presented before engineering societies, and other reports of current interest which are not published in *Welding Research.* A large number of the published bulletins are pertinent for vessel designers.

**Care of Pressure Vessels** Protection against *excessive pressure* is largely taken care of by code requirements for relief devices. Exposure to fire is also covered by the code. The code, however, does not provide for the possibility of local overheating and weakening of a vessel in a fire. Insulation reduces the required relieving capacity and also reduces the possibility of local overheating.

A pressure-reducing valve in a line leading to a pressure vessel is not adequate protection against overpressure. Its failure will subject the vessel to full line pressure.

Vessels that have an operating cycle which involves the solidification and remelting of solids can develop excessive pressures. A solid plug of material may seal off one end of the vessel. If heat is applied at that end to cause melting, the expansion of the liquid can build up a high pressure and possibly result in yielding or rupture. Solidification in connecting piping can create similar problems.

Some vessels may be exposed to a runaway chemical reaction or even an explosion. This requires relief valves, rupture disks, or, in extreme cases, a frangible roof design or barricade (the vessel is expendable). A vessel with a large rupture disk needs anchors designed for the jet thrust when the disk blows.

*Vacuum* must be considered. It is nearly always possible that the contents of a vessel might contract or condense sufficiently to subject it to an internal vacuum. If the vessel cannot withstand the vacuum, it must have vacuum-breaking valves.

Improper operation of a process may result in the vessel's *exceeding design temperature.* Proper control is the only solution to this problem. Maintenance procedures can also cause excessive temperatures. Sometimes the contents of a vessel may be burned out with torches. If the flame impinges on the vessel shell, overheating and damage may occur.

*Excessively low temperature* may involve the hazard of brittle fracture. A vessel that is out of use in cold weather could be at a subzero temperature and well below its nil-ductility temperature. In startup, the vessel should be warmed slowly and uniformly until it is above the NDT. A safe value is 38°C (100°F) for plate if the NDT is unknown. The vessel should not be pressurized until this temperature is exceeded. Even after the NDT has been passed, excessively rapid heating or cooling can cause high thermal stresses.

*Corrosion* is probably the greatest threat to vessel life. Partially filled vessels frequently have severe pitting at the liquid-vapor interface. Vessels usually do not have a corrosion allowance on the outside. Lack of protection against the weather or against the drip of corrosive chemicals can reduce vessel life. Insulation may contain damaging substances. Chlorides in insulating materials can cause cracking of stainless steels. Water used for hydrotesting should be free of chlorides.

Pressure vessels should be *inspected periodically.* No rule can be given for the frequency of these inspections. Frequency depends on operating conditions. If the early inspections of a vessel indicate a low corrosion rate, intervals between inspections may be lengthened. Some vessels are inspected at 5-year intervals; others, as frequently as once a year. Measurement of corrosion is an important inspection item. One of the most convenient ways of measuring thickness (and corrosion) is to use an ultrasonic gauge. The location of the corrosion and whether it is uniform or localized in deep pits should be observed and reported. Cracks, any type of distortion, and leaks should be observed. Cracks are particularly dangerous because they can lead to sudden failure. Insulation is usually left in place during inspection of insulated vessels. If, however, severe external corrosion is suspected, the insulation should be removed. All forms of nondestructive testing are useful for examinations.

There are many ways in which a pressure vessel can suffer *mechanical damage*. The shells can be dented or even punctured; they can be dropped or have hoisting cables improperly attached; bolts can be broken; flanges are bent by excessive bolt tightening; gasket contact faces can be scratched and dented; rotating paddles can drag against the shell and cause wear; and a flange can be bolted up with a gasket half in the groove and half out. Most of these forms of damage can be prevented by taking care and using common sense. If damage is repaired by straightening, as with a dented shell, it may be necessary to stress-relieve the repaired area. Some steels are susceptible to embrittlement by aging after severe straining. A safer procedure is to cut out the damaged area and replace it.

The National Board Inspection Code, published by the National Board of Boiler and Pressure Vessel Inspectors, Columbus, Ohio, is helpful. Any repair, however, is acceptable if it is made in accordance with the rules of the Pressure Vessel Code.

Care in *reassembling* the vessel is particularly important. Gaskets should be properly located, particularly if they are in grooves. Bolts should be

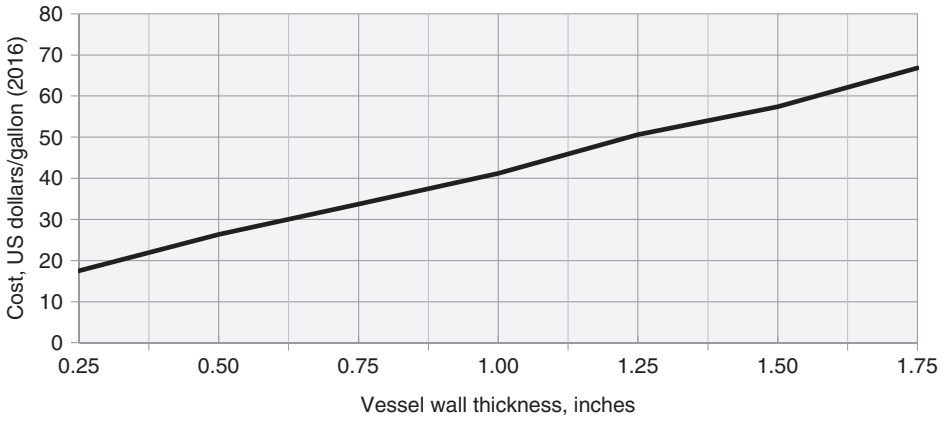

**FIG. 10-185** Carbon-steel pressure-vessel cost as a function of wall thickness. 1 gal = 0.003875 $m^3$; 1 in = 0.0254 m. (*Courtesy of E. S. Fox, Ltd.*)

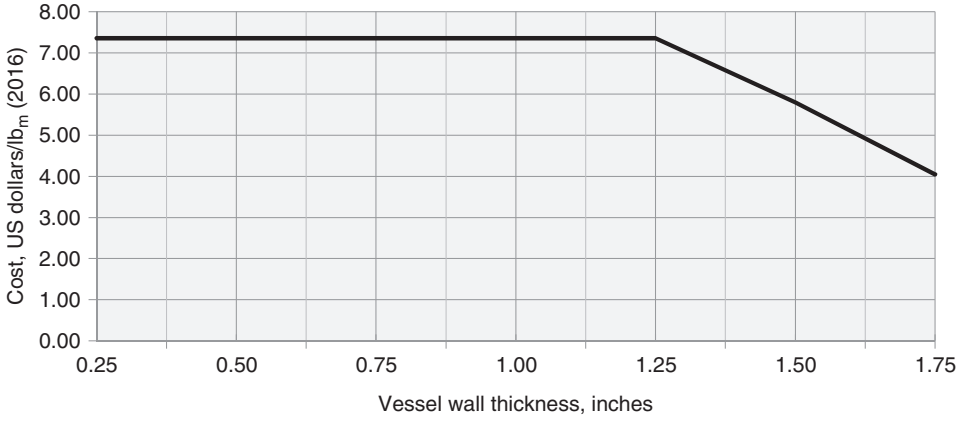

**FIG. 10-186** Carbon-steel pressure-vessel cost as a function of wall thickness. 1 gal = 0.003875 $m^3$; 1 in = 0.0254 m; 1 lb = 0.4536 kg. (*Courtesy of E. S. Fox, Ltd.*)

tightened in proper sequence. In some critical cases and with large bolts, it is necessary to control bolt tightening by torque wrenches, micrometers, patented bolt-tightening devices, or heating bolts. After assembly, vessels are sometimes given a hydrostatic test.

**Pressure-Vessel Cost and Weight** Figure 10-185 can be used for estimating carbon-steel vessel cost when a weight estimate is not available and Fig. 10-186 with a weight estimate. Weight and cost include skirts and other supports. The cost is based on several 2016 pressure vessels. Costs are for vessels not of unusual design. Complicated vessels could cost considerably more. Guthrie [*Chem. Eng.* **76**(6): 114–142 (1969)] also gives pressure-vessel cost data.

When vessels have complicated construction (large, heavy bolted connections, support skirts, etc.), it is preferable to estimate their weight and apply a unit cost in dollars per pound.

Pressure-vessel weights are obtained by calculating the cylindrical shell and heads separately and then adding the weights of nozzles and attachments. Steel has a density of 7817 kg/$m^3$ (488 lb/$ft^3$). Metal in heads can be approximated by calculating the area of the blank (disk) used for forming the head. The required diameter of the blank can be calculated by multiplying the head outside diameter by the approximate factors given in Table 10-60. These factors make no allowance for the straight flange which is a cylindrical extension that is formed on the head. The blank diameter obtained from these factors must be increased by twice the length of straight flange, which is usually 1½ to 2 in but can be up to several inches in length. Manufacturers' catalogs give weights of heads.

Forming a head thins it in certain areas. To obtain the required minimum thickness of a head, it is necessary to use a plate that is initially thicker. Table 10-61 gives allowances for additional thickness.

Nozzles and flanges may add considerably to the weight of a vessel. Their weights can be obtained from manufacturers' catalogs (Taylor Forge Division of Gulf & Western Industries, Inc., Tube Turns Inc., Ladish Co., Lenape Forge, and others). Other parts such as skirts, legs, support brackets, and other details must be calculated.

**TABLE 10-60 Factors for Estimating Diameters of Blanks for Formed Heads**

| | Ratio $d/t$ | Blank diameter factor |
|---|---|---|
| ASME head | Over 50 | 1.09 |
| | 30–50 | 1.11 |
| | 20–30 | 1.15 |
| Ellipsoidal head | Over 20 | 1.24 |
| | 10–20 | 1.30 |
| Hemispherical head | Over 30 | 1.60 |
| | 18–30 | 1.65 |
| | 10–18 | 1.70 |

$d$ = head diameter
$t$ = nominal minimum head thickness

**TABLE 10-61 Extra Thickness Allowances for Formed Heads***

| | Extra thickness, in | | |
|---|---|---|---|
| | ASME and ellipsoidal | | |
| Minimum head thickness, in | Head OD up to 150 in incl. | Head OD over 150 in | Hemispherical |
| Up to 0.99 | 1/16 | 1/8 | 3/16 |
| 1 to 1.99 | 1/8 | 1/8 | 3/8 |
| 2 to 2.99 | 1/4 | 1/4 | 5/8 |

# THERMAL DESIGN OF HEAT-TRANSFER EQUIPMENT

## INTRODUCTION TO THERMAL DESIGN

Designers commonly use computer software to design heat exchangers. The best sources of such software are Heat Transfer Research, Inc. (HTRI), and Heat Transfer and Fluid Flow Services (HTFFS), a division of ASPENTECH. These companies develop proprietary correlations based on their research and provide software that utilizes these correlations. However, it is important that engineers understand the fundamental principles underlying the framework of the software. Therefore, design methods for several important classes of process heat-transfer equipment are presented in later subsections of this section. Mechanical descriptions and specifications of equipment are given in this subsection and should be read in conjunction with the use of this subsequent design material. However, it is impossible to present here a comprehensive treatment of heat exchanger selection, design, and application. The best general references in this field are Hewitt, Shires, and Bott, *Process Heat Transfer*, CRC Press, Boca Raton, FL, 1994; and Schlünder (ed.), *Heat Exchanger Design Handbook*, Begell House, New York, 2002.

**Approach to Heat Exchanger Design** The proper use of basic heat-transfer knowledge in the design of practical heat-transfer equipment is an art. Designers must be constantly aware of the differences between the idealized conditions for and under which the basic knowledge was obtained and the real conditions of the mechanical expression of their design and its environment. The result must satisfy process and operational requirements (such as availability, flexibility, and maintainability) and do so economically. An important part of any design process is to consider and offset the consequences of error in the basic knowledge, in its subsequent incorporation into a design method, in the translation of design into equipment, or in the operation of the equipment and the process. Heat exchanger design is not a highly accurate art under the best of conditions.

The design of a process heat exchanger usually proceeds through the following steps:

1. Process conditions (stream compositions, flow rates, temperatures, pressures) must be specified.
2. Required physical properties over the temperature and pressure ranges of interest must be obtained.
3. The type of heat exchanger to be employed is chosen.
4. A preliminary estimate of the size of the exchanger is made, using a heat-transfer coefficient appropriate to the fluids, process, and equipment.
5. A first design is chosen, complete in all details necessary to carry out the design calculations.
6. The design chosen in step 5 is evaluated, or *rated*, as to its ability to meet the process specifications with respect to both heat transfer and pressure drop.
7. On the basis of the result of step 6, a new configuration is chosen if necessary and step 6 is repeated. If the first design was inadequate to meet the required heat load, it is usually necessary to increase the size of the exchanger while still remaining within specified or feasible limits of pressure drop, tube length, shell diameter, etc. This will sometimes mean going to multiple-exchanger configurations. If the first design more than meets heat load requirements or does not use all the allowable pressure drop, a less expensive exchanger can usually be designed to fulfill process requirements.
8. The final design should meet process requirements (within reasonable expectations of error) at lowest cost. The lowest cost should include operation and maintenance costs and credit for ability to meet long-term process changes, as well as installed (capital) cost.

Exchangers should not be selected entirely on a lowest-first-cost basis, which frequently results in future penalties.

**Overall Heat-Transfer Coefficient** The basic design equation for a heat exchanger is

$$dA = dQ/U\,\Delta T \tag{11-1}$$

where $dA$ is the element of surface area required to transfer an amount of heat $dQ$ at a point in the exchanger where the overall heat-transfer coefficient is $U$ and where the overall bulk temperature difference between the two streams is $\Delta T$. The overall heat-transfer coefficient is related to the individual film heat-transfer coefficients and fouling and wall resistances by Eq. (11-2). Basing $U_o$ on the outside surface area $A_o$ results in

$$U_o = \frac{1}{1/h_o + R_{do} + xA_o/k_wA_{wm} + (1/h_t + R_{dt})A_o/A_t} \tag{11-2}$$

Equation (11-1) can be formally integrated to give the outside area required to transfer the total heat load $Q_T$:

$$A_o = \int_0^{Q_T} \frac{dQ}{U_o \Delta T} \tag{11-3}$$

To integrate Eq. (11-3), $U_o$ and $\Delta T$ must be known as functions of $Q$. For some problems, $U_o$ varies strongly and nonlinearly throughout the exchanger. In these cases, it is necessary to evaluate $U_o$ and $\Delta T$ at several intermediate values and numerically or graphically integrate. For many practical cases, it is possible to calculate a constant mean overall coefficient $U_{om}$ from Eq. (11-2) and define a corresponding mean value of $\Delta T_m$, such that

$$A_o = Q_T/U_{om}\,\Delta T_m \tag{11-4}$$

Care must be taken that $U_o$ does not vary too strongly, that the proper equations and conditions are chosen for calculating the individual coefficients, and that the mean temperature difference is the correct one for the specified exchanger configuration.

**Mean Temperature Difference** The temperature difference between the two fluids in the heat exchanger will, in general, vary from point to point. The *mean temperature difference* ($\Delta T_m$ or MTD) can be calculated from the terminal temperatures of the two streams if the following assumptions are valid:

1. All elements of a given fluid stream have the same thermal history in passing through the exchanger.*
2. The exchanger operates at steady state.
3. The specific heat is constant for each stream (or if either stream undergoes an isothermal phase transition).
4. The overall heat-transfer coefficient is constant.
5. Heat losses are negligible.

**Countercurrent or Cocurrent Flow** If the flow of the streams is either *completely* countercurrent or completely cocurrent or if one or both streams are isothermal (condensing or vaporizing a pure component with negligible pressure change), then the correct MTD is the *logarithmic-mean temperature difference* (LMTD), defined as

$$\text{LMTD} = \Delta T_{\text{lm}} = \frac{(t_1' - t_2'') - (t_2' - t_1'')}{\ln\left(\dfrac{t_1' - t_2''}{t_2' - t_1''}\right)} \tag{11-5a}$$

for *countercurrent flow* (Fig. 11-1*a*) and

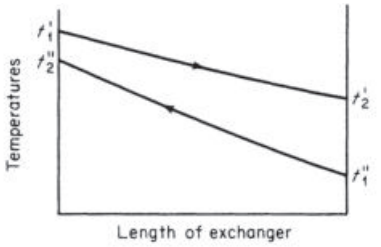
$$\text{LMTD} = \Delta T_{\text{lm}} = \frac{(t_1' - t_1'') - (t_2' - t_2'')}{\ln\left(\dfrac{t_1' - t_1''}{t_2' - t_2''}\right)} \tag{11-5b}$$

for *cocurrent flow* (Fig. 11-1*b*).

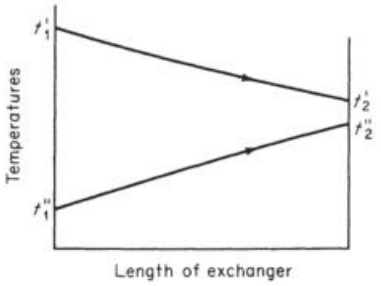
If $U$ is not constant but a linear function of $\Delta T$, then the correct value of $U_{om}\Delta T_m$ to use in Eq. (11-4) is [Colburn, *Ind. Eng. Chem.* **25:** 873 (1933)]

$$U_{om}\,\Delta T_m = \frac{U_o''(t_1' - t_2'') - U_o'(t_2' - t_1'')}{\ln\left(\dfrac{U_o''(t_1' - t_2'')}{U_o'(t_2' - t_1'')}\right)} \tag{11-6a}$$

*This assumption is vital but is usually omitted or less satisfactorily stated as "each stream is well mixed at each point." In a heat exchanger with substantial bypassing of the heat-transfer surface, e.g., a typical baffled shell-and-tube exchanger, this condition is not satisfied. However, the error is offset to some degree if the same MTD formulation used in reducing experimental heat-transfer data to obtain the basic correlation is used in applying the correlation to design a heat exchanger. The compensation is not in general exact, and insight and judgment are required in the use of the MTD formulations. Particularly, in the design of an exchanger with a very close temperature approach, bypassing may result in an exchanger that is inefficient and even thermodynamically incapable of meeting specified outlet temperatures.



(*a*)



(*b*)

**FIG. 11-1** Temperature profiles in heat exchangers. (*a*) Countercurrent. (*b*) Cocurrent.

for *countercurrent flow*, where $U_o''$ is the overall coefficient evaluated when the stream temperatures are $t_1'$ and $t_2''$ and $U_o'$ is evaluated at $t_2'$ and $t_1''$. The corresponding equation for *cocurrent flow* is

$$U_{om}\,\Delta T_m = \frac{U_o''(t_1' - t_1'') - U_o'(t_2' - t_2'')}{\ln\left(\dfrac{U_o''(t_1' - t_1'')}{U_o'(t_2' - t_2'')}\right)} \qquad (11\text{-}6b)$$

where $U_o'$ is evaluated at $t_2'$ and $t_2''$ and $U_o''$ is evaluated at $t_1'$ and $t_1''$. To use these equations, it is necessary to calculate two values of $U_o$.

The use of Eq. (11-6) will frequently give satisfactory results even if $U_o$ is not strictly linear with temperature difference.

**Reversed, Mixed, or Cross-Flow** If the flow pattern in the exchanger is not completely countercurrent or cocurrent, it is necessary to apply a *correction factor* $F_T$ by which the LMTD is multiplied to obtain the appropriate MTD. These corrections have been mathematically derived for flow patterns of interest, still by making assumptions 1 to 5 [see Bowman, Mueller, and Nagle, *Trans. Am. Soc. Mech. Eng.* **62:** 283 (1940) or Hewitt, Shires, and Bott, *Process Heat Transfer*, CRC Press, Boca Raton, FL, 1994]. For a common flow pattern, the 1-2 exchanger (Fig. 11-2), the correction factor $F_T$ is given in Fig. 11-4*a*, which is also valid for finding $F_T$ for a 1-2 exchanger in which the shell-side flow direction is reversed from that shown in Fig. 11-2. Figure 11-4*a* is also applicable with negligible error to exchangers with one shell pass and any number of tube passes. Values of $F_T$ less than 0.8 (0.75 at the very lowest) are generally unacceptable because the exchanger configuration chosen is inefficient; the chart is difficult to read accurately; and even a small violation of the first assumption underlying the MTD will invalidate the mathematical derivation and lead to a thermodynamically inoperable exchanger.

Correction factor charts are also available for exchangers with more than one shell pass provided by a longitudinal shell-side baffle. However, these exchangers are seldom used in practice because of mechanical complications in their construction. Also thermal and physical leakages across the longitudinal baffle further reduce the mean temperature difference and are not properly incorporated into the correction factor charts. Such charts are useful, however, when it is necessary to construct a multiple-shell exchanger train such as that shown in Fig. 11-3 and are included here for two, three, four, and six *separate*, *identical* shells and two or more tube passes per shell in Fig. 11-4*b*, *c*, *d*, and *e*. If only one tube pass per shell is required, the piping can and should be arranged to provide pure countercurrent flow, in which case the LMTD is used with no correction.

Cross-flow exchangers of various kinds are also important and require correction to be applied to the LMTD calculated by assuming countercurrent flow. Several cases are given in Fig. 11-4*f*, *g*, *h*, *i*, and *j*.

Many other MTD correction factor charts have been prepared for various configurations. The $F_T$ charts are often employed to make approximate corrections for configurations even in cases for which they are not completely valid.

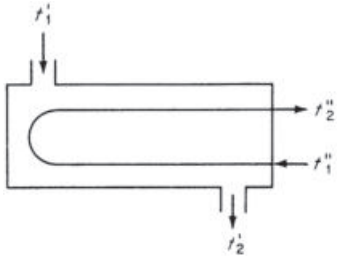


**FIG. 11-2** Diagram of a 1-2 exchanger (one well-baffled shell pass and two tube passes with an equal number of tubes in each pass).

## THERMAL DESIGN FOR SINGLE-PHASE HEAT TRANSFER

**Double-Pipe Heat Exchangers** The design of double-pipe heat exchangers is straightforward. It is generally conservative to neglect natural convection and entrance effects in turbulent flow. In laminar flow, natural convection effects can increase the theoretical Graetz prediction by a factor of 3 or 4 for fully developed flows. Pressure drop is calculated by using the correlations given in Sec. 6.

If the inner tube is longitudinally finned on the outside surface, the equivalent diameter is used as the characteristic length in both the Reynolds number and the heat-transfer correlations. The fin efficiency must also be known to calculate an *effective* outside area to use in Eq. (11-2).

Fittings contribute strongly to the pressure drop on the annulus side. General methods for predicting this are not reliable, and manufacturer's data should be used when available.

Double-pipe exchangers are often piped in complex series-parallel arrangements on both sides. The MTD to be used has been derived for some of these arrangements and is reported in Kern (*Process Heat Transfer*, McGraw-Hill, New York, 1950). More complex cases may require trial-and-error balancing of the heat loads and rate equations for subsections or even for individual exchangers in the bank.

**Baffled Shell-and-Tube Exchangers** The method given here is based on the research summarized in Final Report, Cooperative Research Program on Shell and Tube Heat Exchangers, *Univ. Del. Eng. Exp. Sta. Bull.* 5 (June 1963). The method assumes that the shell-side heat-transfer and pressure-drop characteristics are equal to those of the ideal tube bank corresponding to the cross-flow sections of the exchanger, modified for the distortion of flow pattern introduced by the baffles and the presence of leakage and bypass flow through the various clearances required by mechanical construction.

It is assumed that process conditions and physical properties are known and the following are known or specified: tube outside diameter $D_o$, tube geometric arrangement (unit cell), shell inside diameter $D_s$, shell outer tube limit $D_{otl}$, baffle cut $l_c$, baffle spacing $l_s$, and number of sealing strips $N_{ss}$. The effective tube length between tube sheets $L$ may be either specified or calculated after the heat-transfer coefficient has been determined. If additional specific information (e.g., tube-baffle clearance) is available, the exact values (instead of estimates) of certain parameters may be used in the calculation with some improvement in accuracy. To complete the rating, it is necessary to know also the tube material and wall thickness or inside diameter.

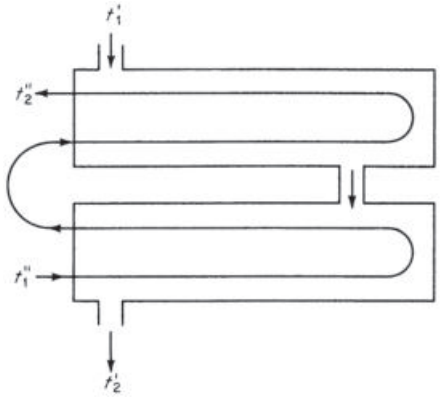

**FIG. 11-3** Diagram of a 2-4 exchanger (two separate identical well-baffled shells and four or more tube passes).

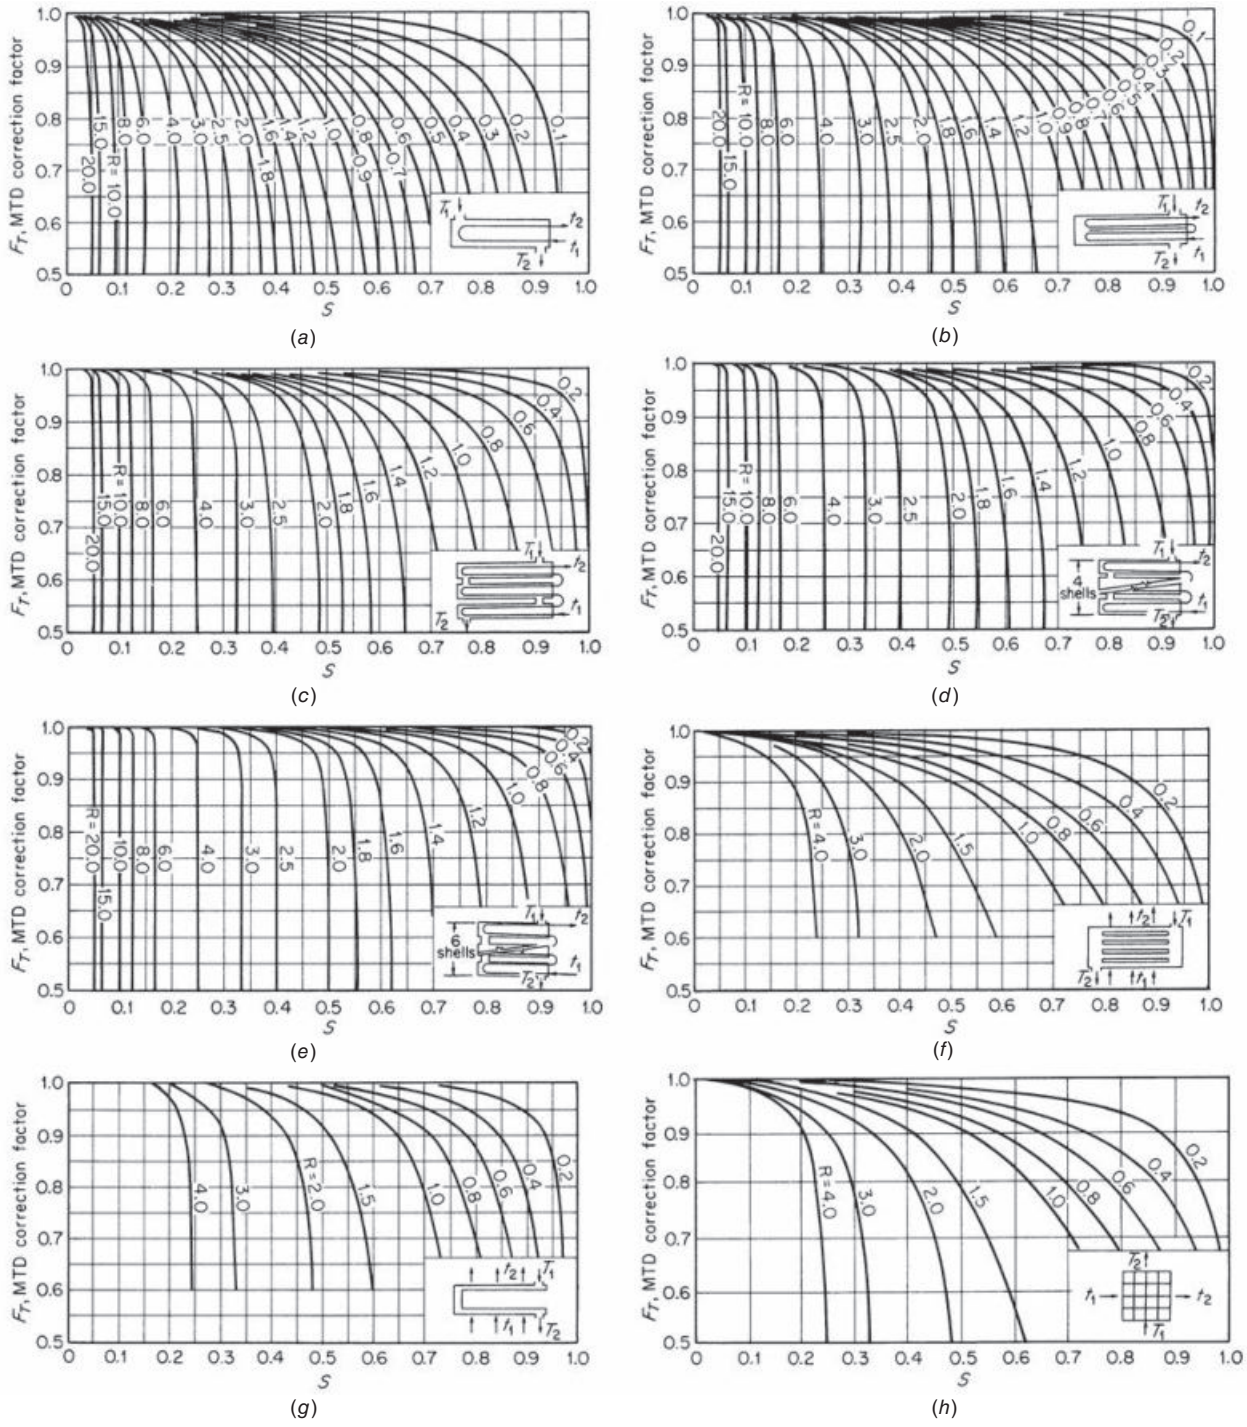

**FIG. 11-4** LMTD correction factors for heat exchangers. In all charts, $R = (T_1 - T_2)/(t_2 - t_1)$ and $S = (t_2 - t_1)/(T_1 - t_1)$. (*a*) One shell pass, two or more tube passes. (*b*) Two shell passes, four or more tube passes. (*c*) Three shell passes, six or more tube passes. (*d*) Four shell passes, eight or more tube passes. (*e*) Six shell passes, twelve or more tube passes. (*f*) Cross-flow, one shell pass, one or more parallel rows of tubes. (*g*) Cross-flow, two passes, two rows of tubes; for more than two passes, use $F_T = 1.0$. (*h*) Cross-flow, one shell pass, one tube pass, both fluids unmixed. (*i*) Cross-flow (drip type), two horizontal passes with U-bend connections (trombone type). (*j*) Cross-flow (drip type), helical coils with two turns.

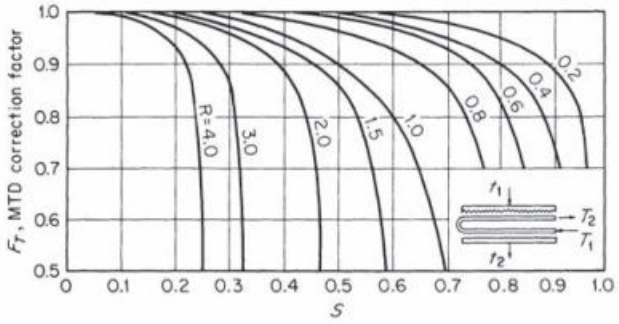
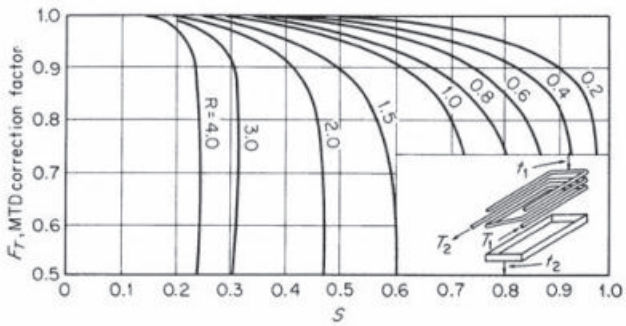


(*i*)



(*j*)

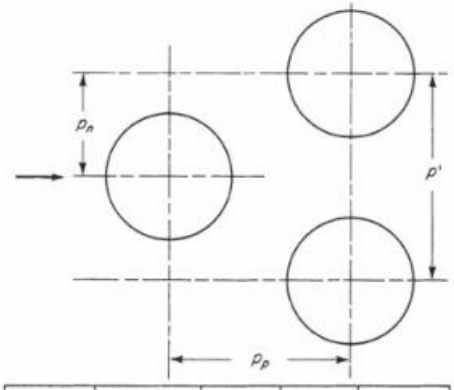
**FIG. 11-4** (*Continued*)

This rating method, though apparently generally the best in the open literature, is not extremely accurate. An exhaustive study by Palen and Taborek [*Chem. Eng. Prog. Symp. Ser.* 92, **65:** 53 (1969)] showed that this method predicted shell-side coefficients from about 50 percent low to 100 percent high, while the pressure drop range was from about 50 percent low to 200 percent high. The mean error for heat transfer was about 15 percent low (safe) for all Reynolds numbers, while the mean error for pressure drop was from about 5 percent low (unsafe) at Reynolds numbers above 1000 to about 100 percent high at Reynolds numbers below 10.

***Calculation of Shell-Side Geometric Parameters***

1. *Total number of tubes in exchanger $N_t$.* If this is not known by direct count, estimate by using Eq. (11-74) or (11-75).

2. *Tube pitch parallel to flow $p_p$ and normal to flow $p_n$.* These quantities are needed only for estimating other parameters. If a detailed drawing of the exchanger is available, it is better to obtain these other parameters by direct count or calculation. The pitches are described by Fig. 11-5 and read therefrom for common tube layouts.



| Tube O.D. $D_o$, in. | Tube pitch $p'$, in. | Layout | $p_p$, in. | $p_n$, in. |
|---|---|---|---|---|
| 0.625 | 0.812 | → | 0.704 | 0.406 |
| 0.750 | 0.938 | → | 0.814 | 0.469 |
| 0.750 | 1 | → | 1.000 | 1.000 |
| 0.750 | 1 | → | 0.707 | 0.707 |
| 0.750 | 1 | → | 0.866 | 0.500 |
| 1.000 | 1.250 | → | 1.250 | 1.250 |
| 1.000 | 1.250 | → | 0.884 | 0.884 |
| 1.000 | 1.250 | → | 1.082 | 0.625 |

**FIG. 11-5** Values of tube pitch for common tube layouts. To convert inches to meters, multiply by 0.0254. Note that $D_o$, $p'$, $p_p$, and $p_n$ have units of inches.

3. *Number of tube rows crossed in one cross-flow section $N_c$.* Count from the exchanger drawing or estimate from

$$N_c = \frac{D_s[1-2(l_c/D_s)]}{p_p} \tag{11-7}$$

4. *Fraction of total tubes in cross-flow $F_c$*

$$F_c = \frac{1}{\pi}\left[\pi + 2\frac{D_s - 2l_c}{D_{otl}}\sin\left(\cos^{-1}\frac{D_s-2l_c}{D_{otl}}\right) - 2\cos^{-1}\frac{D_s-2l_c}{D_{otl}}\right] \tag{11-8}$$

where $F_c$ is plotted in Fig. 11-6. This figure is strictly applicable only to split-ring, floating-head construction but may be used for other situations with minor error.

5. *Number of effective cross-flow rows in each window $N_{cw}$*

$$N_{cw} = \frac{0.8l_c}{p_p} \tag{11-9}$$

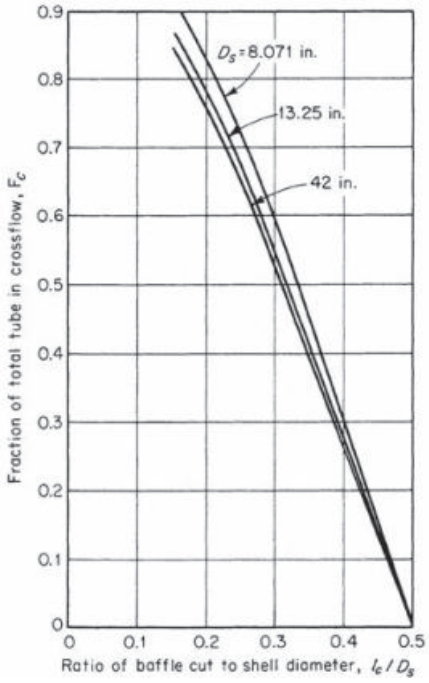


**FIG. 11-6** Estimation of fraction of tubes in cross-flow $F_c$ [Eq. (11-8)]. To convert inches to meters, multiply by 0.0254. Note that $l_c$ and $D_s$ have units of inches.

6. *Cross-flow area at or near centerline for one cross-flow section* $S_m$

*a.* For rotated and in-line square layouts:

$$S_m = l_s\left[D_s - D_{otl} + \frac{D_{otl} - D_o}{p_n}(p' - D_o)\right] \quad \text{m}^2(\text{ft}^2) \qquad (11\text{-}10a)$$

*b.* For triangular layouts:

$$S_m = l_s\left[D_s - D_{otl} + \frac{D_{otl} - D_o}{p'}(p' - D_o)\right] \quad \text{m}^2(\text{ft}^2) \qquad (11\text{-}10b)$$

7. *Fraction of cross-flow area available for bypass flow* $F_{bp}$

$$F_{bp} = \frac{(D_s - D_{otl})l_s}{S_m} \qquad (11\text{-}11)$$

8. *Tube-to-baffle leakage area for one baffle* $S_{tb}$. Estimate from

$$S_{tb} = bD_oN_T(1 + F_c) \qquad \text{m}^2(\text{ft}^2) \qquad (11\text{-}12)$$

where $b = (6.223)(10^{-4})$ (SI) or $(1.701)(10^{-4})$ (USCS). These values are based on the Tubular Exchanger Manufacturers Association (TEMA) Class R construction which specifies 1/32-in diametral clearance between tube and baffle. Values should be modified if extra tight or loose construction is specified or if clogging by dirt is anticipated.

9. *Shell-to-baffle leakage area for one baffle* $S_{sb}$. If diametral shell-baffle clearance $\delta_{sb}$ is known, then $S_{sb}$ can be calculated from

$$S_{sb} = \frac{D_s\,\delta_{sb}}{2}\left[\pi - \cos^{-1}\left(1 - \frac{2l_c}{D_s}\right)\right] \quad \text{m}^2(\text{ft}^2) \qquad (11\text{-}13)$$

where the value of the term $\cos^{-1}(1 - 2l_c/D_s)$ is in radians and is between 0 and $\pi/2$. Shell-to-baffle leakage area $S_{sb}$ is plotted in Fig. 11-7, based on TEMA Class R standards. Since pipe shells are generally limited to diameters below 24 in, the larger sizes are shown by using the rolled-shell specification. Allowance should be made for especially tight or loose construction.

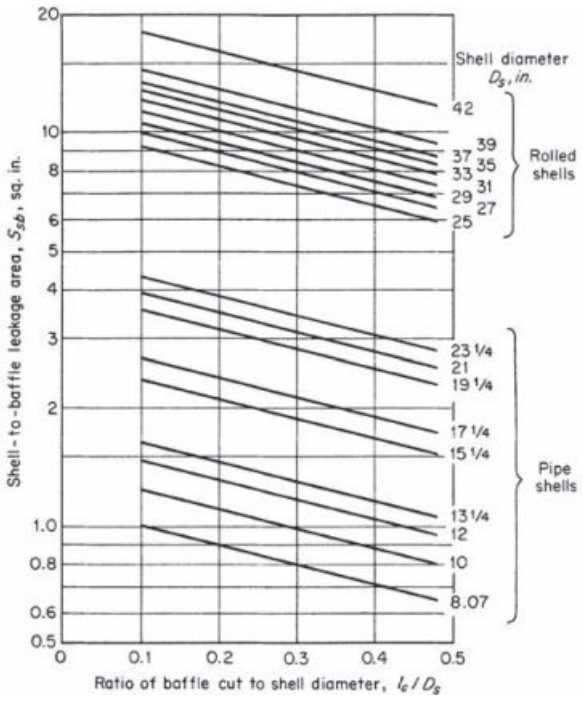

**FIG. 11-7** Estimation of shell-to-baffle leakage area [Eq. (11-13)]. To convert inches to meters, multiply by 0.0254; to convert square inches to square meters, multiply by $(6.45)(10^{-4})$. Note that $l_c$ and $D_s$ have units of inches.

10. *Area for flow through window* $S_w$. This area is obtained as the difference between the gross window area $S_{wg}$ and the window area occupied by tubes $S_{wt}$:

$$= S_{wg} - S_{wt} \qquad (11\text{-}14)$$

$$S_{wg} = \frac{D_s^2}{4}\left[\cos^{-1}\left(1 - 2\frac{l_c}{D_s}\right) - \left(1 - 2\frac{l_c}{D_s}\right)\sqrt{1 - \left(1 - 2\frac{l_c}{D_s}\right)^2}\right] \quad \text{m}^2(\text{ft}^2)$$

$$(11\text{-}15)$$

$S_{wg}$ is plotted in Fig. 11-8; $S_{wt}$ can be calculated from

$$S_{wt} = (N_T/8)(1 - F_c)\pi D_o^2 \qquad \text{m}^2(\text{ft}^2) \qquad (11\text{-}16)$$

11. *Equivalent diameter of window* $D_w$ [*required only if laminar flow, defined as* $(N_{Re})_s \le 100$, *exists*]

$$D_w = \frac{4S_w}{(\pi/2)N_T(1 - F_c)D_o + D_s\theta_b} \qquad \text{m}(\text{ft}) \qquad (11\text{-}17)$$

where $\theta_b$ is the baffle-cut angle given by

$$\theta_b = 2\cos^{-1}\left(1 - \frac{2l_c}{D_s}\right) \qquad \text{rad} \qquad (11\text{-}18)$$

12. *Number of baffles* $N_b$

$$N_b = \frac{L - 2le}{l_s} + 1 \qquad (11\text{-}19)$$

where *le* is the entrance/exit baffle spacing, often different from the central baffle spacing. The effective tube length $L$ must be known to calculate $N_b$, which is needed to calculate the shell-side pressure drop. In designing an exchanger, the shell-side coefficient may be calculated and the required exchanger length for heat transfer obtained before $N_b$ is calculated.

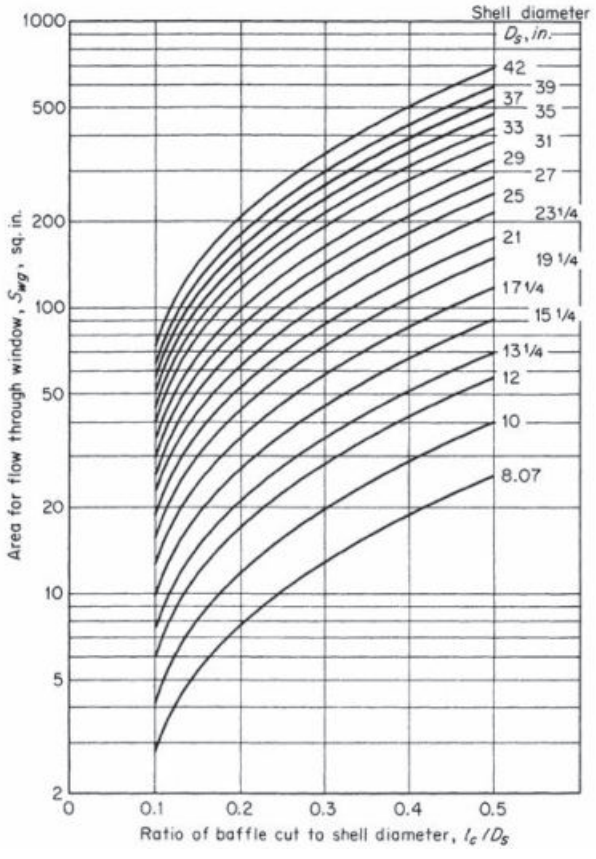

**FIG. 11-8** Estimation of window cross-flow area [Eq. (11-15)]. To convert inches to meters, multiply by 0.0254. Note that $l_c$ and $D_s$ have units of inches.

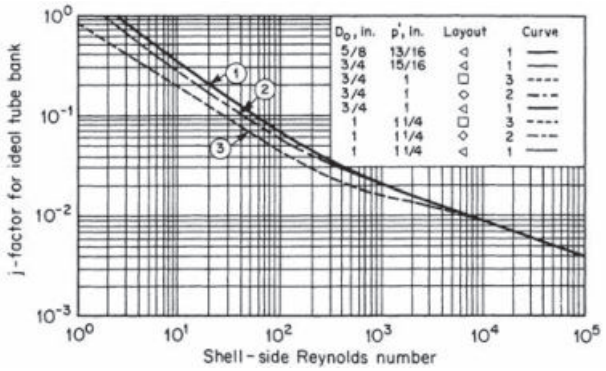

**FIG. 11-9** Correlation of $j$ factor for ideal tube bank. To convert inches to meters, multiply by 0.0254. Note that $p'$ and $D_o$ have units of inches.

***Shell-Side Heat-Transfer Coefficient Calculation***

1. Calculate the *shell-side Reynolds number* $(N_{Re})_s$

$$(N_{Re})_s = D_o W/\mu_b S_m \tag{11-20}$$

where $W$ = mass flow rate and $\mu_b$ = viscosity at bulk temperature. The arithmetic mean bulk shell-side fluid temperature is usually adequate to evaluate all bulk properties of the shell-side fluid. For large temperature ranges or for viscosity that is very sensitive to temperature change, special care must be taken, such as using Eq. (11-6).

2. Find $j_k$ from the ideal-tube bank curve for a given tube layout at the calculated value of $(N_{Re})_s$, using Fig. 11-9, which is adapted from ideal-tube bank data obtained at Delaware by Bergelin et al. [*Trans. Am. Soc. Mech. Eng.* **74:** 953 (1952)] and the Grimison correlation [*Trans. Am. Soc. Mech. Eng.* **59:** 583 (1937)].

3. Calculate the shell-side *heat-transfer coefficient for an ideal tube bank* $h_k$.

$$h_k = j_k c \frac{W}{S_m}\left(\frac{k}{c\mu}\right)^{2/3}\left(\frac{\mu_b}{\mu_w}\right)^{0.14} \tag{11-21}$$

where $c$ is the specific heat, $k$ is the thermal conductivity, and $\mu_w$ is the viscosity evaluated at the mean surface temperature.

4. Find the correction factor for baffle configuration effects $J_c$ from Fig. 11-10.
5. Find the correction factor for baffle leakage effects $J_l$ from Fig. 11-11.
6. Find the correction factor for bundle-bypassing effects $J_b$ from Fig. 11-12.
7. Find the correction factor for adverse temperature-gradient buildup at low Reynolds number $J_r$:
   *a.* If $(N_{Re})_s < 100$, find $J_r^*$ from Fig. 11-13, given $N_b$ and $N_c + N_{cw}$.
   *b.* If $(N_{Re})_s \le 20$, $J_r = J_r^*$.
   *c.* If $20 < (N_{Re})_s < 100$, find $J_r$ from Fig. 11-14, given $J_r^*$ and $(N_{Re})_s$.
8. Calculate the *shell-side heat-transfer coefficient for the exchanger* $h_s$ from

$$h_s = h_k J_c J_l J_b J_r \tag{11-22}$$

***Shell-Side Pressure Drop Calculation***

1. Find $f_k$ from the ideal-tube bank friction factor curve for the given tube layout at the calculated value of $(N_{Re})_s$, using Fig. 11-15*a* for triangular and rotated square arrays and Fig. 11-15*b* for in-line square arrays. These curves are adapted from Bergelin et al. and Grimison.

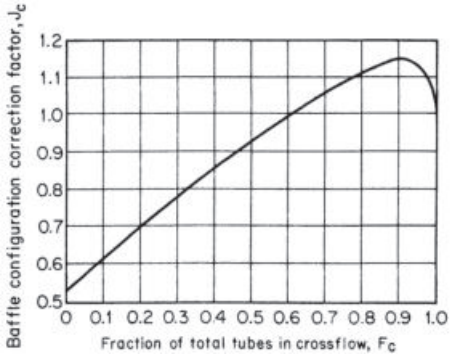

**FIG. 11-10** Correction factor for baffle configuration effects.

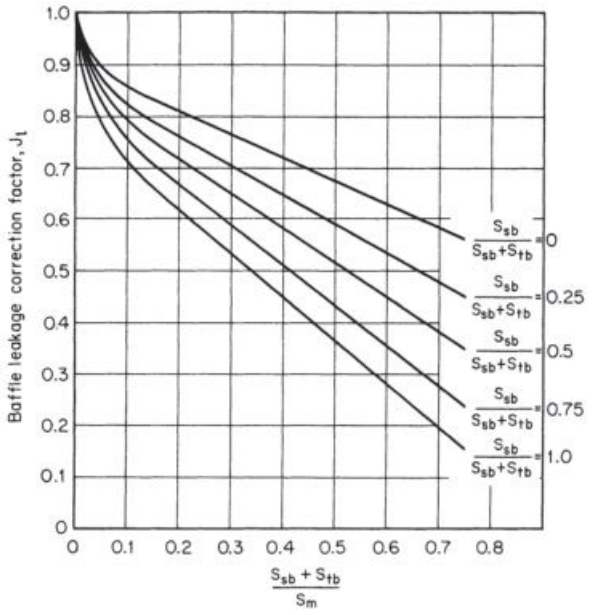

**FIG. 11-11** Correction factor for baffle leakage effects.

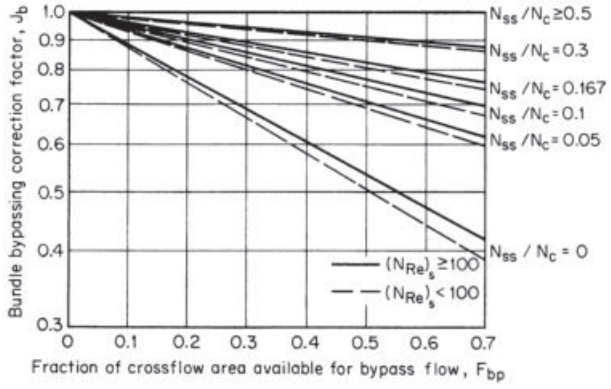

**FIG. 11-12** Correction factor for bypass flow.

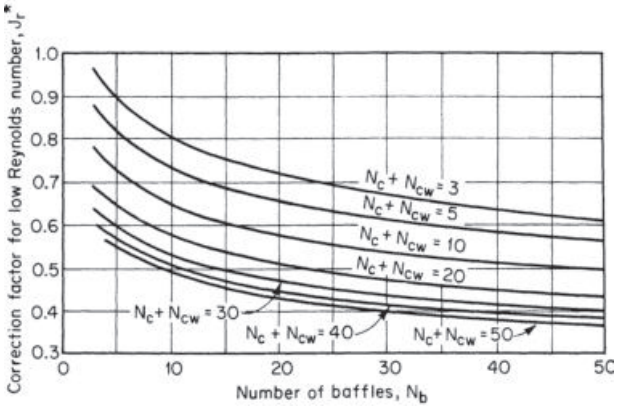

**FIG. 11-13** Basic correction factor for adverse temperature gradient at low Reynolds numbers.

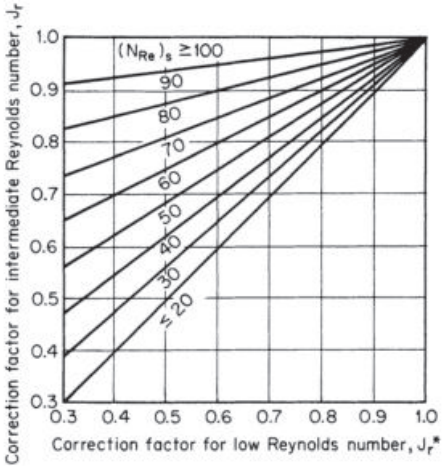

**FIG. 11-14** Correction factor for adverse temperature gradient at intermediate Reynolds numbers.

2. Calculate the *pressure drop for an ideal cross-flow section.*

$$\Delta P_{bk} = b\frac{f_k W^2 N_c}{\rho S_m^2}\left(\frac{\mu_w}{\mu_b}\right)^{0.14} \tag{11-23}$$

where $b = (2.0)(10^{-3})$ (SI) or $(9.9)(10^{-5})$ (USCS).

3. Calculate the *pressure drop for an ideal window section.* If $(N_{Re})_s \geq 100$,

$$\Delta P_{wk} = b\frac{W^2(2+0.6N_w)}{S_m S_w \rho} \tag{11-24a}$$

where $b = (5)(10^{-4})$ (SI) or $(2.49)(10^{-5})$ (USCS).

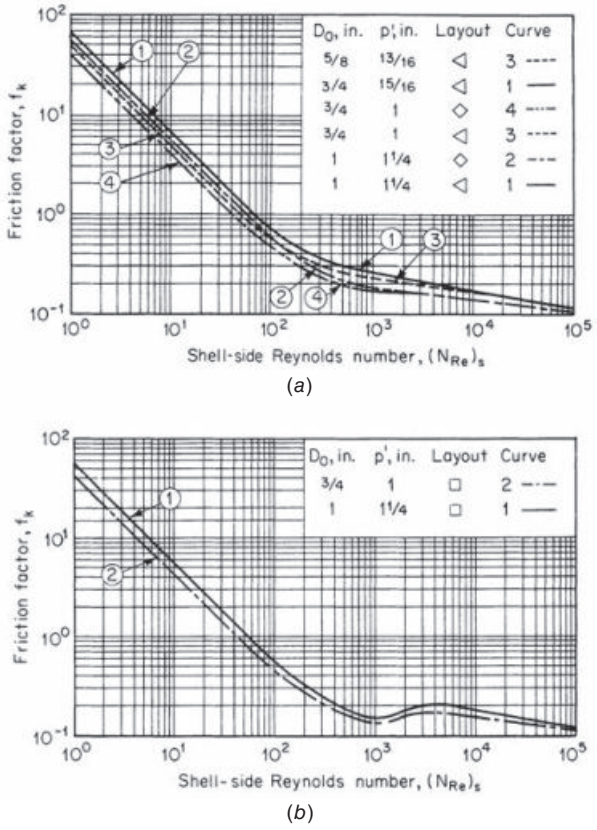

**FIG. 11-15** Correction of friction factors for ideal tube banks. (*a*) Triangular and rotated square arrays. (*b*) In-line square arrays.

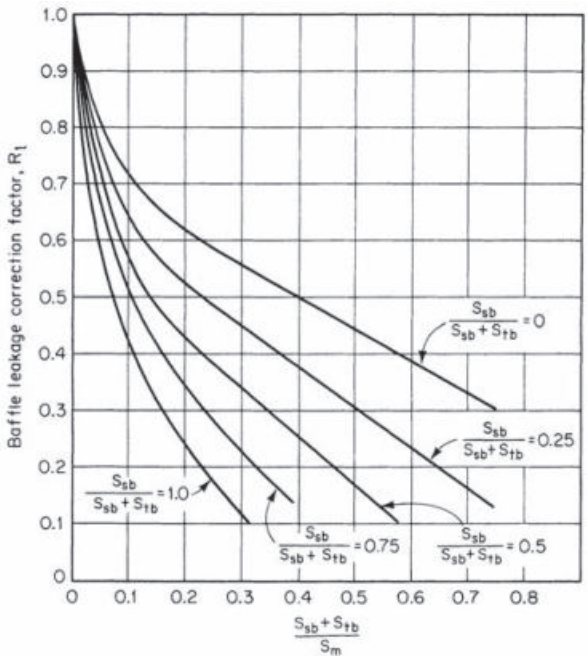

**FIG. 11-16** Correction factor for baffle leakage effect on pressure drop.

If $(N_{Re})_s < 100$,

$$\Delta P_{wk} = b_1\frac{\mu_b W}{S_m S_w \rho}\left(\frac{N_{cw}}{p'-D_o}+\frac{l_s}{D_w^2}\right)+b_2\frac{W^2}{S_m S_w \rho} \tag{11-24b}$$

where $b_1 = (1.681)(10^{-5})$ (SI) or $(1.08)(10^{-4})$ (USCS), and $b_2 = (9.99)(10^{-4})$ (SI) or $(4.97)(10^{-5})$ (USCS).

4. Find the correction factor for the effect of baffle leakage on pressure drop $R_l$ from Fig. 11-16. Curves shown are not to be extrapolated beyond the points shown.

5. Find the correction factor for bundle bypass $R_b$ from Fig. 11-17.

6. Calculate the *pressure drop across the shell side* (excluding nozzles). Units for pressure drop are lbf/ft$^2$.

$$\Delta P_s = [(N_b-1)(\Delta P_{bk})R_b + N_b\,\Delta P_{wk}]\,R_l + 2\Delta P_{bk}R_b\left(1+\frac{N_{cw}}{N_c}\right) \tag{11-25}$$

The values of $h_s$ and $\Delta P_s$ calculated by this procedure are for clean exchangers and are intended to be as accurate as possible, not conservative. A fouled exchanger will generally give lower heat-transfer rates, as reflected by the dirt resistances incorporated into Eq. (11-2), and higher pressure drops. Some estimate of *fouling effects* on pressure drop may be made by using the methods just given and assuming that the fouling deposit blocks the leakage and possibly the bypass areas. The fouling may also decrease the clearance between tubes and significantly increase the pressure drop in cross-flow.

## THERMAL DESIGN OF CONDENSERS

### Single-Component Condensers

***Mean Temperature Difference*** In condensing a single component at its saturation temperature, the entire resistance to heat transfer on the condensing side is generally assumed to be in the layer of condensate. A mean condensing coefficient is calculated from the appropriate correlation and combined with the other resistances in Eq. (11-2). The overall coefficient is then used with the LMTD (no $F_T$ correction is necessary for isothermal condensation) to give the required area, even though the condensing coefficient and hence $U$ are not constant throughout the condenser.

If the vapor is *superheated* at the inlet, the vapor may first be desuperheated by sensible heat transfer from the vapor. This occurs if the surface temperature is above the saturation temperature, and a single-phase heat-transfer correlation is used. If the surface is below the saturation temperature, condensation will occur directly from the superheated vapor,

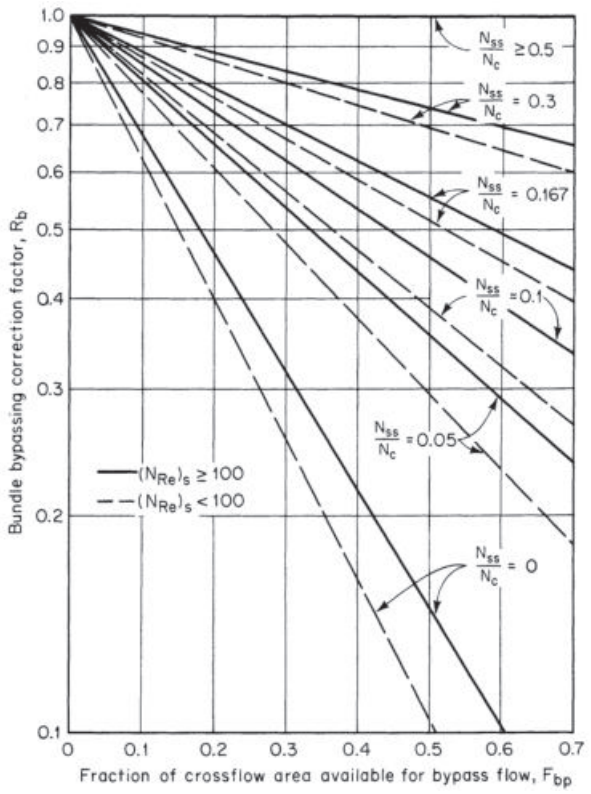

**FIG. 11-17** Correction factor on pressure drop for bypass flow.

and the effective coefficient is determined from the appropriate condensation correlation, using the saturation temperature in the LMTD. To determine whether condensation will occur directly from the superheated vapor, calculate the surface temperature by assuming single-phase heat transfer.

$$T_{surface} = T_{vapor} - \frac{U}{h}(T_{vapor} - T_{coolant}) \tag{11-26}$$

where $h$ is the sensible heat-transfer coefficient for the vapor, $U$ is calculated by using $h$, and both are on the same area basis. If $T_{surface} > T_{saturation}$, no condensation occurs at that point and the heat flux is actually higher than if $T_{surface} \leq T_{saturation}$ and condensation did occur. It is generally conservative to design a pure-component desuperheater-condenser as if the entire heat load were transferred by condensation, using the saturation temperature in the LMTD.

The design of an integral *condensate subcooling section* is more difficult, especially if close temperature approach is required. The condensate layer on the surface is subcooled on average by one-third to one-half of the temperature drop across the film, and this is often sufficient if the condensate is not reheated by raining through the vapor. If the condensing-subcooling process is carried out inside tubes or in the shell of a vertical condenser, the single-phase subcooling section can be treated separately, giving an area that is added onto that needed for condensation. If the subcooling is achieved on the shell side of a horizontal condenser by flooding some of the bottom tubes with a weir or level controller, then the rate and heat-balance equations must be solved for each section to obtain the area required.

*Pressure drop* on the condensing side reduces the final condensing temperature and the MTD and should always be checked. In designs requiring close approach between inlet coolant and exit condensate (subcooled or not), underestimation of pressure drop on the condensing side can lead to an exchanger that cannot meet specified terminal temperatures. Since pressure drop calculations in two-phase flows such as condensation are relatively inaccurate, designers must consider carefully the consequences of a larger than calculated pressure drop.

***Horizontal In-Shell Condensers*** The mean *condensing coefficient* for the outside of a bank of horizontal tubes is calculated from Eq. (5-87) for a single tube, corrected for the number of tubes in a vertical row. For undisturbed laminar flow over all the tubes, Eq. (5-88) is, for realistic condenser sizes, overly conservative because of rippling, splashing, and turbulent flow (*Process Heat Transfer*, McGraw-Hill, New York, 1950). Kern proposed an exponent of $-\frac{1}{6}$ on the basis of experience, while Freon-11 data of Short and Brown (*General Discussion on Heat Transfer*, Institute of Mechanical Engineers, London, 1951) indicate independence of the number of tube rows. It seems reasonable to use no correction for inviscid liquids and Kern's correction for viscous condensates. For a cylindrical tube bundle, where $N$ varies, it is customary to take $N$ equal to two-thirds of the maximum or centerline value.

Baffles in a horizontal in-shell condenser are oriented with the cuts vertical to facilitate drainage and eliminate the possibility of flooding in the upward cross-flow sections. *Pressure drop* on the vapor side can be estimated by the data and method of Diehl and Unruh [*Pet. Refiner* **36**(10): 147 (1957); **37**(10): 124 (1958)].

High vapor velocities across the tubes enhance the condensing coefficient. There is no correlation in the open literature to permit designers to take advantage of this. Since the vapor flow rate varies along the length, an incremental calculation procedure would be required in any case. In general, the pressure drops required to gain significant benefit are above those allowed in most process applications.

***Vertical In-Shell Condensers*** Condensers are often designed so that condensation occurs on the outside of vertical tubes. Equation (5-79) is valid as long as the condensate film is laminar. When it becomes turbulent, Eq. (5-86) or Colburn's equation [*Trans. Am. Inst. Chem. Eng.* **30:** 187 (1933–1934)] may be used.

Some judgment is required in the use of these correlations because of the construction features of the condenser. The tubes must be supported by baffles, usually with maximum cut (45 percent of the shell diameter) and maximum spacing to minimize pressure drop. The flow of the condensate is interrupted by the baffles, which may draw off or redistribute the liquid and which will also cause some splashing of free-falling drops onto the tubes.

For *subcooling*, a liquid inventory may be maintained in the bottom end of the shell by means of a weir or a liquid-level-controller. The subcooling heat-transfer coefficient is given by the correlations for natural convection on a vertical surface [Eq. (5-42)], with the pool assumed to be well mixed (isothermal) at the subcooled condensate exit temperature. Pressure drop may be estimated by the shell-side procedure.

***Horizontal In-Tube Condensers*** Condensation of a vapor inside horizontal tubes occurs in kettle and horizontal thermosiphon reboilers and in air-cooled condensers. In-tube condensation also offers certain advantages for condensation of multicomponent mixtures, discussed in the subsection Multicomponent Condensers. The various in-tube correlations are closely connected to the *two-phase flow pattern* in the tube [*Chem. Eng. Prog. Symp. Ser.* **66**(102): 150 (1970)]. At low flow rates, when gravity dominates the flow pattern, Eq. (5-87) may be used. At high flow rates, the flow and heat transfer are governed by vapor shear on the condensate film, and Eq. (5-86) is valid. A simple and generally conservative procedure is to calculate the coefficient for a given case by both correlations and use the *larger* one.

Pressure drop during condensation inside horizontal tubes can be computed by using the correlations for two-phase flow given in Sec. 6 and neglecting the pressure recovery due to deceleration of the flow.

***Vertical In-Tube Condensation*** Vertical tube condensers are generally designed so that vapor and liquid flow cocurrently downward; if pressure drop is not a limiting consideration, this configuration can result in higher heat-transfer coefficients than for shell-side condensation and has particular advantages for multicomponent condensation. If gravity controls, the mean heat-transfer coefficient for condensation is given by Eq. (5-79). If vapor shear controls, Eq. (5-86) is applicable. It is generally conservative to calculate the coefficients by both methods and choose the *higher* value. The pressure drop can be calculated by using the Lockhart-Martinelli method [*Chem. Eng. Prog.* **45:** 39 (1945)] for friction loss, neglecting momentum and hydrostatic effects.

Vertical in-tube condensers are often designed for *reflux* **or** *knock-back application* in reactors or distillation columns. In this case, vapor flow is upward, countercurrent to the liquid flow on the tube wall; the vapor shear acts to thicken and retard the drainage of the condensate film, reducing the coefficient. Neither the fluid dynamics nor the heat transfer is well understood in this case, but Soliman, Schuster, and Berenson [*J. Heat Transfer* **90:** 267–276 (1968)] discuss the problem and suggest a computational method. The Diehl-Koppany correlation [*Chem. Eng. Prog. Symp. Ser.* 92, **65** (1969)] may be used to estimate the maximum allowable vapor velocity at the tube inlet. If the vapor velocity is great enough, the liquid film will be carried upward; this design has been employed in a few cases in which only part of the stream is to be condensed. This velocity cannot be accurately computed, and a very conservative (high) outlet velocity must be used if unstable flow and flooding are to be avoided; 3 times the vapor velocity given by the Diehl-Koppany correlation for incipient flooding has been suggested as the design value for completely stable operation.

**Multicomponent Condensers**

***Thermodynamic and Mass-Transfer Considerations*** *Multicomponent vapor mixture* includes several different cases: all the components may be liquids at the lowest temperature reached in the condensing side, or there may be components that dissolve substantially in the condensate even though their boiling points are below the exit temperature, or one or more components may be both noncondensible and nearly insoluble.

Multicomponent condensation always involves sensible-heat changes in the vapor and liquid along with the latent-heat load. Compositions of both phases in general change through the condenser, and *concentration gradients* exist in both phases. Temperature and concentration profiles and transport rates at a point in the condenser usually cannot be calculated, but the binary cases have been treated: condensation of one component in the presence of a completely insoluble gas [Colburn and Hougen, *Ind. Eng. Chem.* **26:** 1178–1182 (1934); and Colburn and Edison, *Ind. Eng. Chem.* **33:** 457–458 (1941)] and condensation of a binary vapor [Colburn and Drew, *Trans. Am. Inst. Chem. Eng.* **33:** 196–215 (1937)]. It is necessary to know or calculate diffusion coefficients for the system, and a reasonable approximate method to avoid this difficulty and the reiterative calculations is desirable. To integrate the point conditions over the total condensation requires the temperature, composition enthalpy, and flow-rate profiles as functions of the heat removed. These are calculated from component thermodynamic data if the vapor and liquid are assumed to be in equilibrium at the local vapor temperature. This assumption is not exactly true, since the condensate and the liquid-vapor interface (where equilibrium does exist) are intermediate in temperature between the coolant and the vapor.

In calculating the condensing curve, it is generally assumed that the vapor and liquid flow collinearly and in intimate contact so that composition equilibrium is maintained between the total streams at all points. If, however, the condensate drops out of the vapor (as can happen in horizontal shell-side condensation) and flows to the exit without further interaction, the remaining vapor becomes excessively enriched in light components with a decrease in condensing temperature and in the temperature difference between vapor and coolant. The result may be not only a small reduction in the amount of heat transferred in the condenser but also an inability to condense totally the light ends even at reduced throughput or with the addition of more surface. To prevent the liquid from segregating, in-tube condensation is preferred in critical cases.

***Thermal Design*** If the controlling resistance for heat and mass transfer in the vapor is sensible-heat removal from the cooling vapor, the following design equation is obtained:

$$A = \int_0^{Q_T} \frac{1 + U' Z_H / h_{sv}}{U'(T_v - T_c)}\, dQ \tag{11-27}$$

$U'$ is the overall heat-transfer coefficient between the vapor-liquid interface and the coolant, including condensate film, dirt and wall resistances, and coolant. The condensate film coefficient is calculated from the appropriate equation or correlation for pure vapor condensation for the geometry and flow regime involved, using mean liquid properties. The ratio of the sensible heat removed from the vapor-gas stream to the total heat transferred is $Z_H$; this quantity is obtained from thermodynamic calculations and may vary substantially from one end of the condenser to the other, especially when removing vapor from a noncondensible gas. The sensible-heat-transfer coefficient for the vapor-gas stream $h_{sv}$ is calculated by using the appropriate correlation or design method for the geometry involved, neglecting the presence of the liquid. As the vapor condenses, this coefficient decreases and must be calculated at several points in the process. And $T_v$ and $T_c$ are temperatures of the vapor and the coolant, respectively. This procedure is similar in principle to that of Ward [*Petro/Chem. Eng.* **32**(11): 42–48 (1960)]. It may be nonconservative for condensing steam and other high-latent-heat substances, in which case it may be necessary to increase the calculated area by 25 to 50 percent.

Pressure drop on the condensing side may be estimated by judicious application of the methods suggested for pure-component condensation, taking into account the generally nonlinear decrease of vapor-gas flow rate with heat removal.

## THERMAL DESIGN OF REBOILERS

For a *single-component reboiler design*, attention is focused upon the mechanism of heat and momentum transfer at the hot surface. In *multicomponent systems*, the light components are preferentially vaporized at the surface, and the process becomes limited by their rate of diffusion. The net effect is to decrease the effective temperature difference between the hot surface and the bulk of the boiling liquid. If one attempts to vaporize too high a fraction of the feed liquid to the reboiler, then the temperature difference between surface and liquid is reduced to the point that nucleation and vapor generation on the surface are suppressed and heat transfer to the liquid proceeds at the lower rate associated with single-phase natural convection. The only safe procedure in design for wide boiling-range mixtures is to vaporize such a limited fraction of the feed that the boiling point of the remaining liquid mixture is still at least 5.5°C (10°F) below the surface temperature. Positive flow of the unvaporized liquid through and out of the reboiler should be provided.

**Kettle Reboilers** It has been generally assumed that kettle reboilers operate in the pool boiling mode, but with a lower peak heat flux because of vapor binding and blanketing of the upper tubes in the bundle. There is some evidence that vapor generation in the bundle causes a high circulation rate through the bundle. The result is that, at the lower heat fluxes, the kettle reboiler actually gives higher heat-transfer coefficients than a single tube. Present understanding of the recirculation phenomenon is insufficient to take advantage of this in design. Available nucleate pool boiling correlations are only very approximate, failing to account for differences in the nucleation characteristics of different surfaces. Equation (5-97b) may be used for single components or narrow boiling-range mixtures at low fluxes. For hydrocarbons not listed, approximation may be made assuming *n*-Pentane. Experimental heat-transfer coefficients for pool boiling of a given liquid on a given surface should be used if available. The bundle *peak heat flux* is a function of tube bundle geometry, especially of tube-packing density. But in the absence of better information, Eq. (5-99) may be used for this purpose.

A general method for analyzing kettle reboiler performance is given by Fair and Klip, *Chem. Eng. Prog.* **79**(3): 86 (1983). It is effectively limited to computer application.

Kettle reboilers are generally assumed to require negligible pressure drop. It is important to provide good longitudinal liquid flow paths within the shell so that the liquid is uniformly distributed along the entire length of the tubes and excessive local vaporization and vapor binding are avoided.

This method may also be used for the thermal design of *horizontal thermosiphon reboilers.* The recirculation rate and pressure profile of the thermosiphon loop can be calculated by the methods of Fair [*Pet. Refiner* **39**(2): 105–123 (1960)].

**Vertical Thermosiphon Reboilers** Vertical thermosiphon reboilers operate by natural circulation of the liquid from the still through the downcomer to the reboiler and of the two-phase mixture from the reboiler through the return piping. The flow is induced by the hydrostatic pressure imbalance between the liquid in the downcomer and the two-phase mixture in the reboiler tubes. Thermosiphons do not require any pump for recirculation and are generally regarded as less likely to foul in service because of the relatively high two-phase velocities obtained in the tubes. Heavy components are not likely to accumulate in the thermosiphon, but they are more difficult to design satisfactorily than kettle reboilers, especially in vacuum operation. Several shortcut methods have been suggested for thermosiphon design, but they must generally be used with caution. The method due to Fair (1960), based upon two-phase flow correlations, is the most complete in the open literature but requires a computer for practical use. Fair also suggests a shortcut method that is satisfactory for preliminary design and can be reasonably done by hand.

**Forced-Recirculation Reboilers** In forced-recirculation reboilers, a pump is used to ensure circulation of the liquid past the heat-transfer surface. Forced-recirculation reboilers may be designed so that boiling occurs inside vertical tubes, inside horizontal tubes, or on the shell side. For forced boiling inside vertical tubes, Fair's method may be employed, by making only the minor modification that the recirculation rate is fixed and does not need to be balanced against the pressure available in the downcomer. Excess pressure required to circulate the two-phase fluid through the tubes and back into the column is supplied by the pump, which must develop a positive pressure increase in the liquid.

Fair's method may also be modified to design forced-recirculation reboilers with horizontal tubes. In this case the hydrostatic head pressure effect through the tubes is zero but must be considered in the two-phase return lines to the column.

The same procedure may be applied in principle to design of forced-recirculation reboilers with shell-side vapor generation. Little is known about two-phase flow on the shell side, but a reasonable estimate of the friction pressure drop can be made from the data of Diehl and Unruh [*Pet. Refiner* **36**(10): 147 (1957); **37**(10): 124 (1958)]. No void-fraction data are available to permit accurate estimation of the hydrostatic or acceleration terms. These may be roughly estimated by assuming homogeneous flow.

## THERMAL DESIGN OF EVAPORATORS

Heat duties of evaporator heating surfaces are usually determined by conventional heat and material balance calculations. Heating surface areas are normally, but not always, taken as those in contact with the material being

evaporated. It is the heat transfer $\Delta T$ that presents the greatest difficulty in deriving or applying heat-transfer coefficients. The total $\Delta T$ between heat source and heat sink is never all available for heat transfer. Since energy usually is carried to and from an evaporator body or effect by condensible vapors, loss in pressure represents a loss in $\Delta T$. Such losses include pressure drop through entrainment separators, friction in vapor piping, and acceleration losses into and out of the piping. The latter loss has often been overlooked, even though it can be many times greater than the friction loss. Similarly, friction and acceleration losses past the heating surface, such as in a falling film evaporator, cause a loss of $\Delta T$ that may or may not have been included in the heat transfer $\Delta T$ when reporting experimental results. Boiling-point rise, the difference between the boiling point of the solution and the condensing point of the solvent at the same pressure, is another loss. Experimental data are almost always corrected for boiling-point rise, but plant data are suspect when based on temperature measurements because vapor at the point of measurement may still contain some superheat, which represents but a very small fraction of the heat given up when the vapor condenses but may represent a substantial fraction of the actual net $\Delta T$ available for heat transfer. A loss of $\Delta T$ that must be considered in forced-circulation evaporators is that due to temperature rise through the heater, a consequence of the heat being absorbed there as sensible heat. A further loss may occur when the heater effluent flashes as it enters the vapor-liquid separator. Some of the liquid may not reach the surface and flash to equilibrium with the vapor pressure in the separator, instead of recirculating to the heater, raising the average temperature at which heat is absorbed and further reducing the net $\Delta T$. Whether these $\Delta T$ losses are allowed for in the heat-transfer coefficients reported depends on the method of measurement. Simply basing the liquid temperature on the measured vapor head pressure may ignore both—or only the latter if temperature rise through the heater is estimated separately from known heat input and circulation rate. In general, when one is calculating the overall heat-transfer coefficients from individual-film coefficients, all these losses must be allowed for, while when using reported overall coefficients, care must be exercised to determine which losses may already have been included in the heat transfer $\Delta T$.

**Forced-Circulation Evaporators** In evaporators of this type in which hydrostatic head prevents boiling at the heating surface, *heat-transfer coefficients* can be predicted for forced-convection sensible heating using Eqs. (5-54) and (5-57). The liquid film coefficient is improved if boiling is not completely suppressed. When only the film next to the wall is above the boiling point, Boarts, Badger, and Meisenberg [*Ind. Eng. Chem.* **29:** 912 (1937)] found that results could be correlated by Eq. (5-50) by using a constant of 0.0278 instead of 0.023. In such cases, the course of the liquid temperature can still be calculated from known circulation rate and heat input.

When the bulk of the liquid is boiling in part of the tube length, the film coefficient is even higher. However, the liquid temperature starts dropping as soon as full boiling develops, and it is difficult to estimate the course of the temperature curve. It is certainly safe to estimate heat transfer on the basis that no bulk boiling occurs. Fragen and Badger [*Ind. Eng. Chem.* **28:** 534 (1936)] obtained an *empirical correlation* of overall heat-transfer coefficients in this type of evaporator, based on the $\Delta T$ at the heater inlet:

In USCS units

$$U = 2020 D^{0.57} (V_s)^{3.6/L} / \mu^{0.25}\, \Delta T^{0.1} \qquad (11\text{-}28)$$

where $D$ = mean tube diameter, $V_s$ = inlet velocity, $L$ = tube length, and $\mu$ = liquid viscosity. This equation is based primarily on experiments with copper tubes of 0.022 m (0.866 in) outside diameter, 0.00165 m (0.065 in or 16 gauge) wall thickness, and 2.44 m (8 ft) long, but it includes some work with 0.0127 m (½ in) tubes 2.44 m (8 ft) long and 0.0254 m (1 in) tubes 3.66 m (12 ft) long.

**Long-Tube Vertical Evaporators** In the rising-film version of this type of evaporator, there is usually a nonboiling zone in the bottom section and a boiling zone in the top section. The length of the nonboiling zone depends on heat-transfer characteristics in the two zones and on pressure drop during two-phase flow in the boiling zone. The work of Martinelli and coworkers [Lockhart and Martinelli, *Chem. Eng. Prog.* **45:** 39–48 (January 1949); and Martinelli and Nelson, *Trans. Am. Soc. Mech. Eng.* **70:** 695–702 (August 1948)] permits a prediction of pressure drop, and a number of correlations are available for estimating film coefficients of heat transfer in the two zones. In estimating pressure drop, integrated curves similar to those presented by Martinelli and Nelson are the easiest to use. The curves for pure water are shown in Figs. 11-18 and 11-19, based on the assumption that the flow of both vapor and liquid would be turbulent if each were flowing alone in the tube. Similar curves can be prepared if one or both flows are laminar or if the properties of the liquid differ appreciably from the properties of pure water. The *acceleration pressure drop* $\Delta P_a$ is calculated from the equation

$$\Delta P_a = b r_2 G^2 / 32.2 \qquad (11\text{-}29)$$

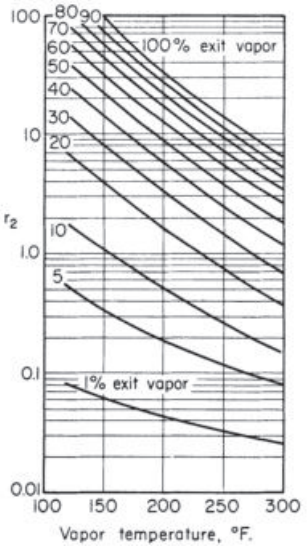

**FIG. 11-18** Acceleration losses in boiling flow. °C = (°F − 32)/1.8.

where $b = (2.6)(10^7)$ (SI) and $b = 1.0$ (USCS) and using $r_2$ from Fig. 11-18. The frictional pressure drop is derived from Fig. 11-19, which shows the ratio of two-phase pressure drop to the entering liquid flowing alone.

Pressure drop due to hydrostatic head can be calculated from liquid holdup $R_1$. For nonfoaming dilute aqueous solutions, $R_1$ can be estimated from $R_1 = 1/[1 + 2.5(V/L)(\rho_1/\rho_v)^{1/2}]$. Liquid holdup, which represents the ratio of liquid-only velocity to actual liquid velocity, also appears to be the principal determinant of the convective coefficient in the boiling zone (Dengler, Sc.D. thesis, MIT, 1952). In other words, the convective coefficient is that calculated from Eq. (5-57) by using the liquid-only velocity divided by $R_1$ in the Reynolds number. Nucleate boiling augments convective heat transfer, primarily when $\Delta T$ values are high and the convective coefficient is low [Chen, *Ind. Eng. Chem. Process Des. Dev.* **5:** 322 (1966)].

Film coefficients for the *boiling of liquids other than water* have been investigated. Coulson and McNelly [*Trans. Inst. Chem. Eng.* **34:** 247 (1956)] derived the following relation, which also correlated the data of Badger and coworkers [*Chem. Metall. Eng.* **46:** 640 (1939); *Chem. Eng.* **61**(2): 183 (1954); and *Trans. Am. Inst. Chem. Eng.* **33:** 392 (1937); **35:** 17 (1939); **36:** 759 (1940)] on water:

$$N_{\mathrm{Nu}} = (1.3 + bD)(N_{\mathrm{Pr}})_l^{0.9} (N_{\mathrm{Re}})_l^{0.23} (N_{\mathrm{Re}})_g^{0.34} \left(\frac{\rho_l}{\rho_g}\right)^{0.25} \left(\frac{\mu_g}{\mu_l}\right) \qquad (11\text{-}30)$$

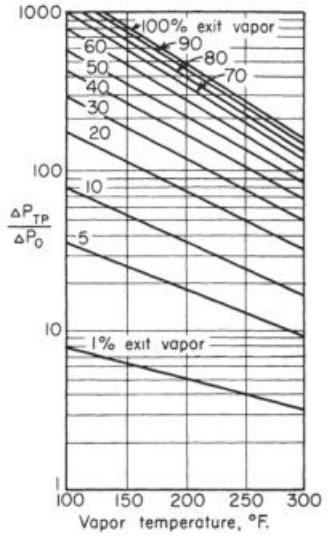

**FIG. 11-19** Friction pressure drop in boiling flow. °C = (°F − 32)/1.8.

where $b$ = 128 (SI) or 39 (USCS), $N_{Nu}$ = Nusselt number based on liquid thermal conductivity, $D$ = tube diameter, and the remaining terms are dimensionless groupings of the liquid Prandtl number, liquid Reynolds number, vapor Reynolds number, and ratios of densities and viscosities. The Reynolds numbers are calculated on the basis of each fluid flowing by itself in the tube.

Additional corrections must be applied when the fraction of vapor is so high that the remaining liquid does not wet the tube wall or when the velocity of the mixture at the tube exits approaches sonic velocity. McAdams, Woods, and Bryan (*Trans. Am. Soc. Mech. Eng.*, 1940), Dengler and Addoms (Dengler, Sc.D. thesis, MIT, 1952), and Stroebe, Baker, and Badger [*Ind. Eng. Chem.* **31:** 200 (1939)] encountered dry-wall conditions and reduced coefficients when the weight fraction of vapor exceeded about 80 percent. Schweppe and Foust [*Chem. Eng. Prog.* **49:** Symp. Ser. 5, 77 (1953)] and Harvey and Foust [*Chem. Eng. Prog.* **49:** Symp. Ser. 5, 91 (1953)] found that "sonic choking" occurred at surprisingly low flow rates.

The simplified method of calculation outlined includes no allowance for the *effect of surface tension.* Stroebe, Baker, and Badger found that by adding a small amount of surface-active agent the boiling-film coefficient varied inversely as the square of the surface tension. Coulson and Mehta [*Trans. Inst. Chem. Eng.* **31:** 208 (1953)] found the exponent to be −1.4. The higher coefficients at low surface tension are offset to some extent by a higher pressure drop, probably because the more intimate mixture existing at low surface tension causes the liquid fraction to be accelerated to a velocity closer to that of the vapor. The pressure drop due to acceleration $\Delta P_a$ derived from Fig. 11-18 allows for some slippage. In the limiting case, such as might be approached at low surface tension, the acceleration pressure drop in which "fog" flow is assumed (no slippage) can be determined from the equation

$$\Delta P'_a = \frac{y(V_g - V_l)G^2}{g_c} \tag{11-31}$$

where $y$ = fraction vapor by weight
$V_g$, $V_l$ = specific volume gas, liquid
$G$ = mass velocity

While the foregoing methods are valuable for detailed evaporator design or for evaluating the effect of changes in conditions on performance, they are cumbersome to use when making preliminary designs or cost estimates. Figure 11-20 gives the general range of *overall long-tube vertical (LTV) evaporator heat-transfer coefficients* usually encountered in commercial practice. The higher coefficients are encountered when evaporating dilute solutions and the lower range when evaporating viscous liquids. The dashed curve represents the approximate lower limit, for liquids with viscosities of about 0.1 Pa·s (100 cP). The LTV evaporator does not work well at low temperature differences, as indicated by the results shown in Fig. 11-21 for seawater in 0.051-m (2-in), 0.0028-m (12-gauge) brass tubes 7.32 m (24 ft) long (W. L. Badger Associates, Inc., U.S. Department of the Interior, Office of Saline Water, Rep. 26, December 1959, OTS Publ. PB 161290). The feed was at its boiling point at the vapor head pressure, and feed rates varied from 0.025 to 0.050 kg/(s·tube) [200 to 400 lb/(h·tube)] at the higher temperature to 0.038 to 0.125 kg/(s·tube) [300 to 1000 lb/(h·tube)] at the lowest temperature.

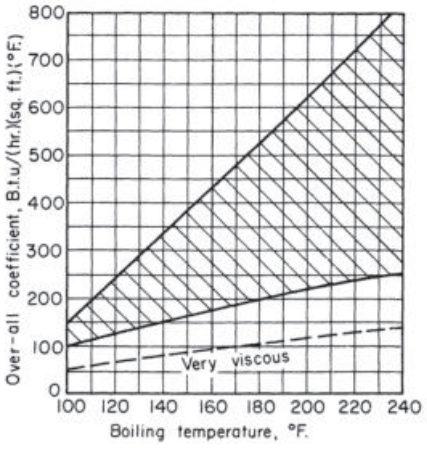

**FIG. 11-20** General range of long-tube vertical (LTV) evaporator coefficients. °C = (°F − 32)/1.8; to convert British thermal units per hour squared per foot per degree Fahrenheit to joules per square meter per second per kelvin, multiply by 5.6783.

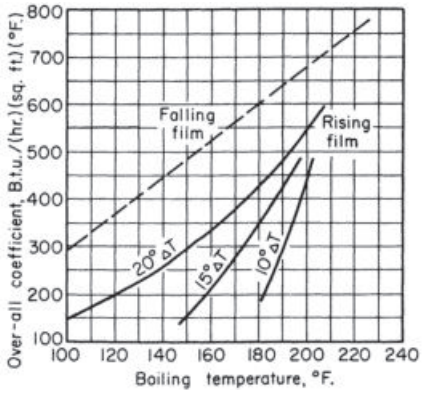

**FIG. 11-21** Heat-transfer coefficients in LTV seawater evaporators. °C = (°F − 32)/1.8; to convert British thermal units per hour per square foot per degree Fahrenheit to joules per square meter per second per kelvin, multiply by 5.6783.

Falling-film evaporators find their widest use at low temperature differences—also at low temperatures. Under most operating conditions encountered, heat transfer is almost all by pure convection, with a negligible contribution from nucleate boiling. Film coefficients on the condensing side may be estimated from Dukler's correlation [*Chem. Eng. Prog.* **55:** 62 (1950)]. The same Dukler correlation presents curves covering falling-film heat transfer to nonboiling liquids that are equally applicable to the falling-film evaporator [Sinek and Young, *Chem. Eng. Prog.* **58:** 12, 74 (1962)]. Kunz and Yerazunis [*J. Heat Transfer* **8:** 413 (1969)] have since extended the range of physical properties covered, as shown in Fig. 11-22. The boiling point in the tubes of such an evaporator is higher than that in the vapor head because of both frictional pressure drop and the head needed to accelerate the vapor to the tube-exit velocity. These factors, which can easily be predicted, make the overall apparent coefficients somewhat lower than those for nonboiling conditions. Figure 11-21 shows overall apparent heat-transfer coefficients determined in a falling-film seawater evaporator using the same tubes and flow rates as for the rising-film tests (W. L. Badger Associates, Inc., U.S. Department of the Interior, Office of Saline Water, Rep. 26, December 1959, OTS Publ. PB 161290).

**Short-Tube Vertical Evaporators** Coefficients can be estimated by the same detailed method described for recirculating LTV evaporators. Performance is primarily a function of temperature level, temperature difference, and viscosity. While liquid level can also have an important influence, this is usually encountered only at levels lower than considered safe in commercial operation. *Overall heat-transfer coefficients* are shown in Fig. 11-23 for a basket-type evaporator (one with an annular downtake) when boiling water with 0.051-m (2-in) outside-diameter 0.0028-m wall (12-gauge), 1.22-m- (4-ft-) long steel tubes [Badger and Shepard, *Chem. Metall. Eng.* **23:** 281 (1920)]. Liquid level was maintained at the top tube sheet. Foust, Baker, and Badger [*Ind. Eng. Chem.* **31:** 206 (1939)] measured recirculating velocities and heat-transfer coefficients in the same evaporator except with 0.064-m (2.5-in) 0.0034-m-wall (10-gauge), 1.22-m- (4-ft-) long tubes and temperature differences from 7°C to 26°C (12°F to 46°F). In the normal range of liquid levels, their results can be expressed as

$$U_c = \frac{b(\Delta T_c)^{0.22} N_{\text{pr}}^{0.4}}{(V_g - V_l)^{0.37}} \tag{11-32}$$
